## Preface

The original edition of this book, written in Chinese for students in mainland China, was published in 2001 jointly by Chinese University Press and Peking University Press. The second edition was published by Peking University Press in 2006. During the preparation of the present English edition, we took the opportunity to correct some errors and to include updated material based on the recent literature.

The book is derived from lecture notes used in various courses taught by the three authors at The Chinese University of Hong Kong and Peking University. The course titles include Chemical Bonding, Structural Chemistry, Structure and Properties of Matter, Advanced Inorganic Chemistry, Quantum Chemistry, Group Theory, and Chemical Crystallography. In total, the authors have accumulated over 100 man-years of teaching at the two universities. The book is designed as a text for senior undergraduates and beginning postgraduate students who need a deeper yet friendly exposure to the bonding and structure of chemical compounds.

Structural chemistry is a branch of science that attempts to achieve a comprehensive understanding of the physical and chemical properties of various compounds from a microscopic viewpoint. In building up the theoretical framework, two main lines of development-electronic and spatial-are followed. In this book, both aspects and the interplay between them are stressed. It is hoped that our presentation will provide students with sufficient background and factual knowledge so that they can comprehend the exciting recent advances in chemical research and be motivated to pursue careers in universities and research institutes.

This book is composed of three Parts. Part I, consisting of the first five chapters, reviews the basic theories of chemical bonding, beginning with a brief introduction to quantum mechanics, which is followed by successive chapters on atomic structure, bonding in molecules, and bonding in solids. Inclusion of the concluding chapter on computational chemistry reflects its increasing importance as an accessible and valuable tool in fundamental research.

Part II of the book, again consisting of five chapters, discusses the symmetry concept and its importance in structural chemistry. Chapter 6 introduces students to symmetry point groups and the rudiments of group theory without delving into intricate mathematical details. Chapter 7 covers group theory's most common chemical applications, including molecular orbital and hybridization theories, molecular vibrations, and selection rules. Chapter 8 utilizes the symmetry concept to discuss the bonding in coordination complexes. The final two
chapters address the formal description of symmetry in the crystalline state and the structures of basic inorganic crystals and some technologically important materials.

Part III constitutes about half of the book. It offers a succinct description of the structural chemistry of the elements in the Periodic Table. Specifically, the maingroup elements (including noble gases) are covered in the first seven chapters, while the last three deal with the rare-earth elements, transition-metal clusters, and supramolecular systems, respectively. In all these chapters, selected examples illustrating interesting aspects of structure and bonding, generalizations of structural trends, and highlights from the recent literature are discussed in the light of the theoretical principles presented in Parts I and II.

In writing the first two Parts, we deliberately avoided the use of rigorous mathematics in treating various theoretical topics. Instead, newly introduced concepts are illustrated with examples based on real chemical compounds or practical applications. Furthermore, in our selective compilation of material for presentation in Part III, we strive to make use of the most up-to-date crystallographic data to expound current research trends in structural inorganic chemistry.

On the ground of hands-on experience, we freely make use of our own research results as examples in the presentation of relevant topics throughout the book. Certainly there is no implication whatsoever that they are particularly important or preferable to alternative choices.

We faced a dilemma in choosing a fitting title for the book and eventually settled on the present one. The adjective "inorganic" is used in a broad sense as the book covers compounds of representative elements (including carbon) in the Periodic Table, organometallics, metal-metal bonded systems, coordination polymers, host-guest compounds and supramolecular assemblies. Our endeavor attempts to convey the message that inorganic synthesis is inherently less organized than organic synthesis, and serendipitous discoveries are being made from time to time. Hopefully, discussion of bonding and structure on the basis of X-ray structural data will help to promote a better understanding of modern chemical crystallography among the general scientific community.

Many people have contributed to the completion of this book. Our past and present colleagues at The Chinese University of Hong Kong and Peking University have helped us in various ways during our teaching careers. Additionally, generations of students have left their imprint in the lecture notes on which this book is based. Their inquisitive feedback and suggestions for improvement have proved to be invaluable. Of course, we are solely responsible for deficiencies and errors and would most appreciate receiving comments and criticisms from prospective readers.

The publication of the original Chinese edition was financed by a special grant from Chinese University Press, to which we are greatly indebted. We dedicate this book to our mentors: S.M. Blinder, You-Qi Tang, James Trotter and the late Hson-Mou Chang. Last but not least, we express our gratitude to
our wives, Oi-Ching Chong Li, Zhi-Fen Liu, and Gloria Sau-Hing Mak, for their sacrifice, encouragement and unflinching support.

## Contents

List of Contributors ..... xxi
Part I Fundamentals of Bonding Theory ..... 1
1 Introduction to Quantum Theory ..... 3
1.1 Dual nature of light and matter ..... 4
1.2 Uncertainty principle and probability concept ..... 5
1.3 Electronic wavefunction and probability density function ..... 6
1.4 Electronic wave equation: the Schrödinger equation ..... 10
1.5 Simple applications of the Schrödinger equation ..... 13
1.5.1 Particle in a one-dimensional box ..... 13
1.5.2 Particle in a three-dimensional box ..... 17
1.5.3 Particle in a ring ..... 21
1.5.4 Particle in a triangle ..... 23
References ..... 28
2 The Electronic Structure of Atoms ..... 29
2.1 The Hydrogen Atom ..... 29
2.1.1 Schrödinger equation for the hydrogen atom ..... 29
2.1.2 Angular functions of the hydrogen atom ..... 31
2.1.3 Radial functions and total wavefunctions of the hydrogen atom ..... 34
2.1.4 Relative sizes of hydrogenic orbitals and the probability criterion ..... 38
2.1.5 Energy levels of hydrogenic orbitals; summary ..... 42
2.2 The helium atom and the Pauli exclusion principle ..... 42
2.2.1 The helium atom: ground state ..... 43
2.2.2 Determinantal wavefunction and the Pauli Exclusion Principle ..... 48
2.2.3 The helium atom: the $1 \mathrm{~s}^{1} 2 \mathrm{~s}^{1}$ configuration ..... 51
2.3 Many-electron atoms: electronic configuration and spectroscopic terms ..... 54
2.3.1 Many-electron atoms ..... 54
2.3.2 Ground electronic configuration for many-electron atoms ..... 55
2.3.3 Spectroscopic terms arising from a given electronic configuration ..... 56
2.3.4 Hund's rules on spectroscopic terms ..... 60
2.3.5 $j$-j Coupling ..... 62
2.4 Atomic properties ..... 64
2.4.1 Ionization energy and electron affinity ..... 64
2.4.2 Electronegativity: the spectroscopic scale ..... 67
2.4.3 Relativistic effects on the properties of the elements ..... 71
References ..... 76
3 Covalent Bonding in Molecules ..... 77
3.1 The hydrogen molecular ion: bonding and antibonding molecular orbitals ..... 77
3.1.1 The variational method ..... 77
3.1.2 The hydrogen molecular ion: energy consideration ..... 79
3.1.3 The hydrogen molecular ion: wavefunctions ..... 82
3.1.4 Essentials of molecular orbital theory ..... 84
3.2 The hydrogen molecule: molecular orbital and valence bond treatments ..... 85
3.2.1 Molecular orbital theory for $\mathrm{H}_{2}$ ..... 85
3.2.2 Valence bond treatment of $\mathrm{H}_{2}$ ..... 86
3.2.3 Equivalence of the molecular orbital and valence bond models ..... 89
3.3 Diatomic molecules ..... 91
3.3.1 Homonuclear diatomic molecules ..... 92
3.3.2 Heteronuclear diatomic molecules ..... 96
3.4 Linear triatomic molecules and $\mathrm{sp}^{n}$ hybridization schemes ..... 99
3.4.1 Beryllium hydride, $\mathrm{BeH}_{2}$ ..... 99
3.4.2 Hybridization scheme for linear triatomic molecules ..... 100
3.4.3 Carbon dioxide, $\mathrm{CO}_{2}$ ..... 101
3.4.4 The sp ${ }^{n}(n=1-3)$ hybrid orbitals ..... 104
3.4.5 Covalent radii ..... 109
3.5 Hückel molecular orbital theory for conjugated polyenes ..... 110
3.5.1 Hückel molecular orbital theory and its application to ethylene and butadiene ..... 110
3.5.2 Predicting the course of a reaction by considering the symmetry of the wavefunction ..... 113
References ..... 116

4.1 Chemical classification of solids ..... 118
4.2 Ionic bond ..... 121
4.2.1 Ionic size: crystal radii of ions ..... 121
4.2.2 Lattice energies of ionic compounds ..... 124
4.2.3 Ionic liquids ..... 126
4.3 Metallic bonding and band theory ..... 128
4.3.1 Chemical approach based on molecular orbital theory ..... 128
4.3.2 Semiconductors ..... 130
4.3.3 Variation of structure types of 4 d and 5 d transition metals ..... 131
4.3.4 Metallic radii ..... 132
4.3.5 Melting and boiling points and standard enthalpies of atomization of the metallic elements ..... 133
4.4 Van der Waals interactions ..... 134
4.4.1 Physical origins of van der Waals interactions ..... 135
4.4.2 Intermolecular potentials and van der Waals radii ..... 138
References ..... 139
5 Computational Chemistry ..... 140
5.1 Introduction ..... 140
5.2 Semi-empirical and ab initio methods ..... 141
5.3 Basis sets ..... 142
5.3.1 Minimal basis set ..... 142
5.3.2 Double zeta and split valence basis sets ..... 143
5.3.3 Polarization functions and diffuse functions ..... 143
5.4 Electron correlation ..... 144
5.4.1 Configuration interaction ..... 145
5.4.2 Perturbation methods ..... 146
5.4.3 Coupled-cluster and quadratic configuration interaction methods ..... 146
5.5 Density functional theory ..... 147
5.6 Performance of theoretical methods ..... 148
5.7 Composite methods ..... 151
5.8 Illustrative examples ..... 152
5.8.1 A stable argon compound: HArF ..... 152
5.8.2 An all-metal aromatic species: $\mathrm{Al}_{4}^{2-}$ ..... 154
5.8.3 A novel pentanitrogen cation: $\mathrm{N}_{5}^{+}$ ..... 156
5.8.4 Linear triatomics with noble gas-metal bonds ..... 158
5.9 Software packages ..... 162
References ..... 163
Part II Symmetry in Chemistry ..... 165
6 Symmetry and Elements of Group Theory ..... 167
6.1 Symmetry elements and symmetry operations ..... 167
6.1.1 Proper rotation axis $C_{n}$ ..... 167
6.1.2 Symmetry plane $\sigma$ ..... 168
6.1.3 Inversion center $i$ ..... 169
6.1.4 Improper rotation axis $S_{n}$ ..... 169
6.1.5 Identity element $E$ ..... 170
6.2 Molecular point groups ..... 170
6.2.1 Classification of point groups ..... 170
6.2.2 Identifying point groups ..... 178
6.2.3 Dipole moment and optical activity ..... 179
6.3 Character tables ..... 180
6.4 The direct product and its use ..... 185
6.4.1 The direct product ..... 185
6.4.2 Identifying non-zero integrals and selection rules in spectroscopy ..... 187
6.4.3 Molecular term symbols ..... 189
References ..... 193
Appendix 6.1 Character tables of point groups ..... 195
7 Application of Group Theory to Molecular Systems ..... 213
7.1 Molecular orbital theory ..... 213
7.1.1 $\quad \mathrm{AH}_{n}(n=2-6)$ molecules ..... 214
7.1.2 Hückel theory for cyclic conjugated polyenes ..... 221
7.1.3 Cyclic systems involving d orbitals ..... 227
7.1.4 Linear combinations of ligand orbitals for $\mathrm{AL}_{4}$ molecules with $T_{\mathrm{d}}$ symmetry ..... 228
7.2 Construction of hybrid orbitals ..... 232
7.2.1 Hybridization schemes ..... 232
7.2.2 Relationship between the coefficient matrices for the hybrid and molecular orbital wavefunctions ..... 233
7.2.3 Hybrids with d-orbital participation ..... 234
7.3 Molecular vibrations ..... 236
7.3.1 The symmetries and activities of the normal modes ..... 236
7.3.2 Some illustrative examples ..... 239
7.3.3 CO stretch in metal carbonyl complexes ..... 246
7.3.4 Linear molecules ..... 252
7.3.5 Benzene and related molecules ..... 254
References ..... 259

## List of Contributors

Wai-Kee Li obtained his B.S. degree from University of Illinois in 1964 and his Ph.D. degree from University of Michigan in 1968. He joined the Chinese University of Hong Kong in July 1968 to follow an academic career that spanned a period of thirty-eight years. He retired as Professor of Chemistry in August 2006 and was subsequently conferred the title of Emeritus Professor of Chemistry. Over the years he taught a variety of courses in physical and inorganic chemistry. His research interests in theoretical and computational chemistry have led to over 180 papers in international journals.
Gong-Du Zhou graduated from Xichuan University in 1953 and completed his postgraduate studies at Peking University in 1957. He then joined the Chemistry Department of Peking University and taught Structural Chemistry, Structure and Properties of Matter, and other courses there till his retirement as a Professor in 1992. He has published more than 100 research papers in X-ray crystallography and structural chemistry, together with over a dozen Chinese chemistry textbooks and reference books.

Thomas Chung Wai Mak obtained his B.Sc. (1960) and Ph.D. (1963) degrees from the University of British Columbia. After working as a NASA Postdoctoral Research Associate at the University of Pittsburgh and an Assistant Professor at the University of Western Ontario, in June 1969 he joined the Chinese University of Hong Kong, where he is now Emeritus Professor of Chemistry and Wei Lun Research Professor. His research interest lies in inorganic synthesis, chemical crystallography, supramolecular assembly and crystal engineering, with over 900 papers in international journals. He was elected as a member of the Chinese Academy of Sciences in 2001.

## Fundamentals of Bonding Theory

The theory of chemical bonding plays an important role in the rapidly evolving field of structural inorganic chemistry. It helps us to understand the structure, physical properties and reactivities of different classes of compounds. It is generally recognized that bonding theory acts as a guiding principle in inorganic chemistry research, including the design of synthetic schemes, rationalization of reaction mechanisms, exploration of structure-property relationships, supramolecular assembly and crystal engineering.

There are five chapters in Part I: Introduction to quantum theory, The electronic structure of atoms, Covalent bonding in molecules, Chemical bonding in condensed phases and Computational chemistry. Since most of the contents of these chapters are covered in popular texts for courses in physical chemistry, quantum chemistry and structural chemistry, it can be safely assumed that readers of this book have some acquaintance with such topics. Consequently, many sections may be viewed as convenient summaries and frequently mathematical formulas are given without derivation.

The main purpose of Part I is to review the rudiments of bonding theory, so that the basic principles can be applied to the development of new topics in subsequent chapters.

# Introduction to Quantum Theory 

In order to appreciate fully the theoretical basis of atomic structure and chemical bonding, we need a basic understanding of the quantum theory. Even though chemistry is an experimental science, theoretical consideration (especially prediction) is now playing a role of increasing importance with the development of powerful computational algorithms. The field of applying quantum theoretical methods to investigate chemical systems is commonly called quantum chemistry.

The key to theoretical chemistry is molecular quantum mechanics, which deals with the transference or transformation of energy on a molecular scale. Although the quantum mechanical principles for understanding the electronic structure of matter has been recognized since 1930, the mathematics involved in their application, i.e. general solution of the Schrödinger equation for a molecular system, was intractable at best in the 50 years or so that followed. But with the steady development of new theoretical and computational methods, as well as the availability of larger and faster computers with reasonable price tags during the past two decades, calculations have sometimes become almost as accurate as experiments, or at least accurate enough to be useful to experimentalists. Additionally, compared to experiments, calculations are often less costly, less time-consuming, and easier to control. As a result, computational results can complement experimental studies in essentially every field of chemistry. For instance, in physical chemistry, chemists can apply quantum chemical methods to calculate the entropy, enthalpy, and other thermochemical functions of various gases, to interpret molecular spectra, to understand the nature of the intermolecular forces, etc. In organic chemistry, calculations can serve as a guide to a chemist who is in the process of synthesizing or designing new compounds; they can also be used to compare the relative stabilities of various molecular species, to study the properties of reaction intermediates and transition states, and to investigate the mechanism of reactions, etc. In analytical chemistry, theory can help chemists to understand the frequencies and intensities of the spectral lines. In inorganic chemistry, chemists can apply the ligand filed theory to study the transition metal complexes. An indication that computational chemistry has been receiving increasing attention in the scientific community was the award of the 1998 Nobel Prize in chemistry to Professor J.A. Pople and Professor W. Kohn for their contributions to quantum chemistry. In Chapter 5, we will briefly describe the kind of questions that may be fruitfully treated by computational chemistry.

## Fundamentals of Bonding Theory

In this chapter, we discuss some important concepts of quantum theory. A clear understanding of these concepts will facilitate subsequent discussion of bonding theory.

### 1.1 Dual nature of light and matter

Around the beginning of the twentieth century, scientists had accepted that light is both a particle and a wave. The wave character of light is manifested in its interference and diffraction experiments. On the other hand, its corpuscular nature can be seen in experiments such as the photoelectric effect and Compton effect. With this background, L. de Broglie in 1924 proposed that, if light is both a particle and a wave, a similar duality also exists for matter. Moreover, by combining Einstein's relationship between energy $E$ and mass $m$,

$$
\begin{equation*}
E=m c^{2} \tag{1.1.1}
\end{equation*}
$$

where $c$ is the speed of light, and Planck's quantum condition,

$$
\begin{equation*}
E=h v \tag{1.1.2}
\end{equation*}
$$

where $h$ is Planck's constant and $v$ is the frequency of the radiation, de Broglie was able to arrive at the wavelength $\lambda$ associated with a photon,

$$
\begin{equation*}
\lambda=\frac{c}{v}=\frac{h c}{h v}=\frac{h c}{m c^{2}}=\frac{h}{m c}=\frac{h}{p} \tag{1.1.3}
\end{equation*}
$$

where $p$ is the momentum of the photon. Then de Broglie went on to suggest that a particle with mass $m$ and velocity $v$ is also associated with a wavelength given by

$$
\begin{equation*}
\lambda=\frac{h}{m v}=\frac{h}{p}, \tag{1.1.4}
\end{equation*}
$$

where $p$ is now the momentum of the particle.
Before proceeding further, it is instructive to examine what kinds of wavelengths are associated with particles having various masses and velocities, as shown in Table 1.1.1.

By examining the results listed in Table 1.1.1, it is seen that the wavelengths of macroscopic objects will be far too short to be observed. On the other hand, electrons with energies on the order of 100 eV will have wavelengths between 100 and 200 pm , approximately the interatomic distances in crystals. In 1927, C.J. Davisson and L.H. Germer obtained the first electron diffraction pattern of a crystal, thus proving de Broglie's hypothesis experimentally. From then on, scientists recognized that an electron has dual properties: it can behave as both a particle and a wave.

Table 1.1.1. Wavelength of different particles travelling with various velocities $(\lambda=h / p=$ $h / m v ; h=6.63 \times 10^{-27} \mathrm{erg} \mathrm{s}=6.63 \times 10^{-34} \mathrm{~J} \mathrm{~s}$ )

| Particles | $m / \mathrm{kg}$ | $v / \mathrm{m} \mathrm{s}^{-1}$ | $\lambda / \mathrm{pm}$ |
| :--- | :--- | :--- | :--- |
| Electron at 298 K | $9.11 \times 10^{-31}$ | $1.16 \times 10^{5}$ | $6270^{*}$ |
| 1-volt electron | $9.11 \times 10^{-31}$ | $5.93 \times 10^{5}$ | 1230 |

| record speed |  |  |  |

$$
\begin{aligned}
{ }^{*} E & =\frac{3}{2} k T=\frac{1}{2} m v^{2} ; v=\left(\frac{3 k T}{m}\right)^{\frac{1}{2}}=\left(\frac{3 \times 1.38 \times 10^{-23} \mathrm{JK} \mathrm{~K}^{-1} \times 298 \mathrm{~K}}{9.11 \times 10^{-33} \mathrm{~kg}}\right)^{\frac{1}{2}}=1.16 \times 10^{5} \mathrm{~m} \mathrm{~s}^{-1} ; \\
\lambda & =\frac{h}{m v}=\frac{6.63 \times 10^{-34} \mathrm{~J} \mathrm{~J}}{9.11 \times 10^{-31} \mathrm{~kg} \times 1.16 \times 10^{5} \mathrm{~m} \mathrm{~s}^{-1}}=6.27 \times 10^{-9} \mathrm{~m}=6270 \mathrm{pm} . \\
{ }^{\dagger} E & =100 \mathrm{eV}=100 \times 1.60 \times 10^{-19} \mathrm{~J}=1.60 \times 10^{-17} \mathrm{~J}=\frac{1}{2} m v^{2}, \\
v & =\left(\frac{2 E}{m}\right)^{\frac{1}{2}}=\left(\frac{2 \times 1.60 \times 10^{-17} \mathrm{~J}}{9.11 \times 10^{-31} \mathrm{~kg}}\right)^{\frac{1}{2}}=5.93 \times 10^{6} \mathrm{~m} \mathrm{~s}^{-1} ; \\
\lambda & =\frac{h}{m v}=\frac{6.63 \times 10^{-34} \mathrm{~J}}{9.11 \times 10^{-31} \mathrm{~kg} \times 5.93 \times 10^{6} \mathrm{~m} \mathrm{~s}^{-1}}=1.23 \times 10^{-10} \mathrm{~m}=123 \mathrm{pm} .
\end{aligned}
$$

This wavelength is similar to the atomic spacing in crystals.

### 1.2 Uncertainty principle and probability Concept

Another important development in quantum mechanics is the Uncertainty Principle set forth by W. Heisenberg in 1927. In its simplest terms, this principle says, "The position and momentum of a particle cannot be simultaneously and precisely determined." Quantitatively, the product of the uncertainty in the $x$ component of the momentum vector $\left(\Delta p_{x}\right)$ and the uncertainty in the $x$ direction of the particle's position $(\Delta x)$ is on the order of Planck's constant:

$$
\begin{equation*}
\left(\Delta p_{x}\right)(\Delta x) \sim \frac{h}{4 \pi}=5.27 \times 10^{-35} \mathrm{~J} \mathrm{s.} \tag{1.2.1}
\end{equation*}
$$

While $h$ is quite small in the macroscopic world, it is not at all insignificant when the particle under consideration is of subatomic scale. Let us use an actual example to illustrate this point. Suppose the $\Delta x$ of an electron is $10^{-14} \mathrm{~m}$, or 0.01 pm . Then, with eq. (1.2.1), we get $\Delta p_{x}=5.27 \times 10^{-21} \mathrm{~kg} \mathrm{~m} \mathrm{~s}^{-1}$. This uncertainty in momentum would be quite small in the macroscopic world. However, for subatomic particles such as an electron, with mass of $9.11 \times 10^{-31}$ kg , such an uncertainty would not be negligible at all. Hence, on the basis of the Uncertainty Principle, we can no longer say that an electron is precisely located at this point with an exactly known velocity. It should be stressed that the uncertainties we are discussing here have nothing to do with the imperfection of the measuring instruments. Rather, they are inherent indeterminacies. If we recall the Bohr theory of the hydrogen atom, we find that both the radius of the orbit and the velocity of the electron can be precisely calculated. Hence the Bohr results violate the Uncertainty Principle.

With the acceptance of uncertainty at the atomic level, we are forced to speak in terms of probability: we say the probability of finding the electron within

## Fundamentals of Bonding Theory

this volume element is how many percent and it has a probable velocity (or momentum) such and such.

### 1.3 Electronic wavefunction and probability density function

Since an electron has wave character, we can describe its motion with a wave equation, as we do in classical mechanics for the motions of a water wave or a stretched string or a drum. If the system is one-dimensional, the classical wave equation is

$$
\begin{equation*}
\frac{\partial^{2} \Phi(x, t)}{\partial x^{2}}=\frac{1}{v^{2}} \frac{\partial^{2} \Phi(x, t)}{\partial t^{2}} \tag{1.3.1}
\end{equation*}
$$

where $v$ is the velocity of the propagation. The wavefunction $\Phi$ gives the displacement of the wave at point $x$ and at time $t$. In three-dimensional space, the wave equation becomes

$$
\begin{equation*}
\left(\frac{\partial^{2}}{\partial x^{2}}+\frac{\partial^{2}}{\partial y^{2}}+\frac{\partial^{2}}{\partial z^{2}}\right) \Phi(x, y, z, t)=\nabla^{2} \Phi(x, y, z, t)=\frac{1}{v^{2}} \frac{\partial^{2} \Phi(x, y, z, t)}{\partial t^{2}} \tag{1.3.2}
\end{equation*}
$$

A typical wavefunction, or a solution of the wave equation, is the familiar sine or cosine function. For example, we can have

$$
\begin{equation*}
\Phi(x, t)=\mathrm{A} \sin (2 \pi / \lambda)(x-v t) \tag{1.3.3}
\end{equation*}
$$

It can be easily verified that $\Phi(x, t)$ satisfies eq. (1.3.1). An important point to keep in mind is that, in classical mechanics, the wavefunction is an amplitude function. As we shall see later, in quantum mechanics, the electronic wavefunction has a different role to play.

Combining the wave nature of matter and the probability concept of the Uncertainty Principle, M. Born proposed that the electronic wavefunction is no longer an amplitude function. Rather, it is a measure of the probability of an event: when the function has a large (absolute) value, the probability for the event is large. An example of such an event is given below.

From the Uncertainty Principle, we no longer speak of the exact position of an electron. Instead, the electron position is defined by a probability density function. If this function is called $\rho(x, y, z)$, then the electron is most likely found in the region where $\rho$ has the greatest value. In fact, $\rho \mathrm{d} \tau$ is the probability of finding the electron in the volume element $\mathrm{d} \tau(\equiv \mathrm{d} x \mathrm{~d} y \mathrm{~d} z)$ surrounding the point $(x, y, z)$. Note that $\rho$ has the unit of volume ${ }^{-1}$, and $\rho \mathrm{d} \tau$, being a probability, is dimensionless. If we call the electronic wavefunction $\psi$, Born asserted that the probability density function $\rho$ is simply the absolute square of $\psi$ :

$$
\begin{equation*}
\rho(x, y, z)=|\psi(x, y, z)|^{2} . \tag{1.3.4}
\end{equation*}
$$

Since $\psi$ can take on imaginary values, we take the absolute square of $\psi$ to make sure that $\rho$ is positive. Hence, when $\psi$ is imaginary,

$$
\begin{equation*}
\rho(x, y, z)=|\psi(x, y, z)|^{2}=\psi^{*} \psi \tag{1.3.5}
\end{equation*}
$$

where $\psi^{*}$ is the complex conjugate (replacing $i$ in $\psi$ by $-i$ ) of $\psi$.
Before proceeding further, let us use some numerical examples to illustrate the determination of the probability of locating an electron in a certain volume element in space. The ground state wavefunction of the hydrogen atom is

$$
\begin{equation*}
\psi_{1 \mathrm{~s}}=\left(\pi a_{0}^{3}\right)^{-\frac{1}{2}} \mathrm{e}^{-\frac{r}{a_{0}}} \tag{1.3.6}
\end{equation*}
$$

where $r$ is the nucleus-electron separation and $a_{0}$, with the value of 52.9 pm , is the radius of the first Bohr orbit (hence is called Bohr radius). In the following we will use $\psi_{1 \text { s }}$ to determine the probability $P$ of locating the electron in a volume element $\mathrm{d} r$ of $1 \mathrm{pm}^{3}$ which is $1 a_{0}$ away from the nucleus.

$$
\begin{aligned}
& \text { At } r=1 a_{0} \\
& \psi_{1 \mathrm{~s}}=\left(\pi a_{0}^{3}\right)^{-\frac{1}{2}} \mathrm{e}^{-\frac{a_{0}}{a_{0}}}=\left[\pi(52.9 \mathrm{pm})^{3}\right]^{-\frac{1}{2}} \mathrm{e}^{-1}=5.39 \times 10^{-4} \mathrm{pm}^{-\frac{3}{2}} \\
& \rho=\left|\psi_{1 \mathrm{~s}}\right|^{2}=\left(5.39 \times 10^{-4} \mathrm{pm}^{-\frac{3}{2}}\right)^{2}=2.91 \times 10^{-7} \mathrm{pm}^{-3} \\
& P=\left|\psi_{1 \mathrm{~s}}\right|^{2} \mathrm{~d} \tau=2.91 \times 10^{-7} \mathrm{pm}^{-3} \times 1 \mathrm{pm}^{3}=2.91 \times 10^{-7}
\end{aligned}
$$

In addition, we can also calculate the probability of finding the electron in a shell of thickness 1 pm which is $1 a_{0}$ away from the nucleus:

$$
\begin{aligned}
\mathrm{d} \tau & =(\text { surface area }) \times(\text { thickness }) \\
& =\left(4 \pi r^{2} \mathrm{dr}\right)=4 \pi(52.9 \mathrm{pm})^{2} \times 1 \mathrm{pm} \\
& =3.52 \times 10^{4} \mathrm{pm}^{3},
\end{aligned}
$$

and

$$
P=\left|\psi_{1 \mathrm{~s}}\right|^{2} \mathrm{~d} \tau=2.91 \times 10^{-7} \mathrm{pm}^{-3} \times 3.52 \times 10^{4} \mathrm{pm}^{3}=1.02 \times 10^{-2}
$$

In other words, there is about $1 \%$ chance of finding the electron in a spherical shell of thickness 1 pm and radius $1 a_{0}$.

In Table 1.3.1, we tabulate $\psi_{1 \mathrm{~s}},\left|\psi_{1 \mathrm{~s}}\right|^{2},\left|\psi_{1 s}\right|^{2} \mathrm{~d} \tau$ (with $\mathrm{d} \tau=1 \mathrm{pm}^{3}$ ), and $4 \pi r^{2}\left|\psi_{1 \mathrm{~s}}\right|^{2} \mathrm{~d} r$ (with $\mathrm{d} r=1 \mathrm{pm}$ ), for various $r$ values.

As $|\psi|^{2} \mathrm{~d} \tau$ represents the probability of finding the electron in a certain region in space, and the sum of all probabilities is $1, \psi$ must satisfy the relation

$$
\begin{equation*}
\int|\psi|^{2} \mathrm{~d} \tau=1 \tag{1.3.7}
\end{equation*}
$$

Table 1.3.1. Values of $\psi_{1 \mathrm{~s}},\left|\psi_{1 \mathrm{~s}}\right|^{2},\left|\psi_{1 \mathrm{~s}}\right|^{2} \mathrm{~d} \tau$ (with $\mathrm{d} \tau=1 \mathrm{pm}^{3}$ ), and $4 \pi r^{2}\left|\psi_{1 \mathrm{~s}}\right|^{2} \mathrm{~d} r$ (with $\mathrm{d} r=1$ $\mathrm{pm})$ for various nucleus-electron distances

| $r(\mathrm{pm})$ | 0 | $26.45\left(\right.$ or $\left.a_{0} / 2\right)$ | $52.9\left(\right.$ or $\left.a_{0}\right)$ | 100 | 200 |
| :--- | :---: | :---: | :---: | :---: | :---: |
| $\psi_{1 \mathrm{~s}}\left(\mathrm{pm}^{-\frac{3}{2}}\right)$ | $1.47 \times 10^{-3}$ | $8.89 \times 10^{-4}$ | $5.39 \times 10^{-4}$ | $2.21 \times 10^{-4}$ | $3.34 \times 10^{-5}$ |
| $\left\|\psi_{1 \mathrm{~s}}\right\|^{2}\left(\mathrm{pm}^{-3}\right)$ | $2.15 \times 10^{-6}$ | $7.91 \times 10^{-7}$ | $2.91 \times 10^{-7}$ | $4.90 \times 10^{-8}$ | $1.12 \times 10^{-9}$ |
| $\left\|\psi_{1 \mathrm{~s}}\right\|^{2} \mathrm{~d} \tau$ | $2.15 \times 10^{-6}$ | $7.91 \times 10^{-7}$ | $2.91 \times 10^{-7}$ | $4.90 \times 10^{-8}$ | $1.12 \times 10^{-9}$ |
| $4 \pi r^{2}\left\|\psi_{1 \mathrm{~s}}\right\|^{2} \mathrm{~d} r$ | 0 | $6.95 \times 10^{-3}$ | $1.02 \times 10^{-2}$ | $6.16 \times 10^{-3}$ | $5.62 \times 10^{-4}$ |

When $\psi$ satisfies eq. (1.3.7), the wavefunction is said to be normalized. On the other hand, if $\int|\psi|^{2} \mathrm{~d} \tau=N$, where $N$ is a constant, then $N^{-1 / 2} \psi$ is a normalized wavefunction and $N^{-1 / 2}$ is called the normalization constant.

For a given system, there are often many or even an infinite number of acceptable solutions: $\psi_{1}, \psi_{2}, \ldots, \psi_{i}, \psi_{j}, \ldots$ and these wavefunctions are "orthogonal" to each other, i.e.

$$
\begin{equation*}
\int \psi_{i}^{*} \psi_{j} \mathrm{~d} \tau=\int \psi_{j}^{*} \psi_{i} \mathrm{~d} \tau=0 \tag{1.3.8}
\end{equation*}
$$

Combining the normalization condition (eq. (1.3.7)) and the orthogonality condition (eq. (1.3.8)) leads us to the orthonormality relationship among the wavefunctions

$$
\begin{align*}
\int \psi_{i}^{*} \psi_{j} \mathrm{~d} \tau & =\int \psi_{j}^{*} \psi_{i} \mathrm{~d} \tau \\
& =\delta_{i j}= \begin{cases}0 & \text { when } i \neq j \\
1 & \text { when } i=j\end{cases} \tag{1.3.9}
\end{align*}
$$

where $\delta_{i j}$ is the Kronecker delta function. Since $|\psi|^{2}$ plays the role of a probability density function, $\psi$ must be finite, continuous, and single-valued.

The wavefunction plays a central role in quantum mechanics. For atomic systems, the wavefunction describing the electronic distribution is called an atomic orbital; in other words, the aforementioned 1 s wavefunction of the ground state of a hydrogen atom is also called the 1 s orbital. For molecular systems, the corresponding wavefunctions are likewise called molecular orbitals.

Once we know the explicit functions of the various atomic orbitals (such as $1 \mathrm{~s}, 2 \mathrm{~s}, 2 \mathrm{p}, 3 \mathrm{~s}, 3 \mathrm{p}, 3 \mathrm{~d}, \ldots$ ), we can calculate the values of $\psi$ at different points in space and express the wavefunction graphically. In Fig. 1.3.1(a), the graph on the left is a plot of $\psi_{1 \mathrm{~s}}$ against $r$; the sphere on the right shows that $\psi$ has the same value for a given $r$, regardless of direction (or $\theta$ and $\varphi$ values). In Fig. 1.3.1(b), the two graphs on the left plot density functions $\left|\psi_{1 \mathrm{~s}}\right|^{2}$ and $4 \pi r^{2}\left|\psi_{1 \mathrm{~s}}\right|^{2}$ against $r$. The probability density describing the electronic distribution is also referred to as an electron cloud, which may be represented by a figure such as that shown on the right side of Fig. 1.3.1(b). This figure indicates that the 1s orbital has maximum density at the nucleus and the density decreases steadily as the electron gets farther and farther away from the nucleus.

In addition to providing probability density functions, the wavefunction may also be used to calculate the value of a physical observable for that state. In quantum mechanics, a physical observable $A$ has a corresponding mathematical operator $\hat{A}$. When $\hat{A}$ satisfies the relation

$$
\begin{equation*}
\hat{A} \psi=a \psi \tag{1.3.10}
\end{equation*}
$$

$\psi$ is called an eigenfunction of operator $\hat{A}$, and $a$ is called the eigenvalue of the state described by $\psi$. In the next section, we shall discuss the Schrödinger equation,

$$
\begin{equation*}
\hat{H} \psi=E \psi . \tag{1.3.11}
\end{equation*}
$$

Here $\psi$ is the eigenfunction of the Hamiltonian operator $\hat{H}$ and the corresponding eigenvalue $E$ is the energy of the system.

If $\psi$ does not satisfy eq. (1.3.10), we can calculate the expectation value (or mean) of $A,\langle A\rangle$, by the expression

$$
\begin{equation*}
<A>=\frac{\int \psi^{*} \hat{A} \psi \mathrm{~d} \tau}{\int|\psi|^{2} \mathrm{~d} \tau} \tag{1.3.12}
\end{equation*}
$$

If $\psi$ is a normalized wavefunction, eq. (1.3.12) becomes

$$
\begin{equation*}
<A>=\int \psi^{*} \hat{A} \psi \mathrm{~d} \tau \tag{1.3.13}
\end{equation*}
$$

Fig. 1.3.1.
(a) The 1s wavefunction and (b) the 1s probability density functions of the hydrogen atom.

## Fundamentals of Bonding Theory

In the ground state of a hydrogen atom, there is no fixed $r$ value for the electron, i.e. there is no eigenvalue for $r$. On the other hand, we can use eq. (1.3.13) to calculate the average value of $r$ :

$$
\begin{align*}
<r> & =\left(\pi a_{0}^{3}\right)^{-1} \int_{0}^{2 \pi} \mathrm{~d} \phi \int_{0}^{\pi} \sin \theta \mathrm{d} \theta \int_{0}^{\infty} \mathrm{e}^{-\frac{r}{a_{0}}} r e^{-\frac{r}{a_{0}}} r^{2} \mathrm{~d} r \\
& =\left(\pi a_{0}^{3}\right)^{-1} \cdot 4 \pi \int_{0}^{\infty} \mathrm{e}^{-\frac{2 r}{a_{0}}} r^{3} \mathrm{~d} r \\
& =3 a_{0} / 2 . \tag{1.3.14}
\end{align*}
$$

In carrying out the integration in eq. (1.3.14), we make use of $\mathrm{d} \tau=$ $r^{2} \mathrm{~d} r \sin \theta \mathrm{~d} \theta \mathrm{~d} \varphi$ and $0 \leq r<\infty, 0 \leq \theta \leq \pi$, and $0 \leq \phi \leq 2 \pi$.

In Fig. 1.3.1(b), in the plot of $4 \pi r^{2}\left|\psi_{1 s}\right|^{2}$ against $r$, the mean value $\langle r\rangle$ is marked on the $r$ axis, separating the graph into two parts. These two parts have unequal areas, the unshaded area being larger than the shaded area. This result implies that it is more likely to find a $r$ value smaller than $\langle r\rangle$ than one larger than $\langle r\rangle$. In addition, the $r$ value corresponding to the maximum in the $4 \pi r^{2}\left|\psi_{1 s}\right|^{2}$ function is labelled $r_{\mathrm{p}}$. At $r_{\mathrm{p}}, r=a_{0}$ and $r_{\mathrm{p}}$ is called the most probable electron distance.

### 1.4 Electronic wave equation: The Schrödinger equation

In 1926, E. Schrödinger developed his famous wave equation for electrons. The validity of the Schrödinger equation rests solely on the fact that it leads to the right answers for a variety of systems. As in the case of Newton's equations, the Schrödinger equation is a fundamental postulate that cannot be deduced from first principles. Hence what is presented below is merely a heuristic derivation. In this presentation, we can see how the particle character is incorporated into a wave equation.

We start with eq. (1.3.2), the general differential equation for wave motion:

$$
\begin{equation*}
\nabla^{2} \Phi(x, y, z, t)=\frac{\partial^{2} \Phi(x, y, z, t)}{v^{2} \partial t^{2}} \tag{1.3.2}
\end{equation*}
$$

Note that wavefunction $\Phi$ has time $t$ as one of its variables. Since our primary concern is the energy of a system and this energy is independent of time (we are ignoring the process of radiation here), we need an equation that is time independent. The wavefunctions obtained from a time-independent equation are called standing (or stationary) waves. To obtain such an equation, we assume $\Phi(x, y, z, t)$ has the form

$$
\begin{equation*}
\Phi(x, y, z, t)=\psi(x, y, z) g(t), \tag{1.4.1}
\end{equation*}
$$

where $\psi$ is a function of space coordinates and $g$ is a function of time $t$. For standing waves, there are several acceptable $g$ functions and one of them is

$$
\begin{equation*}
g(t)=\mathrm{e}^{2 \pi i v t}, \tag{1.4.2}
\end{equation*}
$$

where frequency $v$ is related to propagation velocity $v$ and wavelength $\lambda$ by

$$
\begin{equation*}
v=\frac{v}{\lambda} \tag{1.4.3}
\end{equation*}
$$

If we substitute

$$
\begin{equation*}
\Phi(x, y, z, t)=\psi(x, y, z) e^{2 \pi i v t} \tag{1.4.4}
\end{equation*}
$$

into eq. (1.3.2), we get

$$
\begin{align*}
\mathrm{e}^{2 \pi i \nu \mathrm{t}} \nabla^{2} \psi & =\frac{1}{v^{2}} \psi \frac{\partial^{2} \mathrm{e}^{2 \pi i v t}}{\partial t^{2}} \\
& =-4 \pi^{2} \nu^{2} v^{-2} \mathrm{e}^{2 \pi i v t} \psi \tag{1.4.5}
\end{align*}
$$

or, upon canceling $e^{2 \pi i v t}$,

$$
\begin{equation*}
\nabla^{2} \psi=-4 \pi^{2} v^{2} v^{-2} \psi \tag{1.4.6}
\end{equation*}
$$

Now we incorporate the corpuscular character $(\lambda=h / p)$ into eq. (1.4.6)

$$
\begin{equation*}
v=v \lambda=v\left(\frac{h}{p}\right)=\frac{h v}{p} \tag{1.4.7}
\end{equation*}
$$

and eq. (1.4.6) becomes

$$
\begin{equation*}
\nabla^{2} \psi=\left(\frac{-4 \pi^{2} p^{2}}{h^{2}}\right) \psi \tag{1.4.8}
\end{equation*}
$$

If we rewrite $p^{2}$ in terms of kinetic energy $T$, or total energy $E$, and potential energy $V$,

$$
\begin{equation*}
p^{2}=2 m T=2 m(E-V) \tag{1.4.9}
\end{equation*}
$$

the wave equation now has the form

$$
\begin{equation*}
\nabla^{2} \psi=\left(\frac{-8 m \pi^{2}}{h^{2}}\right)(E-V) \psi \tag{1.4.10}
\end{equation*}
$$

Rearranging eq. (1.4.10) yields,

$$
\begin{equation*}
\left[\left(\frac{-h^{2}}{8 \pi^{2} m}\right) \nabla^{2}+V\right] \psi=E \psi \tag{1.4.11}
\end{equation*}
$$

or

$$
\begin{equation*}
\hat{H} \psi=E \psi \tag{1.4.12}
\end{equation*}
$$

## Fundamentals of Bonding Theory

where the Hamiltonian operator $\hat{H}$ is defined as

$$
\begin{equation*}
\hat{H}=\left(\frac{-h^{2}}{8 \pi^{2} m}\right) \nabla^{2}+V \tag{1.4.13}
\end{equation*}
$$

In other words, $\hat{H}$ has two parts: kinetic energy operator $\left(-h^{2} / 8 \pi^{2} m\right) \nabla^{2}$ and potential energy operator $V$.
To summarize, the quantum mechanical way of studying the electronic structure of an atom or a molecule consists of the following steps:
(1) Write down the Schrödinger equation of the system by filling in the proper potential energy.
(2) Solve the differential equation to obtain the electronic energies $E_{i}$ and wavefunctions $\psi_{i}, i=1,2, \ldots$
(3) Use the wavefunctions $\psi_{i}$ to determine the probability density functions $\left|\psi_{i}\right|^{2}$ and the expectation values of physical observables.

In the following, we use the ground state wavefunction $\psi_{1 \text { s }}$ [eq. (1.3.6)] to determine the energy $E_{1 \mathrm{~s}}$ of this state as well as the expectation values of the kinetic energy, $\langle T\rangle$, and potential energy, $\langle V\rangle$.

By applying the Hamiltonian operator of the hydrogen atom on $\psi_{1 \mathrm{~s}}$, we can readily obtain $E_{1 \mathrm{~s}}$ :

$$
\begin{gather*}
\hat{H} \psi_{1 \mathrm{~s}}=\left[\left(\frac{-h^{2}}{8 \pi^{2} m}\right) \nabla^{2}-\left(\frac{e^{2}}{4 \pi \varepsilon_{0} r}\right)\right] \psi_{1 \mathrm{~s}} \\
=E_{1 \mathrm{~s}} \psi_{1 \mathrm{~s}} \tag{1.4.14}
\end{gather*}
$$

and

$$
\begin{equation*}
E_{1 \mathrm{~s}}=\left(\frac{1}{4 \pi \varepsilon_{0}}\right)\left(\frac{-e^{2}}{2 a_{0}}\right)=-2.18 \times 10^{-18} \mathrm{~J}=-13.6 \mathrm{eV} \tag{1.4.15}
\end{equation*}
$$

The expectation value of potential energy, $\langle V\rangle$, can also be computed easily:

$$
\begin{align*}
<V> & =\int_{0}^{2 \pi} \mathrm{~d} \phi \int_{0}^{\pi} \sin \theta \mathrm{d} \theta \int_{0}^{\infty}\left(\pi a_{0}^{3}\right)^{-1} \mathrm{e}^{-\frac{r}{a_{0}}}\left(\frac{-e^{2}}{4 \pi \varepsilon_{0} r}\right) \mathrm{e}^{-\frac{r}{a_{0}}} r^{2} \mathrm{~d} r \\
& =\left(\frac{-1}{4 \pi \varepsilon_{0}}\right)\left(\frac{e^{2}}{a_{0}}\right) \tag{1.4.16}
\end{align*}
$$

The quantity $<T>$ is simply the difference between $E_{1 \mathrm{~s}}$ and $\langle V\rangle$ :

$$
\begin{equation*}
<T>=E_{1 \mathrm{~s}}-<V>=\left(\frac{1}{4 \pi \varepsilon_{0}}\right)\left(\frac{e^{2}}{2 a_{0}}\right) . \tag{1.4.17}
\end{equation*}
$$

Comparing eqs. (1.4.16) and (1.4.17), we get

$$
\begin{equation*}
<T>=-\frac{<V>}{2} . \tag{1.4.18}
\end{equation*}
$$

which is called the virial theorem for atomic and molecular systems.
In the following section, we treat several systems quantum mechanically to illustrate the method introduced here.

### 1.5 Simple applications of the Schrödinger equation

In the four examples given below, a particle (or electron) is allowed to move freely. The only difference is the shape of the "box," in which the particle travels. As will be seen later, different shapes give rise to different boundary conditions, which in turn lead to different allowed energies (eigenvalues) and wavefunctions (eigenfunctions).

### 1.5.1 Particle in a one-dimensional box

In this system, the box has only one dimension, with length $a$. The potential energy is zero inside the box and infinity at the boundary and outside the box. In other words, the electron can move freely inside the box and it is impossible for it to get out of the box. Mathematically

$$
V=\left\{\begin{array}{cc}
0, & 0<x<a  \tag{1.5.1}\\
\infty, & 0 \geq x \text { or } x \geq a
\end{array}\right.
$$

So the Schrödinger equation has the form

$$
\begin{equation*}
\left(\frac{-h^{2}}{8 \pi^{2} m}\right)\left(\frac{\mathrm{d}^{2} \psi}{\mathrm{~d} x^{2}}\right)=E \psi \tag{1.5.2}
\end{equation*}
$$

or

$$
\begin{equation*}
\frac{\mathrm{d}^{2} \psi}{\mathrm{~d} x^{2}}=\left(\frac{-8 \pi^{2} m E}{h^{2}}\right) \psi=-\alpha^{2} \psi \tag{1.5.3}
\end{equation*}
$$

with

$$
\begin{equation*}
\alpha^{2}=\frac{8 \pi^{2} m E}{h^{2}} \tag{1.5.4}
\end{equation*}
$$

Solutions of eq. (1.5.3) are

$$
\begin{equation*}
\psi=A \sin \alpha x+B \cos \alpha x, \tag{1.5.5}
\end{equation*}
$$

where $A$ and $B$ are constants to be determined by the boundary conditions defined by eq. (1.5.1). At $x=0$ or $x=a$, the potential barrier is infinitely high and the particle cannot be found at or around those points, i.e.

$$
\begin{equation*}
\psi(0)=\psi(a)=0 . \tag{1.5.6}
\end{equation*}
$$

## Fundamentals of Bonding Theory

With $\psi(0)=0$, we get

$$
\begin{equation*}
B=0 . \tag{1.5.7}
\end{equation*}
$$

Also, $\psi(a)=0$ yields

$$
\begin{equation*}
A \sin \alpha a=0, \tag{1.5.8}
\end{equation*}
$$

which means either $A$ or $\sin \alpha a$ vanishes. Since the former is not acceptable, we have

$$
\begin{equation*}
\sin \alpha a=0 \tag{1.5.9}
\end{equation*}
$$

or

$$
\begin{equation*}
\alpha a=n \pi, \quad n=1,2,3, \ldots . \tag{1.5.10}
\end{equation*}
$$

So, the wavefunctions have the form

$$
\begin{equation*}
\psi_{n}(x)=A \sin \left(\frac{n \pi x}{a}\right), \quad n=1,2,3, \ldots . \tag{1.5.11}
\end{equation*}
$$

The constant $A$ can be determined by normalization:

$$
\begin{equation*}
\int_{0}^{a}\left|\psi_{n}\right|^{2} \mathrm{~d} x=A^{2} \int_{0}^{a} \sin ^{2}\left(\frac{n \pi x}{a}\right) \mathrm{d} x=1 \tag{1.5.12}
\end{equation*}
$$

which leads to the following form for the wavefunctions:

$$
\begin{equation*}
\psi_{n}(x)=\left(\frac{2}{a}\right)^{\frac{1}{2}} \sin \left(\frac{n \pi x}{a}\right) . \tag{1.5.13}
\end{equation*}
$$

Note that $\psi$ has the unit of length ${ }^{-1 / 2}$ and $\psi^{2}$ has the unit of length ${ }^{-1}$.
By combining eqs. (1.5.4) and (1.5.10), the energy of the system can also be determined:

$$
\begin{equation*}
\alpha=\frac{n \pi}{a}=\left(\frac{8 \pi^{2} m E}{h^{2}}\right)^{\frac{1}{2}} \tag{1.5.14}
\end{equation*}
$$

or

$$
\begin{equation*}
E_{n}=\frac{n^{2} h^{2}}{8 m a^{2}}, \quad n=1,2,3, \ldots \tag{1.5.15}
\end{equation*}
$$

Figure 1.5.1 summarizes the results of this particle-in-a-box problem. From this figure, it is seen that when the electron is in the ground state $(n=1)$, it is most likely found at the center of the box. On the other hand, if the electron is in the first excited state $(n=2)$, it is most likely found around $x=a / 4$ or $x=3 a / 4$.

Fig. 1.5.1.
Pictorial representations of $E_{n}, \psi_{n}$ (left), and $\left|\psi_{n}\right|^{2}$ (right) for the particle in a one-dimensional box problem.

In the following, we calculate the expectation values $\left\langle p_{x}\right\rangle$ and $\left\langle p_{x}^{2}\right\rangle$, where $p_{x}$ is the momentum of the particle (recall this is a one-dimensional system), for the ground state of this system. First,

$$
\begin{align*}
\left\langle p_{x}^{2}\right\rangle & =2 m<T\rangle=2 m E \\
& =(2 m)\left(\frac{h^{2}}{8 m a^{2}}\right)=\frac{h^{2}}{4 a^{2}} . \tag{1.5.16}
\end{align*}
$$

Next, for $\left\langle p_{x}\right\rangle$, we need to make use of the fact that the quantum mechanical operator $\hat{p}_{x}$ for $p_{x}$ is $(-i h / 2 \pi)(\partial / \partial x)$. So

$$
\begin{equation*}
<p_{x}>=\left(\frac{2}{a}\right) \int_{0}^{a} \sin \left(\frac{\pi x}{a}\right)\left(\frac{-i h}{2 \pi}\right)\left(\frac{\partial}{\partial x}\right) \sin \left(\frac{\pi x}{a}\right) \mathrm{d} x=0 . \tag{1.5.17}
\end{equation*}
$$

So the mean momentum is zero, as the electron is equally likely to travel to the left or to the right. On the other hand, $\left\langle p_{x}^{2}\right\rangle$ is not zero, as the square of a momentum is always positive. From statistics, the uncertainty of momentum, $\Delta p_{x}$, may be expressed in terms of $\left\langle p_{x}\right\rangle$ and $\left\langle p_{x}^{2}\right\rangle$ :

$$
\begin{align*}
\Delta p_{x} & =\left[\left\langle p_{x}^{2}\right\rangle-\left\langle p_{x}\right\rangle^{2}\right]^{\frac{1}{2}} \\
& =\frac{h}{2 a} . \tag{1.5.18}
\end{align*}
$$

## Fundamentals of Bonding Theory

In the following, again for the ground state, we calculate the mean value of position $x$ as well as that of $x^{2}$ :

$$
\begin{align*}
<x> & =\left(\frac{2}{a}\right) \int_{0}^{a} \sin \left(\frac{\pi x}{a}\right) x \sin \left(\frac{\pi x}{a}\right) \mathrm{d} x \\
& =\frac{a}{2} . \tag{1.5.19}
\end{align*}
$$

This result can be obtained by simply examining the function $\left|\psi_{1}\right|^{2}$ shown in Fig. 1.5.1. Meanwhile,

$$
\begin{align*}
<x^{2}> & =\left(\frac{2}{a}\right) \int_{0}^{a} \sin \left(\frac{\pi x}{a}\right) x^{2} \sin \left(\frac{\pi x}{a}\right) \mathrm{d} x \\
& =a^{2}\left(\frac{1}{3}-\frac{1}{2 \pi^{2}}\right) \tag{1.5.20}
\end{align*}
$$

Now we are ready to determine the uncertainty in $x$ :

$$
\begin{align*}
\Delta x & =\left[\left\langle x^{2}\right\rangle-\langle x\rangle^{2}\right]^{\frac{1}{2}} \\
& =a\left[\left(\frac{1}{12}\right)-\left(\frac{1}{2 \pi^{2}}\right)\right]^{\frac{1}{2}} . \tag{1.5.21}
\end{align*}
$$

The product $\Delta x \cdot \Delta p_{x}$ satisfies the Uncertainty Principle:

$$
\begin{equation*}
\Delta x \Delta p_{x}=a\left[\left(\frac{1}{12}\right)-\left(\frac{1}{2 \pi^{2}}\right)\right]^{\frac{1}{2}}\left(\frac{h}{2 a}\right)=1.14\left(\frac{h}{4 \pi}\right)>\frac{h}{4 \pi} \tag{1.5.22}
\end{equation*}
$$

There is a less mathematical way to show that the results of this onedimensional box problem do conform to the Uncertainty Principle. The ground state, or minimum, energy of this system is $h^{2} / 8 m a^{2}$, which has a positive value. On the other hand, when this system is treated classically, the minimum energy would be zero. The residual energy of the (quantum) ground state, or the energy above the classical minimum, is called the zero-point energy. The existence of this energy implies that the kinetic energy, and hence the momentum, of a bound particle cannot be zero. If we take the ground state energy to be $p_{x}^{2} / 2 m$, we get the minimum momentum of the particle to be $\pm h / 2 a$. The uncertainty in momentum, $\Delta p_{x}$, may then be approximated to be $h / a$. If we take the uncertainty in position, $\Delta x$, to be the length of the box, $a$, then $\Delta x \Delta p_{x}$ is (approximately) $h$, which is in accord with the Uncertainty Principle.

The results of the particle in a one-dimensional box problem can be used to describe the delocalized $\pi$ electrons in (linear) conjugated polyenes. Such an approximation is called the free-electron model. Take the butadiene molecule $\mathrm{CH}_{2}=\mathrm{CH}-\mathrm{CH}=\mathrm{CH}_{2}$ as an example. The four $\pi$ electrons of this system would fill up the $\psi_{1}$ and $\psi_{2}$ orbitals, giving rise to the $\left(\psi_{1}\right)^{2}\left(\psi_{2}\right)^{2}$ configuration. If we excite one electron from the $\psi_{2}$ orbital to the $\psi_{3}$ orbital, we need an energy of

$$
\begin{equation*}
\Delta E=\frac{5 h^{2}}{8 m a^{2}}=\frac{h c}{\lambda} \tag{1.5.23}
\end{equation*}
$$

The length of the box, $a$, may be approximated in the following way. Typical $\mathrm{C}-\mathrm{C}$ and $\mathrm{C}=\mathrm{C}$ bond lengths are 154 and 135 pm , respectively. If we allow the $\pi$ electrons to move a bit beyond the terminal carbon atoms, the length of the box may be rounded off to $(4 \times 1.40=560 \mathrm{pm}$. If $a$ is taken to be this value, $\lambda$ in eq. (1.5.23) can be calculated to be 207.0 nm . Experimentally, butadiene absorbs light at $\lambda=210.0 \mathrm{~nm}$. So, even though the model is very crude, the result is fortuitously good.

The free-electron model breaks down readily when it is applied to longer polyenes. For hexatriene, we have $a=6 \times 1.40=840 \mathrm{pm}, \Delta E=E_{4}-E_{3}$, and $\lambda=333 \mathrm{~nm}$. Experimentally this triene absorbs at $\lambda=250 \mathrm{~nm}$. For octatetraene, the box length $a$ now becomes 1120 pm , and $\Delta E=E_{5}-E_{4}$ with $\lambda=460 \mathrm{~nm}$, compared to the experimental value of 330 pm . Despite this shortcoming, the model does predict that when a conjugated polyene is lengthened, its absorption band wavelength becomes longer as well.

When a polyene reaches a certain length, its absorption wavelength will appear in the visible region, i.e. $\lambda$ is between 400 and 700 nm . When this occurs, the polyene is colored. One of the better known colored polyenes is $\beta$-carotene, which is responsible for orange color of carrots. It has the structure:

This polyene has 11 conjugated $\pi$ bonds, with $\lambda=450 \mathrm{~nm}$. Carotene can be cleaved enzymatically into two units of all-trans-vitamin A , which is a polyene with five conjugated $\pi$ bonds:

The absorption peak of this compound appears at $\lambda=325 \mathrm{~nm}$. This molecule plays an important role in the chemistry of vision.

### 1.5.2 Particle in a three-dimensional box

The potential energy of this system has the form

$$
V=\left\{\begin{array}{cccc}
0, & 0<x<a \quad \text { and } \quad 0<y<b & \text { and } \quad 0<z<c  \tag{1.5.24}\\
\infty, & 0 \geq x \geq a & \text { or } \quad 0 \geq y \geq b & \text { or } \quad 0 \geq z \geq c .
\end{array}\right.
$$

## Fundamentals of Bonding Theory

So the Schrödinger equation now is

$$
\begin{equation*}
\left(\frac{-h^{2}}{8 \pi^{2} m}\right) \nabla^{2} \psi=E \psi \tag{1.5.25}
\end{equation*}
$$

To solve this equation, we make use of the technique of separation of variables

$$
\begin{equation*}
\psi(x, y, z)=X(x) Y(y) Z(z) \tag{1.5.26}
\end{equation*}
$$

where $X, Y$, and $Z$ are one-variable functions involving variables, $x, y$, and $z$, respectively. Substituting eq. (1.5.26) into eq. (1.5.25) leads to

$$
\begin{equation*}
\nabla^{2} \psi=\left[\left(\frac{\partial^{2}}{\partial x^{2}}\right)+\left(\frac{\partial^{2}}{\partial y^{2}}\right)+\left(\frac{\partial^{2}}{\partial z^{2}}\right)\right] X Y Z=\left(\frac{-8 \pi^{2} m E}{h^{2}}\right) X Y Z \tag{1.5.27}
\end{equation*}
$$

or

$$
\begin{equation*}
Y Z\left(\frac{\partial^{2} X}{\partial x^{2}}\right)+X Z\left(\frac{\partial^{2} Y}{\partial y^{2}}\right)+X Y\left(\frac{\partial^{2} Z}{\partial z^{2}}\right)=\left(\frac{-8 \pi^{2} m E}{h^{2}}\right) X Y Z . \tag{1.5.28}
\end{equation*}
$$

Dividing eq. (1.5.28) by $X Y Z$ yields.

$$
\begin{equation*}
\frac{1}{X}\left(\frac{\partial^{2} X}{\partial x^{2}}\right)+\frac{1}{Y}\left(\frac{\partial^{2} Y}{\partial y^{2}}\right)+\frac{1}{Z}\left(\frac{\partial^{2} Z}{\partial z^{2}}\right)=\frac{-8 \pi^{2} m E}{h^{2}} \tag{1.5.29}
\end{equation*}
$$

Now it is obvious that each of the three terms on the left side of eq. (1.5.29) is equal to a constant:

$$
\begin{align*}
\frac{1}{X}\left(\frac{\partial^{2} X}{\partial x^{2}}\right) & =-\alpha_{x}^{2}  \tag{1.5.30}\\
\frac{1}{Y}\left(\frac{\partial^{2} Y}{\partial y^{2}}\right) & =-\alpha_{y}^{2}  \tag{1.5.31}\\
\frac{1}{Z}\left(\frac{\partial^{2} Z}{\partial z^{2}}\right) & =-\alpha_{z}^{2} \tag{1.5.32}
\end{align*}
$$

with the constraint on the constants being

$$
\begin{equation*}
\alpha_{x}^{2}+\alpha_{y}^{2}+\alpha_{z}^{2}=\frac{8 \pi^{2} m E}{h^{2}} \tag{1.5.33}
\end{equation*}
$$

In other words, each degree of freedom makes its own contribution to the total energy:

$$
\begin{equation*}
\alpha_{x}^{2}=\frac{8 \pi^{2} m E_{x}}{h^{2}}, \alpha_{y}^{2}=\frac{8 \pi^{2} m E_{y}}{h^{2}}, \alpha_{z}^{2}=\frac{8 \pi^{2} m E_{z}}{h^{2}}, \tag{1.5.34}
\end{equation*}
$$

and

$$
\begin{equation*}
E=E_{x}+E_{y}+E_{z} \tag{1.5.35}
\end{equation*}
$$

Each of eqs. (1.5.30) to (1.5.32) is similar to that of the one-dimensional problem, eq. (1.5.2) or (1.5.3). Hence the solutions of eqs. (1.5.30) to (1.5.32) can be readily written

$$
\begin{align*}
& X_{j}(x)=\left(\frac{2}{a}\right)^{\frac{1}{2}} \sin \left(\frac{j \pi x}{a}\right), \quad j=1,2,3, \ldots  \tag{1.5.36}\\
& Y_{k}(y)=\left(\frac{2}{b}\right)^{\frac{1}{2}} \sin \left(\frac{k \pi y}{b}\right), \quad k=1,2,3, \ldots  \tag{1.5.37}\\
& Z_{\ell}(z)=\left(\frac{2}{c}\right)^{\frac{1}{2}} \sin \left(\frac{\ell \pi z}{c}\right), \quad \ell=1,2,3, \ldots \tag{1.5.38}
\end{align*}
$$

The total wavefunction, as given by eq. (1.5.26), then becomes

$$
\begin{gather*}
\psi_{j, k, \ell}(x, y, z)=\left(\frac{8}{a b c}\right)^{\frac{1}{2}} \sin \left(\frac{j \pi x}{a}\right) \sin \left(\frac{k \pi y}{b}\right) \sin \left(\frac{\ell \pi z}{c}\right), \\
j, k, \ell=1,2,3, \ldots \tag{1.5.39}
\end{gather*}
$$

Now $\psi$ has the unit of volume ${ }^{-1 / 2}$ and $|\psi|^{2}$ has the unit of volume ${ }^{-1}$, as expected for a probability density function of a three-dimensional system.

As in the case of the wavefunctions, the energy of the system is also dependent on three quantum numbers:

$$
\begin{align*}
E_{j, k, \ell} & =\left(E_{x}\right)_{j}+\left(E_{y}\right)_{k}+\left(E_{z}\right)_{\ell} \\
& =\left(\frac{h^{2}}{8 m}\right)\left[\left(\frac{j^{2}}{a^{2}}\right)+\left(\frac{k^{2}}{b^{2}}\right)+\left(\frac{\ell^{2}}{c^{2}}\right)\right], \quad j, k, \ell=1,2,3, \ldots \tag{1.5.40}
\end{align*}
$$

When the box is a cube, i.e. $a=b=c$, eq. (1.5.40) becomes

$$
\begin{equation*}
E_{j, k, \ell}=\left(\frac{h^{2}}{8 m a^{2}}\right)\left(j^{2}+k^{2}+\ell^{2}\right), \quad j, k, \ell=1,2,3, \ldots \tag{1.5.41}
\end{equation*}
$$

An interesting feature of the energy expression given by eq. (1.5.41) is that different states, with different sets of quantum numbers and different wavefunctions, can have the same energy. When different states have the same energy, they are called degenerate states. For examples,

$$
\begin{equation*}
E_{1,1,2}=E_{1,2,1}=E_{2,1,1}=\frac{3 h^{2}}{4 m a^{2}} \tag{1.5.42}
\end{equation*}
$$

or

$$
\begin{equation*}
E_{1,2,3}=E_{2,1,3}=E_{1,3,2}=E_{3,1,2}=E_{3,2,1}=E_{2,3,1}=\frac{7 h^{2}}{4 m a^{2}} \tag{1.5.43}
\end{equation*}
$$

## Fundamentals of Bonding Theory

Now we will apply the particle in a three-dimensional box model to a chemical problem. When sodium vapor is passed over a crystal of NaCl , the crystal exhibits a greenish-yellow color, which is the result of the process

$$
\delta \mathrm{Na}(\mathrm{~g})+\mathrm{NaCl}(\mathrm{c}) \longrightarrow\left(\mathrm{Na}^{+}\right)_{1+\delta}\left(\mathrm{Cl}^{-} e_{\delta}^{-}\right)(\mathrm{c}), \quad \delta \ll 1
$$

In this "solid-state reaction," the adsorbed Na atoms ionize on the crystal surface, and the excess electrons diffuse into the interior and occupy vacant anionic sites, while an equal number of chloride ions migrate toward the surface to preserve charge balance. Trapped electrons occupying anionic vacancies are called color centers or $F$-centers ( $F$ stands for farbe, meaning color in German). A trapped electron within the lattice of crystalline $\left(\mathrm{Na}^{+}\right)_{1+\delta}\left(\mathrm{Cl}^{-} e_{\delta}^{-}\right)$is depicted in Fig. 1.5.2. The color observed in such experiments can be related with a transition between two energy levels of a (free) particle trapped in a box. Before treating this problem quantitatively, it is of interest to note that the color observed in such experiments depends on the nature of the host crystal, but not on the source of the electron. Thus heating KCl in potassium vapor gives a purple color, and NaCl heated in the same potassium vapor emits a greenish-yellow color.

Experimentally, the absorption maxima for NaCl and NaBr crystals have energies $(\Delta E) 4.32 \times 10^{-19} \mathrm{~J}$ (corresponding to $\lambda=460 \mathrm{~nm}$ ) and $3.68 \times 10^{-19}$ $\mathrm{J}(\lambda=540 \mathrm{~nm})$, respectively. If we take this $\Delta E$ as the energy difference between the two lowest levels of a three-dimensional box, $E_{1,1,1}$ and $E_{1,1,2}$, we can readily calculate the dimension of the box (denoted as $\ell$ below):

$$
\Delta E=\frac{3 h^{2}}{8 m \ell^{2}}
$$

In the above expression we have replaced the dimension of the box $a$ in eq. (1.5.41) by $\ell$. Now the $\ell$ values for NaCl and NaBr can be easily calculated to be 647 and 701 pm , respectively. It is noted that the $\ell$ value of NaBr "box" is longer than that of NaCl by 54 pm .

The cubic unit-cell dimensions (a) of NaCl and NaBr crystals are 563 and 597 pm , respectively (Table 10.1.4). As shown in Fig.1.5.2, the side (denoted as $\ell^{\prime}$ below) of the three-dimensional box for an electron occupying a color center can at most be the body diagonal of the unit cell minus twice the cationic radius (the "true" value should be somewhat less):

$$
\ell^{\prime}=(3)^{\frac{1}{2}} a-2 r_{\mathrm{Na}^{+}}
$$

With $r_{\mathrm{Na}^{+}}$being 102 pm , we find that the (maximum) $\ell^{\prime}$ values for NaCl and NaBr crystals are 771 and 830 pm , respectively. Because of the crudeness of the model, these $\ell^{\prime}$ values differ to some extent from the $\ell$ values calculated earlier. Still, a good qualitative correlation between the two crystals is obtained: the difference between the two $\ell$ values, 54 pm , is in good accord with the difference between the two $\ell^{\prime}$ values, 59 pm .

The topic of color centers in NaCl and related crystals will be discussed more fully in Section 10.1.2.

### 1.5.3 Particle in a ring

In this system, the electron can move only along the circumference and therefore polar coordinates can be used to advantage, as shown in Fig. 1.5.3:

$$
V=\left\{\begin{array}{cc}
0, & r=R ; \\
\infty & r \neq R .
\end{array}\right.
$$

The Schrödinger equation is

$$
\begin{equation*}
\left(\frac{-h^{2}}{8 \pi^{2} m}\right) \frac{\mathrm{d}^{2} \psi(x)}{\mathrm{d} x^{2}}=E \psi(x) \tag{1.5.44}
\end{equation*}
$$

We can change the variable $x$ to the angular variable $\phi$ by

$$
\begin{equation*}
x=\phi R . \tag{1.5.45}
\end{equation*}
$$

Now eq. (1.5.44) becomes

$$
\begin{equation*}
\frac{\mathrm{d}^{2} \psi(\phi)}{\mathrm{d} \phi^{2}}=\left(\frac{-8 \pi^{2} m E R^{2}}{h^{2}}\right) \psi(\phi)=-m_{\ell}^{2} \psi(\phi), \tag{1.5.46}
\end{equation*}
$$

with

$$
\begin{equation*}
m_{\ell}^{2}=\frac{8 \pi^{2} m E R^{2}}{h^{2}} \tag{1.5.47}
\end{equation*}
$$

Solutions to eq. (1.5.46) are obvious:

$$
\begin{equation*}
\psi(\phi)=A \mathrm{e}^{i m_{\ell} \phi} \tag{1.5.48}
\end{equation*}
$$

Since $\psi(\phi)$ must be single-valued,

$$
\begin{equation*}
\psi(\phi+2 \pi)=\psi(\phi)=A \mathrm{e}^{i m_{\ell} \phi}=A \mathrm{e}^{i m_{\ell}(\phi+2 \pi)} \tag{1.5.49}
\end{equation*}
$$

In other words,

$$
\begin{equation*}
e^{i m_{\ell}(2 \pi)}=\cos 2 m_{\ell} \pi+i \sin 2 m_{\ell} \pi=1 \tag{1.5.50}
\end{equation*}
$$

For eq. (1.5.50) to hold,

$$
\begin{equation*}
m_{\ell}=0, \pm 1, \pm 2, \ldots \tag{1.5.51}
\end{equation*}
$$

So the wavefunctions have the form

$$
\begin{equation*}
\psi_{m_{\ell}}(\phi)=A \mathrm{e}^{i m_{\ell} \phi}, \quad \mathrm{m}_{\ell}=0, \pm 1, \pm 2, \ldots \tag{1.5.52}
\end{equation*}
$$

The constant $A$ can again be determined with the normalization condition:

$$
\begin{equation*}
A^{2} \int_{0}^{2 \pi}\left|\psi_{m_{\ell}}\right|^{2} \mathrm{~d} \varphi=A^{2} \int_{0}^{2 \pi} \psi_{m_{\ell}}^{*} \psi_{m_{\ell}} \mathrm{d} \phi=A^{2} \int_{0}^{2 \pi} \mathrm{~d} \phi=2 \pi A^{2}=1 \tag{1.5.53}
\end{equation*}
$$

Fig. 1.5.4.
The eigenvalues and eigenfunctions of the particle-in-a-ring problem.

$$
\begin{array}{lll}
9 — — & m_{l}= \pm 3 & \psi_{3}=\frac{1}{(2 \pi)^{1 / 2}} \mathrm{e}^{3 i} \phi \\
4 & \psi_{-3}=\frac{1}{(2 \pi)^{1 / 2}} \mathrm{e}^{-3 i} \phi \\
1- & m_{l}= \pm 2 & \psi_{2}=\frac{1}{(2 \pi)^{1 / 2}} \mathrm{e}^{2 i} \phi
\end{array} \psi_{-2}=\frac{1}{(2 \pi)^{1 / 2}} \mathrm{e}^{-2 i} \phi
$$

or

$$
\begin{equation*}
A=(2 \pi)^{-\frac{1}{2}} \tag{1.5.54}
\end{equation*}
$$

So the normalized wavefunctions are

$$
\begin{equation*}
\psi_{m_{\ell}}=(2 \pi)^{-\frac{1}{2}} \mathrm{e}^{i m_{\ell} \phi}, \quad m_{\ell}=0, \pm 1, \pm 2, \ldots \tag{1.5.55}
\end{equation*}
$$

The allowed energy values for this system can be determined using eq. (1.5.47):

$$
\begin{equation*}
E_{m_{\ell}}=\frac{m_{\ell}^{2} h^{2}}{8 \pi^{2} m R^{2}}, \quad m_{\ell}=0, \pm 1, \pm 2, \ldots \tag{1.5.56}
\end{equation*}
$$

In other words, only the ground state is non-degenerate, while all the excited states are doubly degenerate. The quantum mechanical results of the particle-in-a-ring problem are summarized in Fig. 1.5.4.

If we apply the free-electron model to the six $\pi$ electrons of benzene, we see that the $\psi_{0}, \psi_{1}$, and $\psi_{-1}$ orbitals are filled with electrons, while $\psi_{2}$ and $\psi_{-2}$ and all the higher levels are vacant. To excite an electron from $\psi_{1}$ (or $\psi_{-1}$ ) to $\psi_{2}$ (or $\psi_{-2}$ ), we need an energy of

$$
\Delta E=\frac{3 h^{2}}{8 \pi^{2} m R^{2}}=h c / \lambda
$$

If we take $R=140 \mathrm{pm}$, we get $\lambda=212 \mathrm{~nm}$. Experimentally, benzene absorbs weakly at 268 nm .

Next we apply this simple model to the annulenes. These compounds are monocyclic conjugated polyenes with the general molecular formula $(\mathrm{CH})_{n}$ with $n$ even. Thus benzene may be considered as [6]-annulene. As $n$ increases, essentially all $[n]$-annulenes are non-planar. For instance, cyclooctatetraene, $(\mathrm{CH})_{8}$, has the well-know "tub" structure. However, [18]-annulene is nearly planar, as shown below (bond lengths in picometers are displayed in bold italic font).

Adding up the 18 bond lengths around the ring, we obtain a value of 2510 pm . If we take this to be the circumference of the molecular ring, the radius $R$ of the ring is approximately 400 pm . Thus the lowest electronic transition of this molecule requires an energy of

$$
\Delta E=\frac{9 h^{2}}{8 \pi^{2} m R^{2}}=h c / \lambda
$$

Here $\lambda$ is calculated to be 572 nm . Experimentally, [18]-annulene absorbs at $\lambda=790 \mathrm{~nm}$. Clearly the "agreement" is not very good. But this crude model does arrive at an absorption wavelength that has the correct order of magnitude.

In Section 1.5.1, it was mentioned that the energy of the lowest state of a particle confined in a one-dimensional box is not zero and this residual energy is a consequence of the Uncertainty Principle. Yet the ground state energy of the particle-in-a-ring problem is zero. Does this mean the present result is in violation of the Uncertainty Principle? The answer is clearly no, and the reason is as follows. In a one-dimensional box, variable $x$ starts from 0 and ends at $a$, the length of the box. Hence $\Delta x$ can at most be $a$. On the other hand, in a ring, cyclic variable $\phi$ does not lie within a finite domain. In such a situation, the uncertainty in position cannot be estimated.

### 1.5.4 Particle in a triangle

To conclude this chapter, we present the quantum mechanical results of the particle-in-a-triangle problem. Before going into details, we first need to note that, if the "box" is a scalene triangle, no analytical solution is known. Indeed, the Schrödinger equation is exactly solvable for only a few triangular systems. In addition, for all these solvable (two-dimensional) cases, the wavefunctions are no longer the simple products of two functions each involving only one variable.

In the following discussion, some language and notation of group theory are used for convenience. The meaning of this language or notation is made clear in Chapter 6.

## (1) Isosceles right triangle

The coordinate system chosen for this problem is shown in Fig. 1.5.5.

## Fig. 1.5.5.

Coordinate system for the problem of a particle in an isosceles right triangle.

The Schrödinger equation in this case is simply the two-dimensional analog of eqs. (1.5.2) and (1.5.25):

$$
\begin{equation*}
\left(\frac{-h^{2}}{8 \pi^{2} m}\right)\left(\frac{\partial^{2} \psi}{\partial x^{2}}+\frac{\partial^{2} \psi}{\partial y^{2}}\right)=E \psi \tag{1.5.57}
\end{equation*}
$$

The boundary conditions for this problem are $\psi$ vanishes when $x=0, y=0$ or $x+y=a$. If we apply the technique of separation of variables introduced in Section 1.5 .2 to eq. (1.5.57), we can easily obtain the following wavefunctions and energy values:

$$
\begin{align*}
& \psi_{j, k}(x, y)=\left[\left(\frac{2}{a}\right)^{\frac{1}{2}} \sin \left(\frac{j \pi x}{a}\right)\right]\left[\left(\frac{2}{a}\right)^{\frac{1}{2}} \sin \left(\frac{k \pi y}{a}\right)\right],  \tag{1.5.58}\\
& E_{j, k}=\left(\frac{h^{2}}{8 m a^{2}}\right)\left(j^{2}+k^{2}\right), \quad j, k=1,2,3, \ldots \tag{1.5.59}
\end{align*}
$$

These are the solutions of the particle-in-a-square problem.
Since the expression for $E_{j, k}$ is symmetrical with respect to the exchange of quantum numbers $j$ and $k$, i.e. $E_{j, k}=E_{k, j}$. In other words, $\psi_{j, k}$ and $\psi_{k, j}$ are degenerate wavefunctions.

It is clear that wavefunctions $\psi_{j, k}$ satisfy the boundary condition of $\psi$ vanishes when $x=0$ or $y=0$, but not the condition of $\psi$ vanishes when $x+y=a$. In order to satisfy the latter condition, we first linearly combine $\psi_{j, k}$ and $\psi_{k, j}$ :

$$
\begin{align*}
\psi_{j, k}^{\prime} & =(2)^{-\frac{1}{2}}\left(\psi_{j, k}+\psi_{k, j}\right) \\
& =\left[\frac{(2)^{\frac{1}{2}}}{a}\right]\left[\sin \left(\frac{j \pi x}{a}\right) \sin \left(\frac{k \pi y}{a}\right)+\sin \left(\frac{k \pi x}{a}\right) \sin \left(\frac{j \pi y}{a}\right)\right]  \tag{1.5.60}\\
\psi_{j, k}^{\prime \prime} & =(2)^{-\frac{1}{2}}\left(\psi_{j, k}-\psi_{k, j}\right) \\
& =\left[\frac{(2)^{\frac{1}{2}}}{a}\right]\left[\sin \left(\frac{j \pi x}{a}\right) \sin \left(\frac{k \pi y}{a}\right)-\sin \left(\frac{k \pi x}{a}\right) \sin \left(\frac{j \pi y}{a}\right)\right] . \tag{1.5.61}
\end{align*}
$$

When $j=k, \psi_{j, k}^{\prime}$ is simply $\psi_{j, j}^{\prime}$ (aside from a numerical factor) and $\psi_{j, j}^{\prime \prime}$ vanishes; hence neither $\psi_{j, j}^{\prime}$ nor $\psi_{j, j}^{\prime \prime}$ is an acceptable solution. On the other hand, when $j=k \pm 1, k \pm 3, \ldots, \psi_{j, k}^{\prime}$ vanishes when $x+y=a$; also, when $j=k \pm 2, k \pm 4, \ldots, \psi_{j, k}^{\prime \prime}$ vanishes under the same condition. Thus, $\psi_{j, k}^{\prime}(j=$ $k \pm 1, k \pm 3, \ldots)$ and $\psi_{j, k}^{\prime \prime}(j=k \pm 2, j \pm 4, \ldots)$ are the solutions to the isosceles triangle problem. It is clear that these functions are no longer products of two functions each involving only one variable. In addition, the energy expression now becomes:

$$
\begin{equation*}
E_{j, k}=\left(\frac{h^{2}}{8 m a^{2}}\right)\left(j^{2}+k^{2}\right), \quad j, k=1,2,3, \ldots \text { and } j \neq k \tag{1.5.62}
\end{equation*}
$$

Since only one wavefunction can be written for a set of quantum numbers $(j, k)$, i.e. $\psi_{j, k}^{\prime}=\psi_{k, j}^{\prime}$ and $\psi_{j, k}^{\prime \prime}=\psi_{k, j}^{\prime \prime}$ (aside from a negative sign), the "systematic" degeneracy in the particle-in-a-square problem, i.e. $E_{k, j}=E_{j, k}$ in eq. (1.5.59), is now removed. This is expected as there is a reduction in symmetry from $D_{4 \mathrm{~h}}$ (square box) to $C_{2 \mathrm{v}}$ (isosceles triangular box). Still, some "accidental" degeneracies remain in the right-triangular case; for example, $E_{1,8}=E_{4,7}$. These degeneracies may be dealt with by techniques of elementary number theory, which is clearly beyond the scope of this book. Additional discussions may be found in the references listed at the end of this chapter.

## (2) Equilateral triangle

When the triangle is equilateral, with the coordinates as shown in Fig. 1.5.6, the boundary conditions for eq. (1.5.57) now take the form $\psi=0$ for $y=0$, $y=(3)^{1 / 2} x$ or $y=(3)^{1 / 2}(a-x)$.

There are a number of ways to solve this problem, and the results obtained by these methods appear to be quite different at first sight. In fact, in some formulations, it takes multiple sets of quantum number to specify a single state. In any event, the mathematics involved in all of these treatments is beyond the scope of this book. Here we merely present the results of one approach and discuss the energies and wavefunctions of this system from the symmetry viewpoint.

Fig. 1.5.6.
Coordinate system for an equilateral triangle. Equations of the three sides specify the boundary conditions.

Table 1.5.1. Energies and symmetry of the wavefunctions for the first seven levels of a particle in an equilateral triangle.

| $(p, q)$ | Energy* | Symmetry |
| :--- | :---: | :---: |
| $(1,0)$ | 1 | $A_{1}$ |
| $\left(1^{1 / 3}, 1 / 3\right)$ | $2^{1 / 3}$ | $E$ |
| $(2,0)$ | 4 | $A_{1}$ |
| $\left(1^{2 / 3}, 2 / 3\right)$ | $4^{1 / 3}$ | $E$ |
| $\left(2^{1 / 3,},{ }^{1 / 3}\right)$ | $6^{1 / 3}$ | $E$ |
| $(2,1)$ | 7 | $A_{1}, A_{2}$ |
| $(3,0)$ | 9 | $A_{1}$ |

* In units of ground state energy $E_{0}, 2 h^{2} / 3 m a^{2}$.

For this two-dimensional system, it again takes a set of two quantum numbers to specify a state. The energies of this system may be expressed as

$$
\begin{align*}
E_{p, q} & =\left(p^{2}+p q+q^{2}\right)\left(\frac{2 h^{2}}{3 m a^{2}}\right) \\
\text { with } q & =0, \frac{1}{3}, \frac{2}{3}, 1, \ldots, \quad p=q+1, q+2, \ldots \tag{1.5.63}
\end{align*}
$$

So the ground state energy $E_{0}$ is

$$
\begin{equation*}
E_{0}=E_{1,0}=\frac{2 h^{2}}{3 m a^{2}} \tag{1.5.64}
\end{equation*}
$$

The wavefunctions $\psi_{p, q}$ may be classified according to their symmetry properties. If we take the symmetry point group of this system to be $C_{3 \mathrm{v}}$, there are three symmetry species in this group: $A_{1}$ (symmetric with respect to all operations of this group), $A_{2}$ (symmetric with respect to the threefold rotations but antisymmetric with respect to the vertical symmetry planes), and $E$ (a two-dimensional representation).

For a level with energy $E_{p, 0}$, the wavefunction $\psi_{p, 0}$ has $A_{1}$ symmetry and this level is non-degenerate. On the other hand, a level defined by positive integral quantum numbers $p$ and $q$ with energy $E_{p, q}$ is doubly degenerate. One wavefunction of this level has $A_{1}$ symmetry and the other one has $A_{2}$ symmetry. When $p$ and $q$ are non-integers ( $1 / 3,2 / 3,1^{1 / 3}, \ldots$, etc.), the doubly degenerate functions form an $E$ set. Table 1.5.1 lists the quantum numbers, energies and wavefunction symmetry for the first seven states for a particle in an equilateral triangle.

The wavefunctions $\psi_{p, q}$ have the form

$$
\begin{align*}
\psi_{p, q}\left(A_{1}\right)= & \cos \left[\frac{q(3)^{1 / 2} \pi x}{A}\right] \sin \left[\frac{(2 p+q) \pi y}{A}\right] \\
& -\cos \left[\frac{p(3)^{1 / 2} \pi x}{A}\right] \sin \left[\frac{(2 q+p) \pi y}{A}\right] \\
& -\cos \left[\frac{(p+q)(3)^{1 / 2} \pi x}{A}\right] \sin \left[\frac{(p-q) \pi y}{A}\right] \tag{1.5.65}
\end{align*}
$$

when $q=0$,

$$
\begin{align*}
\psi_{p, 0}\left(A_{1}\right)= & \sin \left[\frac{2 p \pi y}{A}\right]-2 \sin \left[\frac{p \pi y}{A}\right] \cos \left[\frac{p(3)^{1 / 2} \pi x}{A}\right]  \tag{1.5.66}\\
\psi_{p, q}\left(A_{2}\right)= & \sin \left[\frac{q(3)^{1 / 2} \pi x}{A}\right] \sin \left[\frac{(2 p+q) \pi y}{A}\right] \\
& -\sin \left[\frac{p(3)^{1 / 2} \pi x}{A}\right] \sin \left[\frac{(2 q+p) \pi y}{A}\right] \\
& +\sin \left[\frac{(p+q)(3)^{1 / 2} \pi x}{A}\right] \sin \left[\frac{(p-q) \pi y}{A}\right] \tag{1.5.67}
\end{align*}
$$

In eqs. (1.5.65) to (1.5.67), $A$ represents the altitude of the triangle. The two wavefunctions that make up the $E$ set may also be expressed by eqs. (1.5.65) and (1.5.67), but quantum numbers $p$ and $q$ now have non-integral values.

The wavefunctions for the first seven states with energies and symmetries summarized in Table 1.5 .1 are graphically illustrated in Fig. 1.5.7. It is now clear that all levels with non-integral quantum numbers are doubly degenerate and their respective wavefunctions form an $E$ set. Also, the $A_{1}$ wavefunctions are symmetric with respect to the threefold rotations as well as to the symmetry planes, while $A_{2}$ wavefunctions are symmetric with respect to the threefold rotations but antisymmetric with respect to the symmetry planes.

## (3) The $30^{\circ}-60^{\circ}-90^{\circ}$ triangle

This is a triangle that is half of an equilateral triangle. From Fig. 1.5.7, it is obvious that all the $A_{2}$ functions and one component from each pair of the $E$ functions possess a nodal plane which bisects the equilateral triangle into two $30^{\circ}-60^{\circ}-$ $90^{\circ}$ triangles. Thus a particle confined to a $30^{\circ}-60^{\circ}-90^{\circ}$ triangle has energies given by eq. (1.5.67), with the allowed quantum numbers $q=1 / 3,2 / 3,1, \ldots$

Fig. 1.5.7.
Graphical representations of the wavefunctions for the first seven states of the equilateral triangle.
and $p=q+1, q+2, \ldots$ Among the seven states listed in Table 1.5.1, only one component of the $E$ states and the $A_{2}$ states are the acceptable solutions of the $30^{\circ}-60^{\circ}-90^{\circ}$ triangle.

## The Electronic Structure of Atoms

Now we are ready to apply the method of wave mechanics to study the electronic structure of the atoms. At the beginning of this chapter, we concentrate on the hydrogen atom, which consists of one proton and one electron. After treating the hydrogen atom, we will proceed to the other atoms in the Periodic Table.

### 2.1 The hydrogen atom

### 2.1.1 Schrödinger equation for the hydrogen atom

If we place the nucleus of the hydrogen atom at the origin of a set of Cartesian coordinates, the position of the electron would be given by $x, y$, and $z$, as shown in Fig. 2.1.1. However, the solution of the Schrödinger equation for this system becomes intractable if it is done in Cartesian coordinates. Instead, this problem is solved using polar spherical coordinates $r, \theta$, and $\phi$, which are also shown in Fig. 2.1.1. These two sets of coordinates are related by:

$$
\left\{\begin{array}{l}
z=r \cos \theta  \tag{2.1.1}\\
x=r \sin \theta \cos \phi \\
y=r \sin \theta \sin \phi
\end{array}\right.
$$

Some other useful relationships are

$$
\begin{align*}
r^{2} & =x^{2}+y^{2}+z^{2}  \tag{2.1.2}\\
\tan \phi & =\frac{y}{x} \tag{2.1.3}
\end{align*}
$$

Also, these two sets of variables have different ranges:

$$
\begin{gather*}
-\infty<x, y, z<\infty  \tag{2.1.4}\\
\left\{\begin{array}{l}
0 \leq r<\infty \\
0 \leq \theta \leq \pi \\
0 \leq \phi \leq 2 \pi
\end{array}\right. \tag{2.1.5}
\end{gather*}
$$

Fig. 2.1.1.
The coordinate system for a hydrogen-like (one-electron) atom; $Z=1$ for the H atom.

## Fundamentals of Bonding Theory

The Laplacian operator $\nabla^{2}$ has the form

$$
\begin{align*}
\nabla^{2} & =\frac{\partial^{2}}{\partial x^{2}}+\frac{\partial^{2}}{\partial y^{2}}+\frac{\partial^{2}}{\partial z^{2}} \\
& =\frac{1}{r^{2}} \frac{\partial}{\partial r}\left(r^{2} \frac{\partial}{\partial r}\right)+\frac{1}{r^{2} \sin \theta} \frac{\partial}{\partial \theta}\left(\sin \theta \frac{\partial}{\partial \theta}\right)+\frac{1}{r^{2} \sin ^{2} \theta} \frac{\partial^{2}}{\partial \phi^{2}} \tag{2.1.6}
\end{align*}
$$

The volume element $\mathrm{d} \tau$ is given by

$$
\begin{equation*}
\mathrm{d} \tau=\mathrm{d} x \mathrm{~d} y \mathrm{~d} z=r^{2} \mathrm{~d} r \sin \theta \mathrm{~d} \theta \mathrm{~d} \phi \tag{2.1.7}
\end{equation*}
$$

For the hydrogen atom and other hydrogenic ions, the potential energy $V$ is simply the attraction between the proton and the electron:

$$
\begin{equation*}
V=-\frac{Z e^{2}}{4 \pi \varepsilon_{0} r} \tag{2.1.8}
\end{equation*}
$$

So the Schrödinger equation for this system is

$$
\begin{equation*}
\left[\left(-\frac{h^{2}}{8 \pi^{2} m}\right) \nabla^{2}-\left(\frac{Z e^{2}}{4 \pi \varepsilon_{0} r}\right)\right] \psi(r, \theta, \phi)=E \psi(r, \theta, \phi) \tag{2.1.9}
\end{equation*}
$$

or

$$
\begin{align*}
\frac{1}{r^{2}} & \frac{\partial}{\partial r}\left(r^{2} \frac{\partial}{\partial r} \psi\right)+\frac{1}{r^{2} \sin \theta} \frac{\partial}{\partial \theta}\left(\sin \theta \frac{\partial \psi}{\partial \theta}\right) \\
& +\frac{1}{r^{2} \sin ^{2} \theta} \frac{\partial^{2} \psi}{\partial \phi^{2}}+\frac{8 \pi^{2} m}{h^{2}}\left(E+\frac{Z e^{2}}{4 \pi \varepsilon_{0} r}\right) \psi=0 \tag{2.1.10}
\end{align*}
$$

To solve eq. (2.1.10), we first assume that the function $\psi$ (with three variables) is a product of three functions, each of one variable:

$$
\begin{equation*}
\psi(r, \theta, \phi)=R(r) \Theta(\theta) \Phi(\phi) \tag{2.1.11}
\end{equation*}
$$

Upon substituting, we can "factorize" eq. (2.1.10) into the following three equations, each involving only one variable:

$$
\begin{gather*}
\frac{\mathrm{d}^{2} \Phi}{\mathrm{~d} \phi^{2}}=-m_{\ell}^{2} \Phi  \tag{2.1.12}\\
\frac{m_{\ell}^{2} \Theta}{\sin ^{2} \theta}-\frac{1}{\sin \theta} \frac{\mathrm{~d}}{\mathrm{~d} \theta}\left(\sin \theta \frac{\mathrm{~d} \Theta}{\mathrm{~d} \theta}\right)-\beta \Theta=0  \tag{2.1.13}\\
\frac{1}{r^{2}} \frac{\mathrm{~d}}{\mathrm{~d} r}\left(r^{2} \frac{\mathrm{~d} R}{\mathrm{~d} r}\right)-\frac{\beta}{r^{2}} R+\frac{8 \pi^{2} m}{h^{2}}\left(E+\frac{Z \mathrm{e}^{2}}{4 \pi \varepsilon_{0} r}\right) R=0 \tag{2.1.14}
\end{gather*}
$$

In eqs. (2.1.12) to (2.1.14), $m_{\ell}$ and $\beta$ are so-called "separation constants" and they will eventually lead to quantum numbers. Also, $R(r)$ is called the radial function, while the product $\Theta(\theta) \Phi(\phi)$, henceforth called $Y(\theta, \phi)$, is the angular function:

$$
\begin{equation*}
Y(\theta, \phi)=\Theta(\theta) \Phi(\phi) \tag{2.1.15}
\end{equation*}
$$

### 2.1.2 Angular functions of the hydrogen atom

After solving eqs. (2.1.12) and (2.1.13), it is found that, in order for functions to be meaningful, the separation constants $m_{\ell}$ and $\beta$ must take the following values:

$$
\begin{align*}
m_{\ell} & =0, \pm 1, \pm 2, \ldots  \tag{2.1.16}\\
\beta & =\ell(\ell+1), \ell=0,1,2, \ldots, \tag{2.1.17}
\end{align*}
$$

and

$$
\begin{equation*}
m_{\ell}=-\ell,-\ell+1, \ldots, \ell . \tag{2.1.18}
\end{equation*}
$$

The integers $\ell$ and $m_{\ell}$ are called azimuthal (or angular momentum) and magnetic quantum numbers, respectively.

Moreover, the function $\Phi(\phi)$ depends on $m_{\ell}$ and hence is written as $\Phi_{m_{\ell}}(\phi)$, while $\Theta(\theta)$ depends on both $\ell$ and $m_{\ell}$ and is written as $\Theta_{\ell, m_{\ell}}(\theta)$. Their product $Y(\theta, \phi)$ thus also depends on both $\ell$ and $m_{\ell}$ :

$$
\begin{equation*}
Y_{\ell, m_{\ell}}(\theta, \phi)=\Theta_{\ell, m_{\ell}}(\theta) \Phi_{m_{\ell}}(\phi) . \tag{2.1.19}
\end{equation*}
$$

The $Y_{\ell, m_{\ell}}(\theta, \phi)$ functions are called spherical harmonics. They determine the angular character of the electronic wavefunction and will be of primary consideration in the treatment of directional bonding.

Spherical harmonics, which describes the angular parts of the atomic orbitals, are labeled by their $\ell$ values according to the scheme

$$
\begin{align*}
\ell & =0,1,2,3,4, \ldots \\
\text { Label } & =\mathrm{s}, \mathrm{p}, \mathrm{~d}, \mathrm{f}, \mathrm{~g}, \ldots . \tag{2.1.20}
\end{align*}
$$

Table 2.1.1 lists the first few, and the most often encountered, spherical harmonics.

The spherical harmonics $Y_{\ell, m_{\ell}}(\theta, \phi)$ form an orthonormal set of functions:

$$
\begin{align*}
\int_{0}^{2 \pi} \int_{0}^{\pi} Y_{\ell, m_{\ell}}^{*} Y_{\ell^{\prime}, m_{\ell}^{\prime}} \sin \theta \mathrm{d} \theta \mathrm{~d} \phi & =\int_{0}^{2 \pi} \Phi_{m_{\ell}^{\prime}}^{*} \Phi_{m_{\ell}} \mathrm{d} \phi \cdot \int_{0}^{\pi} \Theta_{\ell^{\prime}, m_{\ell}^{\prime}}^{*} \Theta_{\ell, m_{\ell}} \sin \theta \mathrm{d} \theta \\
& = \begin{cases}1, & \text { when } m_{\ell}^{\prime}=m_{\ell} \text { AND } \ell^{\prime}=\ell \\
0, & \text { when } m_{\ell}^{\prime} \neq m_{\ell} \text { OR } \ell^{\prime} \neq \ell\end{cases} \tag{2.1.21}
\end{align*}
$$

Note that the quantum number $m_{\ell}$ appears in the exponential function $\mathrm{e}^{i m_{\ell} \phi}$ in the spherical harmonics. The $Y_{\ell, m_{\ell}}$ functions, being complex, cannot be conveniently drawn in real space. However, we can linearly combine them to make

## Fundamentals of Bonding Theory

Table 2.1.1. Explicit expressions for the spherical harmonics with $\ell=0,1,2,3$

| $Y_{0,0}=\frac{1}{(4 \pi)^{1 / 2}}$ | $Y_{3,3}=\left(\frac{35}{64 \pi}\right)^{1 / 2} \sin ^{3} \theta \mathrm{e}^{3 i \phi}$ |

| $\mathrm{p}_{x}$ | $\left(\frac{3}{4 \pi}\right)^{1 / 2} \sin \theta \cos \phi$ | $\mathrm{f}_{y z^{2}}$ | $\frac{1}{8}\left(\frac{42}{\pi}\right)^{1 / 2} \sin \theta\left(5 \cos ^{2} \theta-1\right) \sin \phi$ |
| $\mathrm{p}_{y}$ | $\left(\frac{3}{4 \pi}\right)^{1 / 2} \sin \theta \sin \phi$ | $\mathrm{f}_{x y z}$ | $\frac{1}{4}\left(\frac{105}{\pi}\right)^{1 / 2} \sin ^{2} \theta \cos \theta \sin 2 \phi$ |
| $\ell=2 \mathrm{~d}_{z^{2}}$ | $\frac{1}{4}\left(\frac{5}{\pi}\right)^{1 / 2}\left(3 \cos ^{2} \theta-1\right)$ | $\mathrm{f}_{z\left(x^{2}-y^{2}\right)}$ | $\frac{1}{4}\left(\frac{105}{\pi}\right)^{1 / 2} \sin ^{2} \theta \cos \theta \cos 2 \phi$ |
| $\mathrm{~d}_{x z}$ | $\frac{1}{4}\left(\frac{15}{\pi}\right)^{1 / 2} \sin 2 \theta \cos \phi$ | $\mathrm{f}_{x\left(x^{2}-3 y^{2}\right)} \frac{1}{8}\left(\frac{70}{\pi}\right)^{1 / 2} \sin ^{3} \theta \cos 3 \phi$ |  |
| $\mathrm{~d}_{y z}$ | $\frac{1}{4}\left(\frac{15}{\pi}\right)^{1 / 2} \sin 2 \theta \sin \phi$ | $\mathrm{f}_{y\left(3 x^{2}-y^{2}\right)} \frac{1}{8}\left(\frac{70}{\pi}\right)^{1 / 2} \sin ^{3} \theta \sin 3 \phi$ |  |
| $\mathrm{~d}_{x^{2}-y^{2}}$ | $\frac{1}{4}\left(\frac{15}{\pi}\right)^{1 / 2} \sin 2 \theta \cos 2 \phi$ |  |  |
| $\mathrm{~d}_{x y}$ | $\frac{1}{4}\left(\frac{15}{\pi}\right)^{1 / 2} \sin ^{2} \theta \sin 2 \phi$ |  |  |

the imaginary parts vanish. For example:

$$
\begin{align*}
\frac{1}{(2)^{1 / 2}}\left(Y_{1,1}+Y_{1,-1}\right) & =\frac{1}{(2)^{1 / 2}} \cdot \frac{1}{2} \cdot\left(\frac{3}{2 \pi}\right)^{1 / 2} \sin \theta\left(\mathrm{e}^{i \phi}+\mathrm{e}^{-i \phi}\right) \\
& =\frac{1}{4}\left(\frac{3}{\pi}\right)^{1 / 2} \sin \theta(\cos \phi+i \sin \phi+\cos \phi-i \sin \phi) \\
& =\frac{1}{2}\left(\frac{3}{\pi}\right)^{1 / 2} \sin \theta \cos \phi \tag{2.1.22}
\end{align*}
$$

As $\sin \theta \cos \phi$ describes the angular dependence of the $x$ component of $r$ [eq. (2.1.1)], the combination $\left(1 /(2)^{1 / 2}\right)\left(Y_{1,1}+Y_{1,-1}\right)$ is hence called

the $\mathrm{p}_{x}$ orbital. The most often used real angular functions are summarized in Table 2.1.2.

The real angular functions given in Table 2.1.2 can be drawn readily. In Fig. 2.1.2, the shapes of the $s, p$, and d orbitals are shown, along with the signs of the lobes in each angular function, and the radial function $R(r)$ is assumed to be a constant. We note once again that these figures represent only the shapes of the orbitals. The curves outlining the shapes are not the contour lines of the atomic orbitals shown in some subsequent figures such as Figs. 2.1.4 and 2.1.6.

From Fig. 2.1.2, we can see that if we have an electron occupying an s orbital, we will have equal probability of finding this electron in all possible directions. On the other hand, for a $\mathrm{p}_{x}$ electron, we will most likely find it along the $+x$ or $-x$ axis. For an electron in the $\mathrm{d}_{x y}$ orbital, the electron is likely found if we look for it in the $x y$ plane and along the directions of $x=y$ or $x=-y$. For the remaining orbitals, the directions along which the electron is most likely to be found can be determined readily with the help of these figures.

Fig. 2.1.2.
The angular functions of the $\mathrm{s}, \mathrm{p}$, and d orbitals.

## Fundamentals of Bonding Theory

### 2.1.3 Radial functions and total wavefunctions of the hydrogen atom

The remaining equation to be solved is the radial equation [eq. (2.1.14)], bearing in mind that $\beta$ is now $\ell(\ell+1)$ [eq. (2.1.17)]. Hence the solution $R(r)$ also depends on $\ell$. In addition, the principal quantum number $n$ arises from the solution of this equation. Thus the radial functions depend on both $n$ and $\ell$, and we write them as $R_{n, \ell}(r)$. Specifically, $n$ and $\ell$ take the values

$$
\begin{align*}
& n=1,2,3,4, \ldots,  \tag{2.1.23}\\
& \ell=0,1,2,3, \ldots, n-1 \tag{2.1.24}
\end{align*}
$$

Also, as energy $E$ appears only in the radial equation, it might be expected to be dependent on $n$ and $\ell$ and independent of $m_{\ell}$. As it turns out, it only depends on $n$.

The explicit forms of the radial functions of hydrogenic orbitals 1s through 4 f are listed in Table 2.1.3, where $Z$ is the nuclear charge of the atom and $a_{0}$ is the Bohr radius:

$$
\begin{equation*}
a_{0}=\varepsilon_{0} h^{2} / \pi m e^{2}=0.529 \times 10^{-10} \mathrm{~m}=52.9 \mathrm{pm} . \tag{2.1.25}
\end{equation*}
$$

Note that the radial functions $R_{n, \ell}$ also form an orthonormal set of functions:

$$
\int_{0}^{\infty} R_{n^{\prime}, \ell} R_{n, \ell} r^{2} \mathrm{~d} r= \begin{cases}1, & \text { when } n^{\prime}=n  \tag{2.1.26}\\ 0, & \text { when } n^{\prime} \neq n\end{cases}
$$

The first six radial functions given in Table 2.1.3 are plotted in Fig. 2.1.3. The squares of these functions, $\left|R_{n, \ell}(r)\right|^{2}$, which is related to the probability density

Fig. 2.1.3.
The first six radial functions of the hydrogen atom drawn to the same scale.
function, will be discussed in detail later. At this point, we are in a position to write down the first few total wavefunctions $\psi(r, \theta, \phi)$, which are simply the products of the angular functions (Table 2.1.2) and the radial functions (Table 2.1.3). These total wavefunctions are listed in Table 2.1.4.

The hydrogenic wavefunctions have the general analytical form:

$$
\begin{equation*}
\psi_{n, \ell, m_{\ell}}(r, \theta, \phi)=R_{n, \ell}(r) \Theta_{\ell, m_{\ell}}(\theta) \Phi_{m_{\ell}}(\phi), \tag{2.1.27}
\end{equation*}
$$

with each part normalized to unity. The total wavefunctions of some representative orbitals are plotted in Fig. 2.1.4.

From Fig. 2.1.4, it is seen that, while all s orbitals are spherically symmetric, the 2 s orbital is larger than the 1 s , and the 3 s is even larger. Note that the 2 s orbital has one node at $r=2 a_{0}$ and the 3 s orbital has two nodes at $r=1.91 a_{0}$ and $r=7.08 a_{0}$ (see below). On the other hand, the $2 \mathrm{p}_{z}$ orbital is no longer spherically symmetric. Instead, its absolute value has a maximum at $\theta=0^{\circ}$ and $\theta=180^{\circ}$ and the function vanishes at $\theta=90^{\circ}$. In other words, the $x y$ plane is a nodal plane. As the figure indicates, the function has a positive value for $0^{\circ}<\theta<90^{\circ}$ and it becomes negative for $90^{\circ}<\theta<180^{\circ}$. The wavefunctions of the other orbitals may be interpreted in a similar manner.

\end{aligned}
$$

In Fig. 2.1.4, the outer lines represent the value of $\psi=0.5 \times 10^{-2}$ or $-0.5 \times 10^{-2}$, in which $\psi_{1 \mathrm{~s}}, r=2.4 a_{0} ; \psi_{2 \mathrm{~s}}, r=10.2 a_{0} ; \psi_{3 \mathrm{~s}}, r=15.8 a_{0}$. These $r$ values and other $r$ values in p and d orbitals can be used to indicate the relative sizes of the orbitals. The radii of node spheres which are shown by broken lines are as follows: $\psi_{2 \mathrm{~s}}, r=2 a_{0} ; \psi_{3 \mathrm{~s}}, r=1.91 a_{0}$ and $7.08 a_{0} ; \psi_{3 \mathrm{p}_{z}}, r=6 a_{0}$.

The following points are noted from the plots in Figs. 2.1.3 and 2.1.4:
(1) The orbitals increase in size as the principal quantum number $n$ increases.
(2) Only s orbitals have finite density at the nucleus.

Fig. 2.1.4.
The total wavefunctions of some hydrogenic orbitals. The + and symbols give the sign of the function in the region indicated, while the dashed lines show the positions of the nodes. The values of $\psi$ contours shown have been multiplied by a factor of 100 .

Fig. 2.1.5.
The three-dimensional shapes of the 2 s , 2 p , and 3d orbitals.
(3) The number of nodes for functions $R_{n, \ell}$ is $n-\ell-1$.
(4) Among orbitals with the same $n$, those with smaller $\ell$ have greater density close to the nucleus, but their principal maximum is further out.

To summarize at this point, it is reiterated that wavefunction $\psi(r, \theta, \phi)$ is a function of $r, \theta$, and $\phi$. When the point is moved to another location in space, the value of the wavefunction is changed accordingly. The three-dimensional shape of each orbital can be represented by a contour surface, on which every point has the same value of $\psi$. The three-dimensional shapes of nine hydrogenic orbitals ( 2 s , 2p, and 3d) are displayed in Fig. 2.1.5. In these orbitals, the nodal surfaces are located at the intersections where $\psi$ changes its sign. For instance, for the $2 \mathrm{p}_{x}$ orbital, the $y z$ plane is a nodal plane. For the $3 \mathrm{~d}_{x y}$ orbital, the $x z$ and $y z$ plane are the nodal planes.

### 2.1.4 Relative sizes of hydrogenic orbitals and the probability criterion

In the Bohr model of the hydrogen atom, the radius of an orbit in terms of unit $a_{0}$ is given by $n^{2}$, and the sizes of the $K, L, M$ and $N$ shells are in the ratio 1:4:9:16.

For hydrogenic orbitals, the average distance of the electron from the nucleus, $\bar{r}$, can be evaluated exactly from the equation

$$
\begin{equation*}
\bar{r}=\int_{0}^{\infty} r D_{n, \ell} \mathrm{~d} r=n^{2}\left[3 / 2-\{\ell(\ell+1)\} / 2 n^{2}\right] . \tag{2.1.28}
\end{equation*}
$$

Table 2.1.5. Average distances $(\bar{r})$, most probable distances ( $r_{\text {max }}$ ), and associated probabilities $(P)$ of hydrogenic orbitals

| Atomic orbital | $\bar{r}$ | Size ratio | $P$ | $r_{\max }$ | $P$ |
| :--- | :---: | :---: | :---: | :---: | :---: |
| 1 s | 1.5 | 1 | 0.58 | 1 | 0.32 |
| 2 s | 6 | 4 | 0.54 | 5.24 | 0.39 |
| 2 p | 5 | 3.33 | 0.56 | 4 | 0.37 |
| 3 s | 13.5 | 9 | 0.49 | 13.07 | 0.44 |
| 3 p | 12.5 | 8.33 | 0.49 | 12 | 0.44 |
| 3d | 10.5 | 7 | 0.55 | 9 | 0.39 |
| 4 s | 24 | 16 | 0.44 | 24.62 | 0.48 |
| 4 p | 23 | 15.33 | 0.44 | 23.58 | 0.48 |
| 4 d | 21 | 14 | 0.45 | 21.21 | 0.47 |
| 4 f | 18 | 12 | 0.46 | 16 | 0.41 |

The $\bar{r}$ values for orbitals 1s through 4 f and their size ratios, calculated relative to the 1 s value as a standard, are given in the second and third columns of Table 2.1.5.

For any given orbital, the probability of finding the electron in the volume element $\mathrm{d} \tau=r^{2} \mathrm{~d} r \sin \theta \mathrm{~d} \theta \mathrm{~d} \phi$ [eq. (2.1.7)] in the vicinity of the point $(r, \theta, \phi)$ is

$$
\begin{equation*}
P=\left|\psi_{n, \ell, m_{\ell}}(r, \theta, \phi)\right|^{2} r^{2} \mathrm{~d} r \sin \theta \mathrm{~d} \theta \mathrm{~d} \phi \tag{2.1.29}
\end{equation*}
$$

If we integrate this expression over all possible values of $\theta$ and $\phi$, we get

$$
\begin{align*}
& \int_{0}^{\pi}\left|\Theta_{\ell, m_{\ell}}\right|^{2} \sin \theta \mathrm{~d} \theta \cdot \int_{0}^{2 \pi}\left|\Phi_{m_{\ell}}\right|^{2} \mathrm{~d} \phi \cdot\left|R_{n, \ell}\right|^{2} r^{2} \mathrm{~d} r \\
& \quad=r^{2} R_{n, \ell}^{2} \mathrm{~d} r \equiv D_{n, \ell} \mathrm{~d} r \tag{2.1.30}
\end{align*}
$$

which represents the probability of finding the electron between distances $r$ and $r+\mathrm{d} r$ from the nucleus regardless of direction. The $D_{n, \ell}$ function in eq. (2.1.30) is called the radial probability distribution function. It is incorrect to write $D_{n, \ell}$ as $4 \pi r^{2} R_{n, \ell}^{2}$, which has the extraneous factor $4 \pi$, or as $4 \pi r^{2} \psi^{2}$ which holds only for the spherically symmetric s orbitals.

Figure 2.1.6 shows plots of the $D_{n, \ell}$ functions against $r$ for the first few hydrogenic orbitals. The positions of the maxima and minima in each curve are as follows:

1 s : maximum at $1 a_{0}$;
2 s : maxima at 0.76 and $5.24 a_{0}$; minimum at $2 a_{0}$;
2 p : maximum at $4 a_{0}$;
$3 \mathrm{~s}: \quad$ maxima at $0.73,4.20$ and $13.07 a_{0}$; minima at 1.91 and $7.08 a_{0}$;
3 p : maxima at 3 and $12 a_{0} ;$ minimum at $6 a_{0}$;
3 d : maximum at $9 a_{0}$.
Take the 1s electron as an example. In the Bohr theory, the electron moves in a fixed orbit of radius $1 a_{0}$. On the other hand, in the wave mechanical treatment, the electron can in principle be found at any distance from the nucleus, and the most probable nucleus-electron separation is $1 a_{0}$. Here we can see

Fig. 2.1.6.
The radial probability function $D_{n, \ell}$ or $\left|r R_{n, \ell}\right|^{2}$, drawn to the same scale, of the first six hydrogenic orbitals.
the philosophical difference between these two models. In addition, while we should look for a $2 \mathrm{p}_{x}$ or $3 \mathrm{p}_{x}$ electron along the $+x$ or $-x$ direction, Fig. 2.1.6 shows that the $2 \mathrm{p}_{x}$ electron is most likely found at a point $4 a_{0}$ from the nucleus, whereas the corresponding distance for a $3 p_{x}$ electron is $12 a_{0}$.

For hydrogenic orbitals with $n-\ell>1$, the most probable distance $r_{\text {max }}$ may be defined as the distance of the "principal maximum," namely the outermost and most prominent of the maxima of the $D_{n, \ell}$ function from the nucleus. The $r_{\text {max }}$ values of the hydrogenic orbitals are listed in the fifth column of Table 2.1.5. It is seen that the size ratios for the $1 \mathrm{~s}, 2 \mathrm{p}, 3 \mathrm{~d}$, and 4 f orbitals, which satisfy the relation $\ell=n-1$, are exactly the same as those of the Bohr orbits, which vary as $n^{2}$. Furthermore, for orbitals in the same shell, $r_{\text {max }}$ decreases as $\ell$ increases, as in the case of $\bar{r}$. The data in Table 2.1 .5 show that orbital size ratios based on $\bar{r}$ are smaller than those based on $r_{\text {max }}$.

A plausible estimate of the spatial extension of a hydrogenic orbital is the radius of a spherical boundary surface within which there is a high probability of finding the electron. In order to develop this criterion on a quantitative basis, it is useful to define a cumulative probability function $P_{n \ell}(\rho)$ which gives the probability of finding the electron at a distance less than or equal to $\rho$ from the nucleus:

$$
\begin{equation*}
P_{n \ell}(\rho)=\int_{0}^{\rho} D_{n, \ell} \mathrm{~d} r \tag{2.1.31}
\end{equation*}
$$

The function $P_{n \ell}(\rho)$ can be expressed in closed form, and the expressions for 1 s through 4 f orbitals are listed in Table 2.1.6. They can be used to give some measure of correlation between the various criteria for orbital size. For

Table 2.1.6. Cumulative probability functions for hydrogenic orbitals

any specified distance $\rho$, the probability of finding the electron within the range $0<r \leq \rho$ can be obtained by direct substitution into these expressions.

The cumulative probability functions listed in Table 2.1.6 can be used to give some measure of correlation between the various criteria for orbital size. Once a particular value for $P$ is chosen, it can be equated to each of the expresssions in turn and the resulting transcendental equation solved numerically. The $\rho$ values thus obtained for $P=0.50,0.90,0.95$, and 0.99 are tabulated in Table 2.1.7. The significant quantites are the size ratios, with the $1 \mathrm{~s} \rho$ value as standard, which provide a rational scale of relative orbital size based on any adopted probability criterion. As the prescribed $P$ value approaches unity, the size ratios gradually decrease in magnitude and orbitals in the same shell tend to converge to a similar size.

The probabilty criterion $P=0.95$ (or 0.99 ) yields the most compact scale of orbital size, according to which the size of the first four qunatum shells are approximately in the ratio of 1:3:6:10. In the fourth and last columns of Tables 2.1.5, the probabilities corresponding to $\bar{r}$ and $r_{\text {max }}$ are listed, respectively. Scrutiny of the data in Tables 2.1.5 and 2.1.7 show that adoption of $\bar{r}$ as an indication of orbital size corresponds fairly closely to a $50 \%$ probability

## Fundamentals of Bonding Theory

criterion. The use of $r_{\text {max }}$ may be roughly matched with a lower criterion of $40 \%$, but the correlation is not as satisfactory.

### 2.1.5 Energy levels of hydrogenic orbitals; summary

As mentioned previously, energy $E$ appears only in the radial equation [eq. (2.1.14)], which does not involve $m_{\ell}$. Hence we readily note that s orbitals are non-degenerate, $p$ orbitals are triply degenerate, $d$ orbitals have fivefold degeneracy, and f orbitals have sevenfold degeneracy. As it turns out, for the hydrogen atom only, $E$ is also independent of $\ell$ :

$$
\begin{equation*}
E_{n}=\frac{-m e^{4} Z^{2}}{8 \varepsilon_{0}^{2} h^{2} n^{2}}=\frac{-Z^{2} e^{2}}{8 \pi \varepsilon_{0} a_{0} n^{2}}=-13.6\left(\frac{Z^{2}}{n^{2}}\right) \mathrm{eV} \tag{2.1.32}
\end{equation*}
$$

To summarize, each hydrogenic orbital is described by three quantum numbers and each quantum number is responsible for some properties:
(1) Principal quantum number $n, n=1,2, \ldots$ : solely responsible for the energy of the orbital and largely accountable for the orbital size;
(2) Azimuthal quantum number $\ell, \ell=0,1,2, \ldots, n-1$ : mainly accounting for the shape of the orbital; and
(3) Magnetic quantum number $m_{\ell}, m_{\ell}=-\ell,-\ell+1, \ldots, \ell$ : describes the orientation of the orbital.

Comparing the results of the Bohr and the wave mechanical models, we find that:
(a) Both theories lead to the same energy expression.
(b) It can be shown that wavefunctions may be used to determine other atomic properties such as the intensity of the spectral lines, etc.
(c) Quantum numbers appear naturally in solving of the Schrödinger equation (even though this has not been explicitly shown here). But they are inserted arbitrarily in the Bohr model.
(d) Electrons in the Bohr theory occupy planet-like orbits. In the wave mechanical model they occupy delocalized orbitals. Experimental evidences support the Schrödinger picture.

### 2.2 The helium atom and the Pauli Exclusion Principle

Before we embark on this topic, we first introduce the "atomic units," which are defined in Table 2.2.1.

In the quantum mechanical treatment we have studied so far, we always try to obtain the wavefunction $\psi$ and energy $E$ by solving the Schrödinger equation:

$$
\begin{equation*}
\hat{H} \psi=E \psi \tag{2.2.1}
\end{equation*}
$$

However, it often happens that an exact solution of the Schrödinger equation is impossible. Instead we usually rely on approximation methods. If we have $\psi^{\prime}$

Table 2.2.1. Atomic units (a.u.)

| Length | 1 a.u. $=a_{0}=5.29177 \times 10^{-11} \mathrm{~m}$ (Bohr radius) |
| :--- | :--- |
| Mass | 1 a.u. $=m_{e}=9.109382 \times 10^{-31} \mathrm{~kg}$ (rest mass of electron) |
| Charge | 1 a.u. $=\|e\|=1.6021764 \times 10^{-19} \mathrm{C}$ (charge of electron) |
| Energy | 1 a.u. $=\frac{e^{2}}{4 \pi \varepsilon_{0} a_{0}}=27.2114 \mathrm{eV}$ (potential energy between two electrons <br> when they are $1 a_{0}$ apart) |
| Angular momentum | 1 a.u. $=\frac{h}{2 \pi}(\equiv \hbar)=1.05457 \times 10^{-34} \mathrm{~J} \mathrm{~s}$ |
| Scale factor | $4 \pi \varepsilon_{0}=1$ |

as an approximation solution of eq. (2.2.1), its energy is simply

$$
\begin{equation*}
E=\frac{\int \psi^{\prime *} \hat{H} \psi^{\prime} d \tau}{\int \psi^{\prime *} \psi^{\prime} d \tau} \tag{2.2.2}
\end{equation*}
$$

### 2.2.1 The helium atom: ground state

Now we turn to the helium atom, whose coordinate system is shown in Fig. 2.2.1. The potential energy of this system (in a.u.) is

$$
\begin{equation*}
V=-\frac{Z}{r_{1}}-\frac{Z}{r_{2}}+\frac{1}{r_{12}}, \tag{2.2.3}
\end{equation*}
$$

and the Schrödinger equation takes the form

$$
\begin{equation*}
\left(-\frac{1}{2} \nabla_{1}^{2}-\frac{1}{2} \nabla_{2}^{2}-\frac{Z}{r_{1}}-\frac{Z}{r_{2}}+\frac{1}{r_{12}}\right) \psi=E \psi \tag{2.2.4}
\end{equation*}
$$

where $\psi=\psi\left(r_{1}, \theta_{1}, \phi_{1}, r_{2}, \theta_{2}, \phi_{2}\right)=\psi(1,2)$. Note that operators $\nabla_{1}^{2}$ and $\nabla_{2}^{2}$ affect the coordinates of electrons 1 and 2, respectively. Equation (2.2.4) cannot be solved exactly and, in the following treatment, we will attempt to solve it by approximation. As a first (and very drastic) approximation, we ignore the electronic repulsion term $\frac{1}{r_{12}}$ in eq. (2.2.3) or eq. (2.2.4). Now eq. (2.2.4) becomes

$$
\begin{equation*}
\left[-\frac{1}{2} \nabla_{1}^{2}-\frac{Z}{r_{1}}\right] \psi(1,2)+\left[-\frac{1}{2} \nabla_{2}^{2}-\frac{Z}{r_{2}}\right] \psi(1,2)=E \psi(1,2) . \tag{2.2.5}
\end{equation*}
$$

Fig. 2.2.1.
The coordinate system for the helium atom.

## Fundamentals of Bonding Theory

If we separate the variables in $\psi(1,2)$,

$$
\begin{equation*}
\psi(1,2)=\psi_{1}(1) \psi_{2}(2) \tag{2.2.6}
\end{equation*}
$$

and substitute this version of $\psi(1,2)$ into eq. (2.2.5), we have

$$
\begin{equation*}
\psi_{2}(2)\left[-\frac{1}{2} \nabla_{1}^{2}-\frac{Z}{r_{1}}\right] \psi_{1}(1)+\psi_{1}(1)\left[-\frac{1}{2} \nabla_{2}^{2}-\frac{Z}{r_{2}}\right] \psi_{2}(2)=E \psi_{1}(1) \psi_{2}(2) \tag{2.2.7}
\end{equation*}
$$

Dividing eq. (2.2.7) by $\psi_{1}(1) \psi_{2}(2)$ leads to

$$
\begin{equation*}
\frac{\left[-\frac{1}{2} \nabla_{1}^{2}-\frac{Z}{r_{1}}\right] \psi_{1}(1)}{\psi_{1}(1)}+\frac{\left[-\frac{1}{2} \nabla_{2}^{2}-\frac{Z}{r_{2}}\right] \psi_{2}(2)}{\psi_{2}(2)}=E \tag{2.2.8}
\end{equation*}
$$

It is obvious that both terms on the left side of eq. (2.2.8) must each be equal to a constant, corresponding to $E_{\mathrm{a}}$ and $E_{\mathrm{b}}$, respectively, and

$$
\begin{equation*}
E_{\mathrm{a}}+E_{\mathrm{b}}=E \tag{2.2.9}
\end{equation*}
$$

So the simplified Schrödinger equation eq. (2.2.7) can be separated into two (familiar) equations, each involving only the coordinates of one electron:

$$
\begin{align*}
& {\left[-\frac{1}{2} \nabla_{1}^{2}-\frac{Z}{r_{1}}\right] \psi_{1}(1)=E_{\mathrm{a}} \psi_{1}(1)}  \tag{2.2.10}\\
& {\left[-\frac{1}{2} \nabla_{2}^{2}-\frac{Z}{r_{2}}\right] \psi_{2}(2)=E_{\mathrm{b}} \psi_{2}(2)} \tag{2.2.11}
\end{align*}
$$

We have already solved eqs. (2.2.10) and (2.2.11) in the treatment of the hydrogen atom; the only difference is that now $Z=2$. If we take the ground state wavefunction and energy (in a.u.),

$$
\begin{align*}
& \psi_{1}(1)=\psi_{1 \mathrm{~s}}(1)=\frac{1}{(\pi)^{1 / 2}} Z^{\frac{3}{2}} \mathrm{e}^{-Z r_{1}}  \tag{2.2.12}\\
& \psi_{2}(2)=\psi_{1 \mathrm{~s}}(2)=\frac{1}{(\pi)^{1 / 2}} Z^{\frac{3}{2}} \mathrm{e}^{-Z r_{2}} \tag{2.2.13}
\end{align*}
$$

and

$$
\begin{align*}
\psi(1,2) & =\left(\frac{1}{(\pi)^{1 / 2}} Z^{\frac{3}{2}} \mathrm{e}^{-Z r_{1}}\right)\left(\frac{1}{(\pi)^{1 / 2}} Z^{\frac{3}{2}} \mathrm{e}^{-Z r_{2}}\right) ;  \tag{2.2.14}\\
E_{\mathrm{a}} & =E_{\mathrm{b}}=E_{1 \mathrm{~s}}=-\frac{1}{2} Z^{2} \text { a.u. } \tag{2.2.15}
\end{align*}
$$

and

$$
\begin{equation*}
E=-Z^{2} \text { a.u. }=-108.8 \mathrm{eV} \tag{2.2.16}
\end{equation*}
$$

The experimental energy is -79.0 eV .
To improve on this result, we need to understand what causes the error in the solution given by eq. (2.2.14), aside from the fact that electronic repulsion has been ignored. From $\psi_{1}(1), \psi_{2}(2)$, and $\psi(1,2)$ given by eqs. (2.2.12) to (2.2.14), we can see that, in our approximation, each electron "sees" a nuclear charge of +2 . As illustrated in Fig. 2.2.2, when electron 2 is completely outside electron 1 , the charge it "sees" is about +1 , as the +2 nuclear charge is shielded by the -1 electron cloud. On the other hand, if electron 2 is deep inside the electron cloud of electron 1 , the charge it "sees" is close to +2 . Hence a more realistic picture would be that each electron should "see" an "effective nuclear charge" ( $Z_{\text {eff }}$ ) between 1 and 2:

$$
\begin{equation*}
1<Z_{\mathrm{eff}}<2 \tag{2.2.17}
\end{equation*}
$$

If that is the case, $\psi_{1}(1)$ and $\psi_{2}(2)$ in eqs. (2.2.12) and (2.2.13) now become

$$
\begin{align*}
& \psi_{1}(1)=\frac{1}{(\pi)^{1 / 2}} Z_{\text {eff }}^{\frac{3}{2}} \mathrm{e}^{-Z_{\text {eff }} r_{1}},  \tag{2.2.18}\\
& \psi_{2}(2)=\frac{1}{(\pi)^{1 / 2}} Z_{\text {eff }}^{\frac{3}{3}} \mathrm{e}^{-Z_{\text {eff }} r_{2}}, \tag{2.2.19}
\end{align*}
$$

Again,

$$
\begin{equation*}
\psi(1,2)=\psi_{1}(1) \psi_{2}(2) . \tag{2.2.6}
\end{equation*}
$$

To determine the energy of the trial wavefunction given by eq. (2.2.18), (2.2.19), and (2.2.6), we make use of eq. (2.2.2):

$$
\begin{align*}
E & =E\left(Z_{\text {eff }}\right) \\
& =\frac{\iint \psi(1,2)\left[-\frac{1}{2} \nabla_{1}^{2}-\left(\frac{Z}{r_{1}}\right)-\frac{1}{2} \nabla_{2}^{2}-\left(\frac{Z}{r_{2}}\right)+\left(\frac{1}{r_{12}}\right)\right] \psi(1,2) \mathrm{d} \tau_{1} \mathrm{~d} \tau_{2}}{\iint|\psi(1,2)|^{2} \mathrm{~d} \tau_{1} \mathrm{~d} \tau_{2}} . \tag{2.2.20}
\end{align*}
$$

Fig. 2.2.2.
Screening of the nucleus by one of the electrons in the helium atom.

## Fundamentals of Bonding Theory

It should be clear that $E$ is dependent on $Z_{\text {eff }}$. To calculate $E$ is not very difficult, except for the integral involving $1 / r_{12}$. Still, we are going to skip the mathematical details here and will only be concerned with the results:

$$
\begin{equation*}
E=\left(Z_{\mathrm{eff}}^{2}-2 Z Z_{\mathrm{eff}}+\frac{5 Z_{\mathrm{eff}}}{8}\right) \text { a.u. } \tag{2.2.21}
\end{equation*}
$$

To determine the optimal (or best) value for $Z_{\text {eff }}$, we vary $Z_{\text {eff }}$ until $E$ is at the minimum:

$$
\begin{equation*}
\frac{\mathrm{d} E}{\mathrm{~d} Z_{\mathrm{eff}}}=2 Z_{\mathrm{eff}}-2 Z+\frac{5}{8}=0 \tag{2.2.22}
\end{equation*}
$$

or

$$
\begin{equation*}
Z_{\mathrm{eff}}=Z-\left(\frac{5}{16}\right) \tag{2.2.23}
\end{equation*}
$$

For the specific case of helium, $Z=2$, we get

$$
\begin{equation*}
Z_{\mathrm{eff}}=\frac{27}{16}=1.6875 \tag{2.2.24}
\end{equation*}
$$

This value of $Z_{\text {eff }}$ is within the range we wrote down in eq. (2.2.17). Substituting eq. (2.2.23) into eq. (2.2.21) leads to

$$
\begin{equation*}
E_{\min }=-Z_{\text {eff }}^{2} \text { a.u. }=-\left[Z-\left(\frac{5}{16}\right)\right]^{2} \text { a.u. } \tag{2.2.25}
\end{equation*}
$$

For helium, with $Z=2$, we have

$$
\begin{equation*}
E_{\min }=-(1.6875)^{2} \text { a.u. }=-2.85 \text { a.u. }=-77.5 \mathrm{eV}, \tag{2.2.26}
\end{equation*}
$$

recalling that experimentally helium has the energy of -79.0 eV . So, with such a simple treatment, a very reasonable result is obtained. However, to close the remaining gap of 1.5 eV , considerable effort is required (see below).

What we have applied to helium is called the variational method, which usually consists of the following steps:
(1) Set up a trial function with one or more parameters $\psi\left(\alpha_{1}, \alpha_{2}, \ldots\right)$;
(2) Calculate $E\left(\alpha_{1}, \alpha_{2}, \ldots\right)=\frac{\int \psi^{*} \hat{H} \psi \mathrm{~d} \tau}{\int \psi^{*} \psi \mathrm{~d} \tau}$.
(3) Obtain the optimal values of $\alpha_{1}, \alpha_{2}, \ldots$ and hence the minimum energy by setting $\partial E / \partial \alpha_{1}=\partial E / \partial \alpha_{2}=\cdots=0$.

In 1959, C. L. Pekeris, by optimizing a 1,078-term wavefunction for helium, obtained an energy essentially identical to the experimental value.

Before concluding this section, we will take a closer look at the relatively simple trial wavefunctions for helium, i.e., those functions with one or two adjustable parameters. While neglecting the mathematical details of the calculations, we will pay particular attention to the physical meaning of the
parameters. In so doing we will acquire a better understanding on the design of trial wavefunctions.

First we rewrite the trial wavefunction for helium given by eqs. (2.2.18), (2.2.19), and (2.2.6) as

$$
\psi_{\mathrm{a}}=\mathrm{e}^{-\alpha\left(r_{1}+r_{2}\right)}
$$

As mentioned previously, parameter $\alpha$ may be viewed as the effective nuclear charge "felt" by either one of the two electrons. Such an interaction is commonly called the screening effect. Furthermore, as described by this wavefunction, the two electrons move independently of each other, i.e., angular correlation is ignored. Electron correlation may be taken as the tendency of the electrons to avoid each other. For helium, angular correlation describes the two electrons' inclination to be on opposite sides of the nucleus. On the other hand, radial correlation, or screening effect, is the tendency for one electron to be closer to the nucleus, while the other one is farther away. A one-parameter trial function that does take angular correlation into account is

$$
\psi_{\mathrm{b}}=\mathrm{e}^{-Z\left(r_{1}+r_{2}\right)}\left(1+c r_{12}\right)
$$

As will be shown later, $\psi_{\mathrm{b}}$ is actually a better trial function than $\psi_{\mathrm{a}}$. Thus it is surprising, and a pity, that $\psi_{\mathrm{b}}$ has not been included in most of the text books.

Proceeding to trial functions with two parameters, we can see that a function that includes both the screening effect and angular correlation is

$$
\psi_{\mathrm{c}}=e^{-\alpha\left(r_{1}+r_{2}\right)}\left(1+c r_{12}\right)
$$

Clearly this function is an improvement on both $\psi_{\mathrm{a}}$ and $\psi_{\mathrm{b}}$.
Recall $\psi_{\mathrm{a}}$ assumes that both electrons in helium experience the same effective nuclear charge $\alpha$. While this may be so in an average sense, such an approximation fails to take into account that, at a given instant, the two electrons are not likely to be equidistant from the nucleus and hence the effective nuclear charges they feel should not be the same. Taking this into consideration, C. Eckart proposed the following trial function in 1930:

$$
\psi_{\mathrm{d}}=\mathrm{e}^{-\alpha r_{1}} \mathrm{e}^{-\beta r_{2}}+\mathrm{e}^{-\beta r_{1}} \mathrm{e}^{-\alpha r_{2}}
$$

It is clear in $\psi_{\mathrm{d}}$ one electron is allowed to move closer to the nucleus and the other is allowed to be farther away. Once again, angular correlation is not explicitly included in this function. It is noted that this function has two terms because the two electrons are indistinguishable from each other. If we only take the first term, electron 1 is labeled by effective nuclear charge $\alpha$, while the other electron is labeled by $\beta$. This is not allowed in quantum mechanics. The indistinguishability of electrons will also be discussed in the next section.

The results for the aforementioned four trial wavefunctions are summarized in Table 2.2.2.

Examining the tabulated results, it is clear that, between the one-parameter trial functions, $\psi_{\mathrm{b}}$ is "better" than $\psi_{\mathrm{a}}$. Physically, this implies that angular

## Fundamentals of Bonding Theory

Table 2.2.2. Summary of four trial wavefunctions of helium atom in its ground state

| Trial wavefunction | Optimized parameter value(s) | IE(calc) $(\mathrm{eV})^{*}$ |
| :--- | :--- | :---: |
| $\psi_{\mathrm{a}}=\mathrm{e}^{-\alpha\left(r_{1}+r_{2}\right)}$ | $\alpha=1.6875$ (exact) | 23.1 |
| $\psi_{\mathrm{b}}=\mathrm{e}^{-Z\left(r_{1}+r_{2}\right)}\left(1+c r_{12}\right)$ | $c=0.5572$ | 23.9 |
| $\psi_{\mathrm{c}}=\mathrm{e}^{-\alpha\left(r_{1}+r_{2}\right)}\left(1+c r_{12}\right)$ | $\alpha=1.8497 ; c=0.3658$ | 24.2 |
| $\psi_{\mathrm{d}}=\mathrm{e}^{-\alpha r_{1}} \mathrm{e}^{-\beta r_{2}}+\mathrm{e}^{-\beta r_{1}} \mathrm{e}^{-\alpha r_{2}}$ | $\alpha=1.1885 ; \beta=2.1832$ | 23.8 |

* IE, ionization energy. The experimental IE of He is 24.6 eV .
correlation is a more important factor than the screening effect. Indeed, $\psi_{\mathrm{b}}$ is even slightly better than the two-parameter function $\psi_{d}$. This once again underscores the importance of angular correlation. In $\psi_{d}$, we can see that one optimized parameter is close to 2 , the nuclear charge, while the other is close to 1 . That means one electron is close to the nucleus and the other is effectively screened by the inner electron. Finally, since $\psi_{\mathrm{c}}$ takes both screening effect and angular correlation into consideration, it is naturally the best trial function among the four considered here.

### 2.2.2 Determinantal wavefunction and the Pauli Exclusion Principle

In our treatment of helium, each electron occupies a 1 s -like orbital, and hence the wavefunctions given in eqs. (2.2.18), (2.2.19), and (2.2.6) may be written as

$$
\begin{equation*}
\psi_{\mathrm{He}}(1,2)=1 \mathrm{~s}(1) 1 \mathrm{~s}(2) \tag{2.2.27}
\end{equation*}
$$

However, we cannot handle atoms with more than two electrons in the same manner. For instance, for lithium, the wavefunction

$$
\begin{equation*}
\psi_{\mathrm{Li}}(1,2,3)=1 \mathrm{~s}(1) 1 \mathrm{~s}(2) 1 \mathrm{~s}(3) \tag{2.2.28}
\end{equation*}
$$

is not acceptable at all, since it denotes an electronic configuration $\left(1 \mathrm{~s}^{3}\right)$ that violates the Pauli Exclusion Principle. This principle states that no two electrons can have the same set of quantum numbers.

For atomic systems, it is often said that each electron is defined by four quantum numbers: $n, \ell, m_{\ell}$, and $m_{s}$. Actually, there is a fifth quantum number, $s$, which has the value of $1 / 2$ for all electrons. Quantum number $m_{s}$ can be either $1 / 2$ or $-1 / 2$, corresponding to spin function $\alpha$ (spin up) and $\beta$ (spin down), respectively. Spin functions $\alpha$ and $\beta$ form an orthonormal set,

$$
\begin{equation*}
\int \alpha \alpha \mathrm{d} \gamma=\int \beta \beta \mathrm{d} \gamma=1 \tag{2.2.29}
\end{equation*}
$$

and

$$
\begin{equation*}
\int \alpha \beta \mathrm{d} \gamma=0 \tag{2.2.30}
\end{equation*}
$$

where $\gamma$ is called a spin variable. If we add spin function to the spatial wavefunction given by eq. (2.2.27) to yield the total wavefunction for helium,

$$
\begin{equation*}
\psi_{\mathrm{p}}(1,2)=1 \mathrm{~s} \alpha(1) 1 \mathrm{~s} \beta(2) \tag{2.2.31}
\end{equation*}
$$

However, function $\psi_{\mathrm{p}}$ implies that electrons are distinguishable: electron 1 has its spin up and electron 2 spin down. Similarly, we should also consider the following in the total wavefunction for helium:

$$
\begin{equation*}
\psi_{\mathrm{q}}(1,2)=1 \mathrm{~s} \alpha(2) 1 \mathrm{~s} \beta(1) \tag{2.2.32}
\end{equation*}
$$

There are two ways of combining $\psi_{\mathrm{p}}$ and $\psi_{\mathrm{q}}$ in order to make the two electrons indistinguishable:

$$
\begin{equation*}
\frac{1}{(2)^{1 / 2}}\left[\psi_{\mathrm{p}}(1,2)+\psi_{\mathrm{q}}(1,2)\right]=\frac{1}{(2)^{1 / 2}}[1 \mathrm{~s} \alpha(1) 1 \mathrm{~s} \beta(2)+1 \mathrm{~s} \alpha(2) 1 \mathrm{~s} \beta(1)] \tag{1}
\end{equation*}
$$

which is symmetric with respect to the exchange of the two electrons;

$$
\begin{equation*}
\frac{1}{(2)^{1 / 2}}\left[\psi_{\mathrm{p}}(1,2)-\psi_{\mathrm{q}}(1,2)\right]=\frac{1}{(2)^{1 / 2}}[1 \mathrm{~s} \alpha(1) 1 \mathrm{~s} \beta(2)-1 \mathrm{~s} \alpha(2) 1 \mathrm{~s} \beta(1)] \tag{2}
\end{equation*}
$$

which is antisymmetric with respect to the exchange of the two electrons. Note that in expressions (2.2.33) and (2.2.34), the factor $1 /(2)^{1 / 2}$ is a normalization constant.

It is found that electronic wavefunctions must be antisymmetric with respect to the exchange of the coordinates of any two electrons. Hence, only the function given by expression (2.2.34) is acceptable for the helium atom:

$$
\begin{align*}
\psi(1,2) & =\frac{1}{(2)^{1 / 2}}[1 \mathrm{~s} \alpha(1) 1 \mathrm{~s} \beta(2)-1 \mathrm{~s} \alpha(2) 1 \mathrm{~s} \beta(1)] \\
& =1 \mathrm{~s}(1) 1 \mathrm{~s}(2)\left\{\frac{1}{(2)^{1 / 2}}[\alpha(1) \beta(2)-\beta(1) \alpha(2)]\right\} \\
& =(\text { symmetric spatial part }) \times(\text { antisymmetric spin part }) . \tag{2.2.35}
\end{align*}
$$

In our previous treatment of helium, we only used the spatial function 1s(1) 1s(2) to calculate the energy, while ignoring the spin part. This is acceptable because energy is independent of spin.

In eq. (2.2.35) we see that the helium wavefunction can be factorized into spatial (or orbital) and spin parts. It should be noted that such a factorization is possible only for two-electron systems. Yet another way of writing $\psi(1,2)$ of He as given in eq. (2.2.35) is

$$
\begin{align*}
\psi(1,2) & =\frac{1}{(2)^{1 / 2}}[1 \mathrm{~s} \alpha(1) 1 \mathrm{~s} \beta(2)-1 \mathrm{~s} \alpha(2) 1 \mathrm{~s} \beta(1)] \\
& =\frac{1}{(2)^{1 / 2}}\left|\begin{array}{cc}
1 \mathrm{~s} \alpha(1) & 1 \mathrm{~s} \beta(1) \\
1 \mathrm{~s} \alpha(2) & 1 \mathrm{~s} \beta(2)
\end{array}\right| \tag{2.2.36}
\end{align*}
$$

## Fundamentals of Bonding Theory

This is called a Slater determinant, in honor of physicist J. C. Slater. Since a determinant changes its sign upon the exchange of any two rows or columns, any wavefunction written in determinantal form must be antisymmetric with respect to electron exchange. If we take the determinantal function in eq. (2.2.36) and exchange its two rows:

$$
\begin{align*}
\psi(2,1) & =\frac{1}{(2)^{1 / 2}}\left|\begin{array}{cc}
1 \mathrm{~s} \alpha(2) & 1 \mathrm{~s} \beta(2) \\
1 \mathrm{~s} \alpha(1) & 1 \mathrm{~s} \beta(1)
\end{array}\right| \\
& =\frac{1}{(2)^{1 / 2}}[1 \mathrm{~s} \alpha(2) 1 \mathrm{~s} \beta(1)-1 \mathrm{~s} \alpha(1) 1 \mathrm{~s} \beta(2)]=-\psi(1,2) . \tag{2.2.37}
\end{align*}
$$

Also, such an antisymmetric function automatically satisfies the Pauli Exclusion Principle. For instance, if we write a function for helium having both electrons in the 1 s orbital with spin up,

$$
\frac{1}{(2)^{1 / 2}}\left|\begin{array}{ll}
1 \mathrm{~s} \alpha(1) & 1 \mathrm{~s} \alpha(1)  \tag{2.2.38}\\
1 \mathrm{~s} \alpha(2) & 1 \mathrm{~s} \alpha(2)
\end{array}\right|=\frac{1}{(2)^{1 / 2}}[1 \mathrm{~s} \alpha(1) 1 \mathrm{~s} \alpha(2)-1 \mathrm{~s} \alpha(1) 1 \mathrm{~s} \alpha(2)]=0 .
$$

Such a function vanishes because any determinant with two identical rows or columns vanishes. In other words, any system having both electrons in the 1 s orbital with $\alpha$ spin cannot exist. Now we see there is an alternative way of saying the Pauli Exclusion Principle: A wavefunction for a system with two or more electrons must be antisymmetric with respect to the interchange of labels of any two electrons.

Returning to the lithium atom, it is now clear the 1s orbital cannot accommodate all three electrons. Rather, two electrons are in the 1 s orbital with opposite spins, while the remaining electron is in the 2 s orbital with either $\alpha$ or $\beta$ spin. Hence two determinantal wavefunctions can be written for the ground state of lithium:

$$
\psi(1,2,3)=\frac{1}{(6)^{1 / 2}}\left|\begin{array}{lll}
1 \mathrm{~s} \alpha(1) & 1 \mathrm{~s} \beta(1) & 2 \mathrm{~s} \alpha(1)  \tag{2.2.39}\\
1 \mathrm{~s} \alpha(2) & 1 \mathrm{~s} \beta(2) & 2 \mathrm{~s} \alpha(2) \\
1 \mathrm{~s} \alpha(3) & 1 \mathrm{~s} \beta(3) & 2 \mathrm{~s} \alpha(3)
\end{array}\right|,
$$

and

$$
\psi(1,2,3)=\frac{1}{(6)^{1 / 2}}\left|\begin{array}{lll}
1 \mathrm{~s} \alpha(1) & 1 \mathrm{~s} \beta(1) & 2 \mathrm{~s} \beta(1)  \tag{2.2.40}\\
1 \mathrm{~s} \alpha(2) & 1 \mathrm{~s} \beta(2) & 2 \mathrm{~s} \beta(2) \\
1 \mathrm{~s} \alpha(3) & 1 \mathrm{~s} \beta(3) & 2 \mathrm{~s} \beta(3)
\end{array}\right|
$$

Since there are two determinantal functions for lithium, its ground state is a spin doublet. On the other hand, only one determinantal function can be written for helium [eq. (2.2.36)], and its ground state is a spin singlet.

Another notation describing the ground state of helium and lithium is $1 \mathrm{~s}^{2}$ and $1 s^{2} 2 s^{1}$, respectively. From this notation, we can tell quickly which orbitals accommodate the electrons and how the electron spins are related to each other. Such an assignment for the electrons is called the electronic configuration of the atom.

### 2.2.3 The helium atom: the $1 s^{1} 2 s^{1}$ configuration

When one of the electrons in helium is excited from the 1 s to the 2 s orbital, the configuration $1 \mathrm{~s}^{1} 2 \mathrm{~s}^{1}$ is obtained. Taking the indistinguishibility of electrons into account, two spatial wavefunctions can be written:

> symmetric spatial part: $\frac{1}{(2)^{1 / 2}}[1 \mathrm{~s}(1) 2 \mathrm{~s}(2)+1 \mathrm{~s}(2) 2 \mathrm{~s}(1)]$
> antisymmetric spatial part: $\frac{1}{(2)^{1 / 2}}[1 \mathrm{~s}(1) 2 \mathrm{~s}(2)-1 \mathrm{~s}(2) 2 \mathrm{~s}(1)]$

On the other hand, four functions can be written for the spin part:
symmetric spin part: $\quad \alpha(1) \alpha(2)$,
symmetric spin part: $\quad \beta(1) \beta(2)$,
symmetric spin part: $\quad \frac{1}{(2)^{1 / 2}}[\alpha(1) \beta(2)+\alpha(2) \beta(1)]$,
antisymmetric spin part: $\frac{1}{(2)^{1 / 2}}[\alpha(1) \beta(2)-\alpha(2) \beta(1)]$.

Since the total (spatial $\times$ spin) wavefunction must be antisymmetric, four acceptable functions can be written from expressions (2.2.41) to (2.2.46):

$$
\begin{align*}
\psi_{1}(1,2) & =\frac{1}{(2)^{1 / 2}}[1 \mathrm{~s}(1) 2 \mathrm{~s}(2)+1 \mathrm{~s}(2) 2 \mathrm{~s}(1)] \cdot \frac{1}{(2)^{1 / 2}}[\alpha(1) \beta(2)-\alpha(2) \beta(1)] \\
& =\frac{1}{(2)^{1 / 2}}\left[\frac{1}{(2)^{1 / 2}}\left|\begin{array}{ll}
1 \mathrm{~s} \alpha(1) & 2 \mathrm{~s} \beta(1) \\
1 \mathrm{~s} \alpha(2) & 2 \mathrm{~s} \beta(2)
\end{array}\right|-\frac{1}{(2)^{1 / 2}}\left|\begin{array}{cc}
1 \mathrm{~s} \beta(1) & 2 \mathrm{~s} \alpha(1) \\
1 \mathrm{~s} \beta(2) & 2 \mathrm{~s} \alpha(2)
\end{array}\right|\right. \tag{2.2.47}
\end{align*}
$$

$$
\begin{align*}
\psi_{2}(1,2) & =\frac{1}{(2)^{1 / 2}}[1 \mathrm{~s}(1) 2 \mathrm{~s}(2)-1 \mathrm{~s}(2) 2 \mathrm{~s}(1)] \cdot \alpha(1) \alpha(2) \\
& =\frac{1}{(2)^{1 / 2}}\left|\begin{array}{cc}
1 \mathrm{~s} \alpha(1) & 2 \mathrm{~s} \alpha(1) \\
1 \mathrm{~s} \alpha(2) & 2 \mathrm{~s} \alpha(2)
\end{array}\right| \tag{2.2.48}
\end{align*}
$$

$\psi_{3}(1,2)=\frac{1}{(2)^{1 / 2}}[1 \mathrm{~s}(1) 2 \mathrm{~s}(2)-1 \mathrm{~s}(2) 2 \mathrm{~s}(1)] \cdot \beta(1) \beta(2)$

$$
=\frac{1}{(2)^{1 / 2}}\left|\begin{array}{ll}
1 \mathrm{~s} \beta(1) & 2 \mathrm{~s} \beta(1)  \tag{2.2.49}\\
1 \mathrm{~s} \beta(2) & 2 \mathrm{~s} \beta(2)
\end{array}\right|
$$

$$
\left.\begin{array}{rl}
\psi_{4}(1,2) & =\frac{1}{(2)^{1 / 2}}[1 \mathrm{~s}(1) 2 \mathrm{~s}(2)-1 \mathrm{~s}(2) 2 \mathrm{~s}(1)] \cdot \frac{1}{(2)^{1 / 2}}[\alpha(1) \beta(2)+\alpha(2) \beta(1)] \\
& =\frac{1}{(2)^{1 / 2}}\left[\frac{1}{(2)^{1 / 2}}\left|\begin{array}{ll}
1 \mathrm{~s} \alpha(1) & 2 \mathrm{~s} \beta(1) \\
1 \mathrm{~s} \alpha(2) & 2 \mathrm{~s} \beta(2)
\end{array}\right|+\frac{1}{(2)^{1 / 2}}\left|\begin{array}{cc}
1 \mathrm{~s} \beta(1) & 2 \mathrm{~s} \alpha(1) \\
1 \mathrm{~s} \beta(2) & 2 \mathrm{~s} \alpha(2)
\end{array}\right|\right. \tag{2.2.50}
\end{array}\right] .
$$

## Fundamentals of Bonding Theory

As $E=\int \psi^{*} \hat{H} \psi \mathrm{~d} \tau$ and $\hat{H}$ is spin-independent, it is clear that $\psi_{2}, \psi_{3}$, and $\psi_{4}$ have the same energy and form a spin triplet, while $\psi_{1}$ has different energy value and is called a spin singlet. In the following, we denote the orbital (or spatial) part of the singlet [eq. (2.2.41) and triplet [eq. (2.2.42)] functions by ${ }^{1} \psi$ and ${ }^{3} \psi$, respectively:

$$
\begin{align*}
& { }^{1} \psi(1,2)=\frac{1}{(2)^{1 / 2}}[1 \mathrm{~s}(1) 2 \mathrm{~s}(2)+1 \mathrm{~s}(2) 2 \mathrm{~s}(1)]  \tag{2.2.51}\\
& { }^{3} \psi(1,2)=\frac{1}{(2)^{1 / 2}}[1 \mathrm{~s}(1) 2 \mathrm{~s}(2)-1 \mathrm{~s}(2) 2 \mathrm{~s}(1)] \tag{2.2.52}
\end{align*}
$$

Now we evaluate the energies ${ }^{1} E$ and ${ }^{3} E$ for the singlet and triplet states, respectively. Recall, for helium, in atomic units

$$
\begin{equation*}
\hat{H}=\left(-\frac{1}{2} \nabla_{1}^{2}-\frac{Z}{r_{1}}\right)+\left(-\frac{1}{2} \nabla_{2}^{2}-\frac{Z}{r_{2}}\right)+\frac{1}{r_{12}} . \tag{2.2.53}
\end{equation*}
$$

It can be shown that

$$
\begin{align*}
{ }^{1} E & =\iint{ }^{1} \psi^{*} \hat{H}{ }^{1} \psi \mathrm{~d} \tau_{1} \mathrm{~d} \tau_{2} \\
& =E_{1 \mathrm{~s}}+E_{2 \mathrm{~s}}+J+K \tag{2.2.54}
\end{align*}
$$

where $J$ (coulomb integral) and $K$ (exchange integral) have the form

$$
\begin{align*}
& J=\iint 1 \mathrm{~s}(1) 2 \mathrm{~s}(2)\left(\frac{1}{r_{12}}\right) 1 \mathrm{~s}(1) 2 \mathrm{~s}(2) \mathrm{d} \tau_{1} \mathrm{~d} \tau_{2}=\frac{34}{81} \text { a.u. }=0.420 \text { a.u. }  \tag{2.2.55}\\
& K=\iint 1 \mathrm{~s}(1) 2 \mathrm{~s}(2)\left(\frac{1}{r_{12}}\right) 1 \mathrm{~s}(2) 2 \mathrm{~s}(1) \mathrm{d} \tau_{1} \mathrm{~d} \tau_{2}=\frac{32}{729} \text { a.u }=0.044 \text { a.u. } \tag{2.2.56}
\end{align*}
$$

In deriving eq. (2.2.54), we have skipped some mathematical steps. Recall from the treatment of hydrogen atom:

$$
\begin{equation*}
E_{n}=-\frac{Z^{2}}{2 n^{2}} \text { a.u. } \tag{2.2.57}
\end{equation*}
$$

Hence, for helium, with $Z=2$,

$$
\begin{gather*}
E_{1 \mathrm{~s}}=-2 \text { a.u., }  \tag{2.2.58}\\
E_{2 \mathrm{~s}}=-1 / 2 \text { a.u. } \tag{2.2.59}
\end{gather*}
$$

and

$$
\begin{equation*}
{ }^{1} E=(-2.500+0.420+0.044) \text { a.u. }=-2.036 \text { a.u. } \tag{2.2.60}
\end{equation*}
$$

In a similar manner, it can be shown that

$$
\begin{align*}
{ }^{3} E & =\left(-2 \frac{1}{2}+J-K\right) \text { a.u. } \\
& =(-2.500+0.420-0.044) \text { a.u. }=-2.124 \text { a.u. }<^{1} E \tag{2.2.61}
\end{align*}
$$

The way we have arrived at the energies of the singlet and triplet states arising from the $1 \mathrm{~s}^{1} 2 \mathrm{~s}^{1}$ configuration is illustrated pictorially in Fig. 2.2.3. From the above discussion and the example of the $1 \mathrm{~s}^{1} 2 \mathrm{~s}^{1}$ configuration for the helium atom, it is seen that more than one state can arise from a given configuration. Furthermore, the energy difference for these states is due to the electronic repulsion term.

To conclude this section, we note the following:
(1) For the ground configuration $1 \mathrm{~s}^{2}$ of helium, only one wavefunction can be written [eq. (2.2.36)]. Hence the ground state of helium is a singlet.
(2) For the ground configuration $1 s^{2} 2 s^{1}$ of lithium, two wavefunctions can be written [eqs. (2.2.39) and (2.2.40)]. Hence the ground state of lithium is a doublet.
(3) For the excited configuration $1 s^{1} 2 s^{1}$ of helium, two states can be derived. One is a singlet and the other is a triplet, with the latter having the lower energy.

As a final remark, from (3), it can be seen that, it is not proper to speak of an electronic transition by mentioning only the configurations involved, such as $1 \mathrm{~s}^{2} \rightarrow 1 \mathrm{~s}^{1} 2 \mathrm{~s}^{1}$. This is because, in this particular case, it does not specify the final state of the transition. Hence, to cite an electronic transition, we need to specify both the initial and final electronic states. Only stating the initial and final configurations is not precise enough. We will have more discussion on this later.

Fig. 2.2.3.
Determination of the energies of the singlet and triplet states arising from the $1 \mathrm{~s}^{1} 2 \mathrm{~s}^{1}$ configuration of the helium atom.

### 2.3 Many-electron atoms: electronic configuration and spectroscopic terms

### 2.3.1 Many-electron atoms

For an atom with $n$ electrons, the Schrödinger equation has the form (in a.u.)

$$
\begin{equation*}
\left(-\frac{1}{2} \sum_{i} \nabla_{i}^{2}-\sum_{i} \frac{Z}{r_{i}}+\sum_{i<j} \frac{1}{r_{i j}}\right) \psi(1,2, \ldots, n)=E \psi(1,2, \ldots, n) . \tag{2.3.1}
\end{equation*}
$$

This equation cannot be solved exactly. The most often used approximation model to solve this equation is called the self-consistent field (SCF) method, first introduced by D. R. Hartree and V. A. Fock. The physical picture of this method is very similar to our treatment of helium: each electron "sees" an effective nuclear charge contributed by the nuclear charge and the remaining electrons.

Figure 2.3.1 shows the radial distribution functions of sodium $\left(1 s^{2} 2 s^{2} 2 p^{6} 3 s^{1}\right)$. The shaded portion shows the electronic distribution of $\mathrm{Na}^{+}$ $\left(1 \mathrm{~s}^{2} 2 \mathrm{~s}^{2} 2 \mathrm{p}^{6}\right)$, which indicates that the $K$ and $L$ shells of $\mathrm{Na}^{+}$are two concentric rings close to the nucleus; such a picture resembles the orbits in the Bohr theory. Also shown in Fig. 2.3.1 are the 3s, 3p, and 3d radial distribution functions. As a general rule, s orbitals are least screened (it "sees" the largest effective nuclear charge), or most penetrating. As $\ell$ increases, the orbital penetrates less into the region close to the nucleus so that the effective nuclear charge experienced by the electron decreases. As a result, for atoms with more than one electron, orbitals having the same $n$ but different $\ell$ values are not degenerate. Recall, for the hydrogen atom, orbitals with the same $n$ but different $\ell$ values have the same energy [eq. (2.1.28)],

$$
\begin{equation*}
E_{n}=-\frac{Z^{2}}{2 n^{2}} \text { a.u., } \tag{2.3.2}
\end{equation*}
$$

but such degeneracies no longer hold true for atoms other than hydrogen.

Fig. 2.3.1.
The radial distribution functions of 3 s , 3 p , and 3 d orbitals together with that of the sodium core $\left(1 s^{2} 2 s^{2} 2 p^{6}\right)$.

In an atom with more than one electron, each electron (or orbital) is characterized by the following quantum numbers:
$n$ : It largely determines the energy associated with the orbital and its size.
$\ell$ : It indicates the shape of the orbital; also, the electronic orbital angular momentum has a magnitude of $\left[(\ell(\ell+1)]^{1 / 2}(h / 2 \pi)\right.$, or $[\ell(\ell+1)]^{1 / 2}$ a.u.
$m_{\ell}$ : It indicates the orientation of the orbital; also, the $z$ component of the orbital angular momentum of the electron is $m_{\ell}(h / 2 \pi)$ or $m_{\ell}$ a.u.
$s$ : It has a value of $1 / 2$ for all electrons; also the electronic spin angular momentum has a magnitude of $[s(s+1)]^{1 / 2}$ a.u. or ${ }^{1 / 2}(3)^{1 / 2}$ a.u.
$m_{s}$ : It has a value of either $1 / 2$ or $-1 / 2$; the $z$ component of the spin angular momentum of an electron is $m_{s}$ a.u.

Note the $\ell$ plus $m_{\ell}$ and $s$ plus $m_{s}$ make two equivalent pairs of angular momentum quantum numbers. The former pair is for the orbital motion, and the latter for the spin motion.

### 2.3.2 Ground electronic configuration for many-electron atoms

By applying the Pauli Exclusion Principle, we can put each successive electron into the available lowest-energy orbital to yield the following electronic configurations for the first 30 elements in the periodic table (Table 2.3.1).

In the last column of Table 2.3.1, [ Ar ] denotes that the first 18 electrons of these elements have the Ar configuration. For $\mathrm{Sc}(Z=21)$, we have $1 s^{2} 2 s^{2} 2 p^{6} 3 s^{2} 3 p^{6}$ for the first 18 electrons. For electron no. 19, $E(3 d)<E(4 s)$, and hence the electron enters into the 3d orbital. For electron no. 20, $E(4 \mathrm{~s})<$ $E(3 \mathrm{~d})$, so it enters into the 4 s orbital. For electron no. $21, E(4 \mathrm{~s})<E(3 \mathrm{~d})$, and thus it enters into the 4 s orbital. Finally, we have the configuration $[\mathrm{Ar}] 3 \mathrm{~d}^{1} 4 \mathrm{~s}^{2}$ for Sc , as well as $[\mathrm{Ar}] 3 \mathrm{~d}^{1} 4 \mathrm{~s}^{1}$ and $[\mathrm{Ar}] 3 \mathrm{~d}^{1}$ for $\mathrm{Sc}^{+}$and $\mathrm{Sc}^{2+}$, respectively.

It is now clear that the energies of the atomic orbitals do not follow an immutable sequence. Rather, the energy ordering depends on both the nuclear charge and electronic configuration under consideration. For example, for electron no. 19 in both $\mathrm{K}(Z=19)$ and $\mathrm{Ca}(Z=20)$, we have $E(4 \mathrm{~s})<E(3 \mathrm{~d})$. For electron no. 19 in $\mathrm{Sc}(Z=21)$, it becomes $E(3 \mathrm{~d})<E(4 \mathrm{~s})$. Furthermore, for electrons no. 20 and no. 21 of Sc , the ordering is reversed.

Table 2.3.1. Electronic configurations for the first 30 elements

| H | $1 \mathrm{~s}^{1}$ | Na | $1 \mathrm{~s}^{2} 2 \mathrm{~s}^{2} 2 \mathrm{p}^{6} 3 \mathrm{~s}^{1}$ | Sc | $[\mathrm{Ar}] 3 \mathrm{~d}^{1} 4 \mathrm{~s}^{2}$ |
| :---: | :---: | :---: | :---: | :---: | :---: |
| He | $1 \mathrm{~s}^{2}$ | Mg | $1 \mathrm{~s}^{2} 2 \mathrm{~s}^{2} 2 \mathrm{p}^{6} 3 \mathrm{~s}^{2}$ | Ti | $[\mathrm{Ar}] 3 \mathrm{~d}^{2} 4 \mathrm{~s}^{2}$ |
| Li | $1 \mathrm{~s}^{2} 2 \mathrm{~s}^{1}$ | Al | $1 \mathrm{~s}^{2} 2 \mathrm{~s}^{2} 2 \mathrm{p}^{6} 3 \mathrm{~s}^{2} 3 \mathrm{p}^{1}$ | V | $[\mathrm{Ar}] 3 \mathrm{~d}^{3} 4 \mathrm{~s}^{2}$ |
| Be | $1 \mathrm{~s}^{2} 2 \mathrm{~s}^{2}$ | Si | $1 s^{2} 2 \mathrm{~s}^{2} 2 \mathrm{p}^{6} 3 \mathrm{~s}^{2} 3 \mathrm{p}^{2}$ | Cr | [Ar] $3 \mathrm{~d}^{5} 4 \mathrm{~s}^{1}$ |
| B | $1 \mathrm{~s}^{2} 2 \mathrm{~s}^{2} 2 \mathrm{p}^{1}$ | P | $1 \mathrm{~s}^{2} 2 \mathrm{~s}^{2} 2 \mathrm{p}^{6} 3 \mathrm{~s}^{2} 3 p^{3}$ | Mn | [ Ar$] 3 \mathrm{~d}^{5} 4 \mathrm{~s}^{2}$ |
| C | $1 \mathrm{~s}^{2} 2 \mathrm{~s}^{2} 2 \mathrm{p}^{2}$ | S | $1 \mathrm{~s}^{2} 2 \mathrm{~s}^{2} 2 \mathrm{p}^{6} 3 \mathrm{~s}^{2} 3 p^{4}$ | Fe | [Ar] $3 \mathrm{~d}^{6} 4 \mathrm{~s}^{2}$ |
| N | $1 \mathrm{~s}^{2} 2 \mathrm{~s}^{2} 2 \mathrm{p}^{3}$ | Cl | $1 \mathrm{~s}^{2} 2 \mathrm{~s}^{2} 2 \mathrm{p}^{6} 3 \mathrm{~s}^{2} 3 p^{5}$ | Co | [Ar] $3 \mathrm{~d}^{7} 4 \mathrm{~s}^{2}$ |
| O | $1 \mathrm{~s}^{2} 2 \mathrm{~s}^{2} 2 \mathrm{p}^{4}$ | Ar | $1 \mathrm{~s}^{2} 2 \mathrm{~s}^{2} 2 \mathrm{p}^{6} 3 \mathrm{~s}^{2} 3 p^{6}$ | Ni | $[\mathrm{Ar}] 3 \mathrm{~d}^{8} 4 \mathrm{~s}^{2}$ |
| F | $1 \mathrm{~s}^{2} 2 \mathrm{~s}^{2} 2 \mathrm{p}^{5}$ | K | $1 s^{2} 2 s^{2} 2 p^{6} 3 s^{2} 3 p^{6} 4 s^{1}$ | Cu | [Ar] $3 \mathrm{~d}^{10} 4 \mathrm{~s}^{1}$ |
| Ne | $1 \mathrm{~s}^{2} 2 \mathrm{~s}^{2} 2 \mathrm{p}^{6}$ | Ca | $1 s^{2} 2 s^{2} 2 p^{6} 3 s^{2} 3 p^{6} 4 s^{2}$ | Zn | $[\mathrm{Ar}] 3 \mathrm{~d}^{10} 4 \mathrm{~s}^{2}$ |

## Fundamentals of Bonding Theory

Note that there are two anomalies in the first transition series: [Ar]3d ${ }^{5} 4 \mathrm{~s}^{1}$ (instead of $[\mathrm{Ar}] 3 \mathrm{~d}^{4} 4 \mathrm{~s}^{2}$ ) for Cr and $[\mathrm{Ar}] 3 \mathrm{~d}^{10} 4 \mathrm{~s}^{1}$ (instead of $[\mathrm{Ar}] 3 \mathrm{~d}^{9} 4 \mathrm{~s}^{2}$ ) for Cu . These two configurations arise from the extra stability of a half-filled or completely filled subshell. Such stability comes from the spherically symmetric electron density around the nucleus for these configurations. Take the simpler case of $\mathrm{p}^{3}$ as an example. The angular portion of the density function is proportional to

$$
\begin{align*}
& \left|\mathrm{p}_{x}\right|^{2}+\left|\mathrm{p}_{y}\right|^{2}+\left|\mathrm{p}_{z}\right|^{2} \\
& \quad=\operatorname{constant}\left[(\sin \theta \cos \phi)^{2}+(\sin \theta \sin \phi)^{2}+(\cos \theta)^{2}\right] \\
& \quad=\text { constant } \tag{2.3.3}
\end{align*}
$$

Similar spherical symmetry also occurs for configurations $d^{5}$ and $f^{7}$.

### 2.3.3 Spectroscopic terms arising from a given electronic configuration

We are now in position to derive the electronic states arising from a given electronic configuration. These states have many names: spectroscopic terms (or states), term symbols, and Russell-Saunders terms, in honor of spectroscopists H. N. Russell and F. A. Saunders. Hence, the scheme we use to derive these states is called Russell-Saunders coupling. It is also simply referred to as $L-S$ coupling.

Each electronic state is defined by three angular momenta: total orbital angular momentum vector $\mathbf{L}$, total spin angular momentum vector $\mathbf{S}$, and total angular momentum vector $\mathbf{J}$. These vectors have the following definitions:

$$
\begin{align*}
& \mathbf{L}=\sum_{i} \ell_{i},  \tag{2.3.4}\\
& \mathbf{S}=\sum_{i} \mathbf{s}_{i}, \tag{2.3.5}
\end{align*}
$$

and

$$
\begin{equation*}
\mathbf{J}=\mathbf{L}+\mathbf{S} \tag{2.3.6}
\end{equation*}
$$

In eqs. (2.3.4) and (2.3.5), $\ell_{i}$ and $\mathbf{s}_{i}$ are the orbital angular momentum vector and spin angular momentum vector of an individual electron, respectively. For a state defined by quantum numbers $L, S$, and $J$, the magnitudes of the total orbital angular momentum, total spin angular momentum, and total angular momentum vectors of the system are $[L(L+1)]^{1 / 2},[S(S+1)]^{1 / 2}$, and $[J(J+1)]^{1 / 2}$ a.u., respectively.

Referring to eq. (2.3.6), in quantum mechanics, when we add two vectors $\mathbf{A}$ and $\mathbf{B}$ to yield a resultant $\mathbf{C}, C$ can take on the values of $A+B, A+B-$ $1, \ldots,|A-B|$ only, where $A, B$, and $C$ are the quantum numbers for the vectors $\mathbf{A}, \mathbf{B}$, and $\mathbf{C}$, respectively. Hence,

$$
\begin{equation*}
J=L+S, L+S-1, \ldots,|L-S| . \tag{2.3.7}
\end{equation*}
$$

Furthermore, each state is labeled by its $L$ value according to:

| $L$ value | 0 | 1 | 2 | 3 | 4 | 5 | $6 \ldots$ |
| :--- | :--- | :--- | :--- | :--- | :--- | :--- | :--- |
| State | $S$ | $P$ | $D$ | $F$ | $G$ | $H$ | $I \ldots$ |

A term symbol is written in the short-hand notation

$$
{ }^{2 S+1} L_{J}
$$

So if we have a state ${ }^{4} G_{3 \frac{1}{2}}$, we can see immediately this state has $L=4$, $S=1^{1 / 2}$, and $J=3^{1 / 2}$. From eq. (2.3.7), we see that, for $L=4$ and $S=1^{1 / 2}$, $J$ can be $5^{1 / 2}, 4^{1 / 2}, 3^{1 / 2}$, and $2^{1 / 2}$. So $3^{1 / 2}$ is one of the allowed values. The superscript $2 S+1$ in the term symbol is called the spin multiplicity of the state. When a state has spin multiplicity $1,2,3,4,5,6, \ldots$, the state is called a singlet, doublet, triplet, quartet, quintet, sextet, ..., respectively. Usually the number of allowed $J$ values is the same as the state's spin multiplicity; an example is the aforementioned ${ }^{4} G$. However, there are exceptions. For example, for the state ${ }^{2} S$, we have $L=0$ and $S=1 / 2$, and $J=1 / 2$ only.

To derive the electronic states, we sometimes also need the $z$ components of angular momenta $\mathbf{L}$ and $\mathbf{S}$, called $L_{z}$ and $S_{z}$, respectively. The magnitudes of $L_{z}$ and $S_{z}$ are $M_{L}$ and $M_{S}$ a.u., respectively, where

$$
\begin{align*}
& M_{L}=\sum_{i}\left(m_{l}\right)_{i}=L, L-1, \ldots,-L  \tag{2.3.8}\\
& M_{S}=\sum_{i}\left(m_{s}\right)_{i}=S, S-1, \ldots,-S \tag{2.3.9}
\end{align*}
$$

Similarly, the total angular momentum vector $\mathbf{J}$ also has its $z$ component $J_{z}$, with its corresponding magnitude being $M_{J}$ a.u., where

$$
\begin{equation*}
M_{J}=M_{L}+M_{S}=J, J-1, \ldots,-J . \tag{2.3.10}
\end{equation*}
$$

Note that the sums in eqs. (2.3.8) to (2.3.10) are numerical sums, not vector sums.

When we only have one electron in a configuration, e.g., $1 \mathrm{~s}^{1}$ for H , we get

$$
L=\ell_{1}=0
$$

which indicates an $S$ state. Also,

$$
S=s_{1}=1 / 2, \quad \text { or } \quad 2 S+1=2
$$

So we have only one term, ${ }^{2} S$. The allowed $J$ value is $1 / 2$. Hence ${ }^{2} S_{1 / 2}$ is the only state arising from the $s^{1}$ configuration. Similarly, it is easy to show the following:

| Configuration | State(s) |
| :--- | :---: |
| $\mathrm{s}^{1}$ | ${ }^{2} S_{1 / 2}$ |
| $\mathrm{p}^{1}$ | ${ }^{2} P_{1^{1 / 2}},{ }^{2} P_{1 / 2}$ |
| $\mathrm{~d}^{1}$ | ${ }^{2} D_{1^{1} / 2}{ }^{2} D_{2^{1 / 2}}$ |
| $\mathrm{f}^{1}$ | ${ }^{2} F_{2^{1} / 2},{ }^{2}{ }^{2} F_{3^{1 / 2}}$ |

Now we proceed to the configuration $\mathrm{s}^{2}$ of, say, helium. Here these electrons are called equivalent electrons, since they have the same $n$ value and also the same $\ell$ value. For such systems, we need to bear the Exclusion Principle in mind. Now the two electrons can only be accommodated in the following manner:

$$
\begin{array}{cccc} 
& 1 \mathrm{~s} \uparrow \downarrow \\
n=1 \quad \ell=0, m_{\ell}=0, & M_{L}=\sum_{i}\left(m_{\ell}\right)_{i} & M_{S}=\sum_{i}\left(m_{s}\right)_{i} \\
n+0=0 & M_{S}=1 / 2+(-1 / 2)=0 .
\end{array}
$$

So the only $\left(M_{L}, M_{S}\right)$ combination is $(0,0)$. Such a combination is also called a microstate. Here the only allowed value of $M_{L}=0$; the same is true for $M_{S}$. From eqs. (2.3.8) and (2.3.9), the only allowed value for $L$ is 0 ; the same also holds for $S$. So the only state from the $\mathrm{s}^{2}$ configuration is ${ }^{1} S_{0}$. Indeed, ${ }^{1} S_{0}$ (with $S=0$ and $L=0$ ) is the only allowed state for all filled configurations:

| Configuration | State |
| :--- | :---: |
| $\mathrm{s}^{2}$ | ${ }^{1} S_{0}$ |
| $\mathrm{p}^{6}$ | ${ }^{1} S_{0}$ |
| $\mathrm{~d}^{10}$ | ${ }^{1} S_{0}$ |
| $\mathrm{f}^{14}$ | ${ }^{1} S_{0}$ |

For the excited configuration $1 s^{1} 2 s^{1}$ of helium, we have the following:

| $n=1, \ell=0, m_{\ell}=0$ | $n=2, \ell=0, m_{\ell}=0$ | $M_{L}$ | $M_{S}$ |
| :---: | :---: | :---: | :---: |
| $\uparrow$ | $\uparrow$ | 0 | 1 |
| $\uparrow$ | $\downarrow$ | 0 | 0 |
| $\downarrow$ | $\uparrow$ | 0 | 0 |
| $\downarrow$ | $\downarrow$ | 0 | -1 |

These four microstates lead to an $\left(M_{L}, M_{S}\right)$ distribution shown below:

$$
M_{L}=0 \begin{array}{|lll}
1 & 2 & 1 \\
-1 & 0 & 1
\end{array} M_{S}
$$

For such a simple distribution, it is obvious that only two terms can arise from it: ${ }^{1} S$ [which requires one microstate: $\left.\left(M_{L}=0, M_{S}=0\right)\right]$ and ${ }^{3} S$ [which requires three microstates: $(0,1),(0,0)$, and $(0,-1)]$. Previously we have already concluded that the $1 \mathrm{~s}^{1} 2 \mathrm{~s}^{1}$ configuration of helium has two states, one singlet and one triplet, with the triplet state having the lower energy. When we put in the proper $J$ values, the states arising from configuration $n \mathrm{~s}^{1} n^{\prime} \mathrm{s}^{1}$ are ${ }^{1} S_{0}$ and ${ }^{3} S_{1}$.

An example often used in texts is the $1 s^{2} 2 s^{2} 2 p^{2}$ configuration of carbon. Since all filled subshells lead to $L=0$ and $S=0$, we only need to be concerned with $\mathrm{p}^{2}$ here. There are 15 microstates for this configuration:

| $m_{\ell}=1$ | $m_{\ell}=0$ | $m_{\ell}=-1$ | $M_{L}$ | $M_{S}$ |
| :---: | :---: | :---: | ---: | ---: |
| $\uparrow \downarrow$ |  |  | 2 | 0 |
|  | $\uparrow \downarrow$ |  | 0 | 0 |
|  |  | $\uparrow \downarrow$ | -2 | 0 |
| $\uparrow$ | $\uparrow$ |  | 1 | 1 |
| $\downarrow$ | $\downarrow$ |  | 1 | -1 |
| $\uparrow$ | $\downarrow$ |  | 1 | 0 |
| $\downarrow$ | $\uparrow$ |  | 1 | 0 |
|  | $\uparrow$ | $\uparrow$ | -1 | 1 |
|  | $\downarrow$ | $\downarrow$ | -1 | -1 |
|  | $\uparrow$ | $\downarrow$ | -1 | 0 |
|  | $\downarrow$ | $\uparrow$ | -1 | 0 |
| $\uparrow$ |  | $\uparrow$ | 0 | 1 |
| $\downarrow$ |  | $\downarrow$ | 0 | -1 |
| $\uparrow$ |  | $\downarrow$ | 0 | 0 |
| $\downarrow$ |  | $\uparrow$ | 0 | 0 |

These 15 microstates have the distribution shown below:

| $M_{L}$ |  |  |  |  |
| :---: | :---: | :---: | :---: | :---: |
| 2 |  | 1 |  |  |
| 1 | 1 | 2 | 1 |  |
| 0 | 1 | 3 | 1 |  |
| -1 | 1 | 2 | 1 |  |
| -2 |  | 1 |  |  |

This large distribution is made up of the following three smaller distributions:

So three terms arise from configuration $\mathrm{p}^{2}:{ }^{1} D,{ }^{3} P$, and ${ }^{1} S$. If we include the allowed $J$ values, we then have ${ }^{1} D_{2},{ }^{3} P_{2},{ }^{3} P_{1},{ }^{3} P_{0}$, and ${ }^{1} S_{0}$. Levels such as ${ }^{3} P_{2},{ }^{3} P_{1}$, and ${ }^{3} P_{0}$ which differ only in their $J$ values are called multiplets. For light elements, the levels of a multiplet will have slightly different energies, while levels from different terms will have larger energy differences.

By writing out the microstates of a given configuration, it is easy to see that configurations $\ell^{n}$ and $\ell^{4 \ell+2-n}$ have the same states. This is because the number

Table 2.3.2. Spectroscopic terms arising from configurations $s^{n}, p^{n}$, and $d^{n}$

| Configuration | $L S$ terms | Configuration | $L S$ terms |
| :--- | :--- | :--- | :--- |
| $\mathrm{p}^{1}, \mathrm{p}^{5}$ | ${ }^{2} P$ | $\mathrm{~d}^{2}, \mathrm{~d}^{8}$ | ${ }^{1} S,{ }^{1} D,{ }^{1} G,{ }^{3} P,{ }^{3} F$ |
| $\mathrm{p}^{2}, \mathrm{p}^{4}$ | ${ }^{1} S,{ }^{1} D,{ }^{3} P$ | $\mathrm{~d}^{3}, \mathrm{~d}^{7}$ | ${ }^{2} D(2),{ }^{2} P,{ }^{2} F,{ }^{2} G,{ }^{2} H,{ }^{4} P,{ }^{4} F$ |
| $\mathrm{p}^{3}$ | ${ }^{2} P,{ }^{2} D,{ }^{4} S$ | $\mathrm{~d}^{4}, \mathrm{~d}^{6}$ | ${ }^{1} S(2),{ }^{1} D(2),{ }^{1} F,{ }^{1} G(2),{ }^{1} I,{ }^{3} P(2),{ }^{3} D,{ }^{3} F(2),{ }^{3} G,{ }^{3} H,{ }^{5} D$ |
| $\mathrm{~d}^{1}, \mathrm{~d}^{9}$ | ${ }^{2} D$ | $\mathrm{~d}^{5}$ | ${ }^{2} S,{ }^{2} P,{ }^{2} D(3),{ }^{2} F(2),{ }^{2} G(2),{ }^{2} H,{ }^{2} I,{ }^{4} P,,{ }^{4} D,{ }^{4} F,{ }^{4} G,{ }^{6} S$ |

of ways of assigning electrons to orbitals is equal to the number of ways of assigning vacancies to the same orbitals. Hence carbon $\left(1 \mathrm{~s}^{2} 2 \mathrm{~s}^{2} 2 \mathrm{p}^{2}\right)$ and oxygen $\left(1 \mathrm{~s}^{2} 2 \mathrm{~s}^{2} 2 \mathrm{p}^{4}\right)$ have the same states. Table 2.3.2 lists the term symbols ( $L$ and $S$ values only) arising from a given equivalent electronic configuration. We note that configurations with only one electron in a subshell and configurations with filled subshells have already been dealt with.

Note that the last term given for each configuration is the ground term (see discussions on Hund's rule below). The number in brackets indicates the number of times that term occurs, e.g., there are two different ${ }^{2} D$ terms for the $\mathrm{d}^{3}$ configuration.

### 2.3.4 Hund's rules on spectroscopic terms

When there are many terms arising from a given configuration, it would be of interest to know the relative order of their energies, or at least which is the ground term. To accomplish this, we make use of Hund's rule, in honor of physicist F. Hund:
(1) Of the terms arising from a given configuration, the lowest in energy is the one having the highest spin multiplicity.
(2) Of two or more terms with the same multiplicity, the lowest in energy is the one with the largest $L$ value.
(3) For a configuration less than half-filled, the lowest state is the one with the smallest $J$ value (the multiplet is then called "normal"); if the configuration is more than half-filled, the lowest state is the one with the largest $J$ value (the multiplet is "inverted").

Note that, strictly speaking, Hund's rules should be applied only to equivalent electronic configurations and for the determination of only the ground state. By applying these rules, we can see that both carbon $\left(2 \mathrm{p}^{2}\right)$ and oxygen $\left(2 \mathrm{p}^{4}\right)$ have ${ }^{3} P$ as the ground term. However, the ground state of carbon is ${ }^{3} P_{0}$, while that for oxygen is ${ }^{3} P_{2}$. A complete energy ordering for the state of carbon is given in Fig. 2.3.2. Also, a state ${ }^{2 S+1} L_{J}$ has a $(2 J+1)$-fold degeneracy, as $M_{J}=J, J-1, \ldots,-J$. This degeneracy will be manifested when we apply an external magnetic field to a sample and then take its spectrum (Zeeman effect).

Before leaving this topic, we once again note that electronic transitions occur between states and may or may not involve a change in configuration. Take the states in Fig. 2.3.2 as an example. Transition from ground state ${ }^{3} P_{0}$ to excited state ${ }^{1} D_{2}\left({ }^{3} P_{0} \rightarrow{ }^{1} D_{2}\right)$ [note that this is not an allowed transition in the first

place!] does not involve a change in configuration, as both the initial and final states of the electronic transition arise from configuration $2 \mathrm{p}^{2}$.

To conclude this section, we illustrate how to obtain the ground term of a given configuration without writing out all the microstates. Again we take $p^{2}$ as an example. When we place there two electrons into the three $p$ orbitals we bear in mind that the ground term requires the maximum $S$ (first priority) and $L$ values. To achieve this, we place the electron in the following manner:

$$
m_{\ell} \begin{array}{|l|l|l|}
\hline 1 & 0 & -1 \\
\hline \uparrow & \uparrow & \\
\hline
\end{array} M_{L}=1 \quad M_{S}=1
$$

Since $M_{L}$ runs from $L$ to $-L$ and $M_{S}$ runs from $S$ to $-S$, the maximum $L$ and maximum $S$ values are both 1 in this case. Hence, the ground term is ${ }^{3} P$.

Two more examples are given below:
(1) $p^{3}$

$$
m_{\ell} \ell \begin{array}{c|c|c|}
\hline & 0 & -1 \\
\cline { 2 - 3 } & \uparrow & \uparrow \\
\hline & \uparrow & \uparrow \\
\hline
\end{array} M_{L}=0 \quad M_{S}=1^{1 / 2} 2
$$

We thus have $L=0$ and $S=1^{1 / 2}$ and the ground term is ${ }^{4} S$.
(2) $d^{7}$

$$
m_{\ell} \boldsymbol{m}_{\ell} \begin{array}{|c|c|c|c|c|}
\hline 2 & 1 & 0 & -1 & -2 \\
\hline \uparrow \downarrow & \uparrow \downarrow & \uparrow & \uparrow & \uparrow \\
\hline
\end{array} M_{L}=3 \quad M_{S}=1^{1 / 2} 2
$$

Hence we have $L=3$ and $S=1^{1 / 2}$ and the ground term is ${ }^{4} F$.

Fig. 2.3.2.
Energies of the spectroscopic state for the ground state configuration of carbon (not to scale!).

### 2.3.5 i-i Coupling

In the $L-S$ coupling scheme we have just discussed, it is assumed that the electronic repulsion is much larger than the spin-orbit interaction. This assumption certainly holds for lighter elements, as we have seen in the case of carbon atom (Fig. 2.3.2). However, this assumption becomes less and less valid as we go down the Periodic Table. The breakdown of this coupling scheme is clearly seen from the spectral data given in Table 2.3.3.

Table 2.3.3. Spectral data (in $\mathrm{cm}^{-1}$ ) for the electronic states arising from configurations $n \mathrm{p}^{2}, n=2-6$

|  | ${ }^{3} P_{0}$ | ${ }^{3} P_{1}$ | ${ }^{3} P_{2}$ | ${ }^{1} D_{2}$ | ${ }^{1} S_{0}$ |
| :--- | ---: | ---: | :---: | ---: | ---: |
| C | 0.0 | 16.4 | 43.5 | 10193.7 | 21648.4 |
| Si | 0.0 | 77.2 | 223.31 | 6298.8 | 15394.2 |
| Ge | 0.0 | 557.1 | 1409.9 | 7125.3 | 16367.1 |
| Sn | 0.0 | 1691.8 | 3427.7 | 8613.0 | 17162.6 |
| Pb | 0.0 | 7819.4 | 10650.5 | 21457.9 | 29466.8 |

In the extreme case where the spin-orbit interaction is much larger than electronic repulsion, total orbital angular momentum $L$ and total spin angular momentum $S$ are no longer "good" quantum numbers. Instead, states are defined by total angular momentum $J$, which is the vector sum of all the total angular momenta $j$ values of the individual electrons:

$$
\begin{equation*}
\mathbf{J}=\sum_{i} \dot{j}_{i} \tag{2.3.11}
\end{equation*}
$$

where

$$
\begin{equation*}
\dot{j}_{i}=\ell_{i}+s_{i} \tag{2.3.12}
\end{equation*}
$$

We can illustrate this scheme with a simple example. Consider the electronic configuration $\mathrm{p}^{1} \mathrm{~s}^{1}$. For the p electron, we have $\boldsymbol{j}_{1}=\boldsymbol{\ell}_{1}+\boldsymbol{s}_{1}$, which means that $j_{1}$ can be either $1^{1 / 2}$ and $1 / 2$. On the other hand, for the s electron, we have $j_{2}=1 / 2$. When $j_{1}=1^{1 / 2}$ and $j_{2}=1 / 2$ are coupled, $\mathbf{J}=\boldsymbol{j}_{1}+\boldsymbol{j}_{2}$ and quantum number $J$ can be 1 or 2 . When $j_{1}=1 / 2$ and $j_{2}=1 / 2$ are coupled, $J$ can be 0 or 1 . So for the $\mathrm{p}^{1} \mathrm{~s}^{1}$ configuration, there are four states: $J=0,1,1,2$. These states are "correlated" to the Russell-Saunders terms in the manner shown in Fig. 2.3.3.

To conclude this section, we take up a slightly more complex example: the case of two equivalent p electrons. In the $j-j$ coupling scheme, the Pauli's principle becomes "no two electrons can have the same set of quantum numbers $\left(n, \ell, j, m_{j}\right)$." For configuration $n \mathrm{p}^{2}, \ell_{1}=\ell_{2}=1, s_{1}=s_{2}=1 / 2, j_{1}, j_{2}=1^{1 / 2}$ or $1 / 2$. Once again, as in the case of $L-S$ coupling, there are now 15 microstates, as listed in Table 2.3.4.

Note that in Table 2.3.4 labels 1 and 2 are for convenience only. It is important to bear in mind that electrons are indistinguishable. The five electronic states derived using this scheme may be correlated to those derived with the $L-S$ coupling scheme in Fig. 2.3.2. This correlation diagram is shown in Fig. 2.3.4.

## $L-S$ coupling:

electronic interaction $>$ spin-orbit coupling
$j-j$ coupling:
spin-orbit coupling > electronic interaction

Fig. 2.3.3.
Correlation diagram for electronic states arising from configuration $\mathrm{s}^{1} \mathrm{p}^{1}$ employing $L-S$ and $j-j$ coupling schemes.

Table 2.3.4. The microstates for configuration $n \mathrm{p}^{2}$ employing the $j-j$ coupling scheme

| $j_{1}$ | $j_{2}$ | $\left(m_{j}\right)_{1}$ | $\left(m_{j}\right)_{2}$ | $M_{J}$ | $J$ |
| :--- | :---: | :---: | :---: | :---: | :---: |
| $1 / 2$ | $1 / 2$ | $1 / 2$ | $-1 / 2$ | 0 | 0 |
| $1 / 2$ | $1^{1} / 2$ | $1 / 2$ | $1^{1} / 2$ | 2 |  |
|  |  | $1 / 2$ | $1 / 2$ | 1 |  |
|  |  | $1 / 2$ | $-1 / 2$ | 0 |  |
|  |  | $1 / 2$ | $-1^{1 / 2}$ | -1 |  |

Fundamentals of Bonding Theory

### 2.4 Atomic properties

In this section we discuss the various atomic properties that are the manifestation of the electronic configurations of the atoms discussed in the previous sections. These properties include ionization energy, electron affinity, electronegativity, etc. Other properties such as atomic and ionic radii will be discussed in subsequent chapters, as these properties are related to the interaction between atoms in a molecule. Toward the end of this section, we will also discuss the influence of relativistic effects on the properties of elements.

### 2.4.1 lonization energy and electron affinity

## (1) Ionization energy

The first ionization energy $I_{1}$ of an atom is defined as the energy required to remove the outermost electron from a gaseous atom in its ground state. This energy may be expressed as the enthalpy change of the process

$$
\begin{equation*}
\mathrm{A}(\mathrm{~g}) \rightarrow \mathrm{A}^{+}(\mathrm{g})+e^{-}(\mathrm{g}), \quad \Delta H=I_{1} . \tag{2.4.1}
\end{equation*}
$$

The second ionization energy $I_{2}$ of A is then the energy required to remove an electron from $\mathrm{A}^{+}$:

$$
\begin{equation*}
\mathrm{A}^{+}(\mathrm{g}) \rightarrow \mathrm{A}^{2+}(\mathrm{g})+e^{-}(\mathrm{g}), \quad \Delta H=I_{2} . \tag{2.4.2}
\end{equation*}
$$

The third, fourth, and subsequent ionization energies may be defined in a similar manner. Table 2.4.1 lists the $I_{1}$ and $I_{2}$ values of the elements. The variations of $I_{1}$ and $I_{2}$ against atomic number $Z$ are shown in Fig. 2.4.1.

Examining the overall trend of $I_{1}$ shown in Fig. 2.4.1, it is seen that $I_{1}$ decreases as $Z$ increases. On the other hand, within the same period, $I_{1}$ increases with $Z$. Also, the noble gases occupy the maximum positions, as it is difficult to remove an electron from a filled configuration $\left(n s^{2} n \mathrm{p}^{6}\right)$. Similarly, but to a less extent, $\mathrm{Zn}, \mathrm{Cd}$, and Hg , with configuration $(n-1) \mathrm{d}^{10} n \mathrm{~s}^{2}$, occupy less prominent maxima. Also, N, P, and As, with half-filled subshells, are also in less prominent maximum positions as well.

In the $I_{1}$ curve shown in Fig. 2.4.1, the minimum positions are taken up by the alkali metals. These elements have general configuration $n \mathrm{~s}^{1}$ and this lone electron is relatively easy to remove. On the other hand, in the $I_{2}$ curve, the alkali metals now occupy the maximum positions, as the singly charged cations of the alkali metals have the noble gas electronic configuration. Additionally, the $I_{2}$ values of the alkali metals are very large, in the range $2.2-7.3 \times 10^{3} \mathrm{~kJ}$ $\mathrm{mol}^{-1}$. The chemical properties of these elements may be nicely explained by their ionization energy data. Similarly, elements B, Al, Ga, In, and Tl, with only one lone electron in the p orbital, also have relatively low $I_{1}$ values.

The two valence electrons of alkali earth metals ( $\mathrm{Be}, \mathrm{Mg}, \mathrm{Ca}, \mathrm{Sr}$, and Ba ) are comparatively easy to ionize, as the data in Fig. 2.4.1 show. These elements occupy the minimum positions in the $I_{2}$ curve. Hence the chemistry of these elements is dominated by their $\mathrm{M}^{2+}$ cations. The only exception is Be , which, with the largest $\left(I_{1}+I_{2}\right)$ value in the family, forms mainly covalent compounds.

Table 2.4.1. Ionization energies $\left(\mathrm{MJ} \mathrm{mol}^{-1}\right) I_{1}$ and $I_{2}$ and the electron affinities $\left(\mathrm{kJ} \mathrm{mol}^{-1}\right) Y$ of the elements

Fig. 2.4.1.
The variation of ionization energies, $I_{1}$ and $I_{2}$ against the atomic number $Z$.

Before leaving this topic, it should be noted that ionization energy is only one of the factors that influence the chemistry of the elements. For instance, even though $\mathrm{Ca}^{+}$is easier to form than $\mathrm{Ca}^{2+}$, we have never observed the existence of $\mathrm{Ca}^{+}$. This is because the lattice energy of $\mathrm{CaX}_{2}$ is much larger than that of CaX , enough to compensate the cost of the second ionization energy, which comes to about $10^{3} \mathrm{~kJ} \mathrm{~mol}^{-1}$. In solution, the hydration energy of $\mathrm{Ca}^{2+}$ is much larger than that of $\mathrm{Ca}^{+}$, thus favoring the existence of $\mathrm{Ca}^{2+}$ over $\mathrm{Ca}^{+}$. In short, the cation of calcium exists exclusively in the form $\mathrm{Ca}^{2+}$, either in solution or in the crystalline state.

## (2) Electron affinity

The electron affinity $Y$ of an atom is defined as the energy released when the gaseous atom in its ground state captures an electron to form an anion:

$$
\begin{equation*}
\mathrm{A}(\mathrm{~g})+e^{-}(\mathrm{g}) \rightarrow \mathrm{A}^{-}(\mathrm{g}), \quad-\Delta H=Y \tag{2.4.3}
\end{equation*}
$$

In other words, the electron affinity of A is simply the ionization energy of $\mathrm{A}^{-}$. The electron affinities of the elements are also listed in Table 2.4.1. As the singly charged anions of a number of elements including $\mathrm{Zn}, \mathrm{Cd}, \mathrm{Hg}$, and the noble gases, are unstable, the electron affinities of these elements are missing from the table. Also, there is one element, nitrogen, which has a negative electron affinity. This indicates that $\mathrm{N}^{-}$is an unstable species and it loses an electron spontaneously.

In general, electron affinities have smaller values than ionization energies. Chlorine has the largest electron affinity, $348.8 \mathrm{~kJ} \mathrm{~mol}^{-1}$, which is still smaller than the smallest ionization energy, $375.7 \mathrm{~kJ} \mathrm{~mol}^{-1}$, of Cs.

Among the electron affinities listed in Table 2.4.1, the halogens have the largest values. This is because these atoms will attain the noble gas configuration
upon capturing an electron. The members of the oxygen family, neighbors of the halogens, also have fairly large electron affinities. Another element that has a relatively large electron affinity is gold, which, as in the case of halogens, also forms salts such as CsAu. We shall have a more detailed discussion on this element in the section on relativistic effects. Finally, all the lathanides have similar electron affinities, about $50 \mathrm{~kJ} \mathrm{~mol}^{-1}$. This is the value listed for all lathanides in Table 2.4.1.

There is no element that has a positive second electron affinity; i.e., the electron affinity of any anion $\mathrm{A}^{-}$is always negative. This is understandable as it is difficult to bring together two negatively charged particles. Thus the electron affinities of $\mathrm{O}^{-}$and $\mathrm{S}^{-}$are -744 and $-456 \mathrm{~kJ} \mathrm{~mol}^{-1}$, respectively. Even though $\mathrm{O}^{2-}$ and $\mathrm{S}^{2-}$ are unstable in gas phase, they can exist in solution or in the solid state. The stability of these divalent anions arises from lattice energy, solvation energy, etc. These ions may also hydrolyze to form more stable species, e.g., $\mathrm{O}^{2-}+\mathrm{H}_{2} \mathrm{O} \rightarrow 2 \mathrm{OH}^{-}$.

### 2.4.2 Electronegativity: the spectroscopic scale

Electronegativity is a qualitative concept with a long history and wide application. As early as 1835, Berzelius considered chemical bonding as electrostatic interaction. Also, he took metals and their oxides as electropositive substances and nonmetals and their oxides as electronegative ones. Almost one hundred years later, in 1932, Pauling defined electronegativity as "the power of atom in a molecule to attract electrons to itself." Quantitatively he proposed a scale, hereafter denoted as $\chi_{P}$, in the following manner: the difference between the electronegativities of elements A and $\mathrm{B},\left|\chi_{\mathrm{A}}-\chi_{\mathrm{B}}\right|$, is proportional to $\Delta^{1 / 2}$, where $\Delta$ is the difference between the bond energy of $A B$ and the mean of the bond energies of $A_{2}$ and $B_{2}$. In 1934 to 1935, Mullikan proposed the $\chi_{M}$ scale that the power of an atom to attract electrons should be the average of its ionization energy and electron affinity. Later in 1958, Allred and Rochow proposed their $\chi_{A R}$ scale. They assumed that the electronegativity of an atom is proportional to the effective nuclear charge of its valence electron and inversely proportional to the square of its atomic radius.

More recently, in 1989, Allen developed his spectroscopic scale, $\chi_{S}$, where he equated the electronegativity of an atom to its configuration energy (CE)

$$
\begin{equation*}
\mathrm{CE}=\frac{n \varepsilon_{\mathrm{s}}+m \varepsilon_{\mathrm{p}}}{n+m} \tag{2.4.4}
\end{equation*}
$$

where $n$ and $m$ are the number of s and p valence electrons, respectively, and $\varepsilon_{\mathrm{s}}$ and $\varepsilon_{\mathrm{p}}$ are the corresponding one-electron energies. These energies are the multiplet-averaged total energy differences between the ground state neutral and singly charged cation. As accurate atomic energy level data are readily available, the CE of an atom can be easily calculated. Table 2.4.2 lists the Pauling and spectroscopic electronegativities of the elements.

Before leaving this topic, we discuss in more detail the determination of CE and $\chi_{S}$ values of an element. Table 2.4.3 lists the $\varepsilon_{\mathrm{s}}$ and $\varepsilon_{\mathrm{p}}$, and CE values of the first eight elements in the Periodic Table. For the first four elements, where

| O | $1 \mathrm{~s}^{2} 2 \mathrm{~s}^{2} 2 \mathrm{p}^{4}$ | 15.84 | 32.36 | 21.36 | 3.610 |

only S states are involved, the CE value is simply $I_{1}$ of the element concerned. For the remaining four elements, let us take O as an example.

For O , with configuration $2 \mathrm{~s}^{2} 2 \mathrm{p}^{4}$ and its states ${ }^{3} P,{ }^{1} D$, and ${ }^{1} S$, we can determine its multiplet-averaged energy, using the available spectroscopic data. For
$\mathrm{O}^{+}$, with configuration $2 \mathrm{~s}^{2} 2 \mathrm{p}^{3}$ and its states ${ }^{4} S,{ }^{2} D$, and ${ }^{2} P$, we can also determine this cation's multiplet-averaged energy. Then $\varepsilon_{\mathrm{p}}$ is simply the difference between these two average energies. To determine $\varepsilon_{\mathrm{s}}$, we consider configuration $2 \mathrm{~s}^{1} 2 \mathrm{p}^{4}$ and its states ${ }^{4} P,{ }^{2} D,{ }^{2} P$, and ${ }^{2} S$ and calculate the average energy of this configuration. Then $\varepsilon_{\mathrm{s}}$ is simply the energy difference between configurations $2 s^{2} 2 p^{4}$ and $2 s^{1} 2 p^{4}$. Upon calculating the CE of an element, we can convert it to $\chi_{S}$ by multiplying the factor (2.30/13.60). As we can see from this procedure, $\chi_{\mathrm{S}}$ is related to the average one-electron valence shell ionization energy of an atom, which, we would intuitively think, should be related to its power to attract electrons in a molecule.

Figures 2.4.2 and 2.4.3 show the variations of electronegativities of representative elements and transition metals, respectively, across a given period. As we can see from these two figures, $\chi_{S}$ increases with $Z$ in a period. The noble gases have the largest $\chi_{S}$ values for elements of the same period, as they have very strong tendency to retain the electrons. Among all elements, Ne is the most electronegative, and $\mathrm{F}, \mathrm{He}$, and O are the next ones. Noble gas Xe is less electronegative than F and O . Hence xenon fluorides and oxides are capable of existence. Also, Xe and C have comparable electronegativities, and $\mathrm{Xe}-\mathrm{C}$ bond can be formed under suitable conditions. One such example is $\left[\mathrm{F}_{5} \mathrm{C}_{6} \mathrm{XeNCMe}\right]^{+}\left[\left(\mathrm{C}_{6} \mathrm{~F}_{5}\right)_{2} \mathrm{BF}_{2}\right]^{-} \mathrm{MeCN}$, and the structure of the cation of this compound is shown in Fig. 2.4.4.

From the electronegativities shown in Figs. 2.4.2 and 2.4.3, it is seen that metals are less electronegative, with $\chi_{S}<2$, nonmetals are more electronegative, with $\chi_{S}>2$. Around $\chi_{S} \sim 2$, we have metalloid elements such as $\mathrm{B}, \mathrm{Si}$ $\mathrm{Ge}, \mathrm{Sb}$, and Bi . Most of these elements have semi-conducting properties. For elements of the same group, $\chi_{S}$ decreases as we go down the Periodic Table. However, because of relativistic effects, for transition metals from group 7 to

Fig. 2.4.2.
Variation of electronegativities of representative elements across a given period of the periodic table. Elements of period 6 have electronegativities very similar to those of elements of period 5. For clarity, electronegativities of the elements of period 6 are not shown.

Fig. 2.4.3.
Variation of electronegativities of transition metals across a given period of the periodic table.

Fig. 2.4.4.
Structure of cation $\left[\mathrm{F}_{5} \mathrm{C}_{6} \mathrm{XeNCMe}\right]^{+}$: $\mathrm{C}-\mathrm{Xe}=209.2 \mathrm{pm}, \mathrm{Xe}-\mathrm{N}=268.1 \mathrm{pm}$, $\mathrm{C}-\mathrm{Xe}-\mathrm{N}=174.5^{\circ}$.

group 12, the elements of the sixth period are more electronegative than the corresponding elements of the fifth period.
In 1963, N . Barlett discovered that $\mathrm{PtF}_{6}$ can oxidize $\mathrm{O}_{2}$ to form salt-like $\left[\mathrm{O}_{2}\right]^{+}\left[\mathrm{PtF}_{6}\right]^{-}$. As the $I_{1}$ values of $\mathrm{Xe}\left(1.17 \times 10^{3} \mathrm{~kJ} \mathrm{~mol}^{-1}\right)$ and $\mathrm{O}_{2}\left(1.18 \times 10^{3}\right.$ $\mathrm{kJ} \mathrm{mol}^{-1}$ ) are similar, he reacted Xe with $\mathrm{PtF}_{6}$ to form the first noble gas compound $\mathrm{Xe}^{+}\left[\mathrm{PtF}_{6}\right]^{-}$. Soon afterwards, $\mathrm{XeF}_{2}$ and $\mathrm{XeF}_{4}$ were synthesized and a whole new area of chemistry was discovered. Now many compounds with bonds such as $\mathrm{Xe}-\mathrm{F}, \mathrm{Xe}-\mathrm{O}, \mathrm{Xe}-\mathrm{N}$, and $\mathrm{Xe}-\mathrm{C}$ have been synthesized; an example is shown in Fig. 2.4.4. Even though Kr has a slightly higher $I_{1}$ value than Xe , compounds such as $\mathrm{KrF},[\mathrm{KrF}]^{+}\left[\mathrm{Sb}_{2} \mathrm{~F}_{11}\right]^{-}$, and $\mathrm{CrOF}_{4} \cdot \mathrm{KrF}_{2}$ (structure shown below) have already been made.

Since Ar has an $I_{1}$ value lower than that of F , it is not unreasonable to expect that argon fluorides will be synthesized soon. Recently HArF was detected in a photodissociation study of HF in an Ar environment (see Section 5.8.1). With infrared spectroscopic studies of species such as $\mathrm{H}^{40} \mathrm{ArF}, \mathrm{D}^{40} \mathrm{ArF}$, and $\mathrm{H}^{36} \mathrm{ArF}$, it was determined that the bond lengths of $\mathrm{H}-\mathrm{Ar}$ and $\mathrm{F}-\mathrm{Ar}$ are 133 and 197 pm , respectively. As of now, He and Ne are the only two elements that do not form any stable compounds.

### 2.4.3 Relativistic effects on the properties of the elements

In recent years, relativistic effects on the chemical properties of atoms have received considerable attention. In the theory of relativity, when an electron is traveling with high velocity $v$, its mass $m$ is related to its rest mass $m_{o}$ in the following way,

$$
\begin{equation*}
m=m_{o} /\left[1-\left(\frac{v}{c}\right)^{2}\right]^{1 / 2} \tag{2.4.5}
\end{equation*}
$$

where $c$ is the speed of light. In atomic units,

$$
c=137 \text { a.u. }
$$

The average radial velocity $\left\langle v_{\mathrm{rad}}>\right.$ of a 1s electron in an atom is approximately $Z$ a.u., where $Z$ is the atomic number. Hence, for an electron in Au , with $Z=79$, we have

$$
\begin{equation*}
\frac{v_{\mathrm{rad}}}{c} \sim \frac{79}{137}=0.58 . \tag{2.4.6}
\end{equation*}
$$

Substituting this ratio into eq. (2.4.5), we get

$$
\begin{equation*}
m=\frac{m_{o}}{\left[1-(0.58)^{2}\right]^{1 / 2}}=1.23 m_{o} \tag{2.4.7}
\end{equation*}
$$

In other words, the mass of the electron has increased to $1.23 m_{o}$, which influences significantly the radial distribution of the electron. Recall from Bohr's atomic theory that the radius of the $n$th orbit is given by

$$
r_{n}=\frac{n^{2} h^{2} \varepsilon_{0}}{\pi m e^{2}} .
$$

Hence the ratio between the relativistic 1 s radius, $\left\langle r_{1 \mathrm{~s}}>_{\mathrm{R}}\right.$, to its nonrelativistic counterpart, $\left\langle r_{1 \mathrm{~s}}\right\rangle_{\mathrm{NR}}$ is simply

$$
<r_{1 \mathrm{~s}}>_{\mathrm{R}} /<r_{1 \mathrm{~s}}>_{\mathrm{NR}}=\left(1.23 m_{o}\right)^{-1} / m_{o}^{-1}=0.81 .
$$

That is, relativistic effects have effectively contracted the 1s orbital by $19 \%$.
The contraction of the 1s orbital in heavy atoms also results in a contraction of the s orbitals in higher quantum shells of that atom, which in turn leads to

Fig. 2.4.5.
Calculated orbital contraction ratio $<r_{6 \mathrm{~s}}>\mathrm{R} /<r_{6 \mathrm{~s}}>\mathrm{NR}$ as a function of atomic number $Z$.

lowering of the energies of these orbitals. This is known as the direct relativistic effect, which accounts for orbital contraction and stabilization in s orbitals and, to a lesser extent, in p orbitals.

In contrast, the valence $d$ and $f$ orbitals in heavy atoms are expanded and destabilized by the relativistic effects. This is because the contraction of the s orbitals increases the shielding effect, which gives rise to a smaller effective nuclear charge for the $d$ and $f$ electrons. This is known as the indirect relativistic orbital expansion and destabilization. In addition, if a filled $d$ or $f$ subshell lies just inside a valence orbital, that orbital will experience a larger effective nuclear charge which will lead to orbital contraction and stabilization. This is because the $d$ and $f$ orbitals have been expanded and their shielding effect accordingly lowered.

For heavy atoms with different $Z$ values and various numbers of $d$ and $f$ electrons, the two aforementioned relativistic effects will lead to different degrees of 6 s orbital contraction. Figure 2.4 .5 shows the ratio $<r_{6 \mathrm{~s}}>_{\mathrm{R}} /<r_{6 \mathrm{~s}}>_{\mathrm{NR}}$ as a function of $Z$.
As we can see from Fig. 2.4.5, three of the elements that exhibit the largest relativistic effects are $\mathrm{Au}, \mathrm{Pt}$, and Hg . In these atoms, the (mostly) filled 4 f and $5 d$ orbitals lie just inside the 6 s valence orbital. In the following paragraphs, we discuss some examples where relativistic effects are manifested in the atomic structure and properties of the elements.

## (1) Ground electronic configuration

In the fifth period of the Periodic Table, we find transition metal elements with configurations $4 d^{n} 5 s^{1}$ and $4 d^{n} 5 s^{0}$. For the corresponding elements in the sixth period, the configurations become $5 \mathrm{~d}^{n-1} 6 \mathrm{~s}^{2}$ and $5 \mathrm{~d}^{n-1} 6 \mathrm{~s}^{1}$, respectively. This change is due to the aforementioned stabilization of the 6 s orbital caused by the relativistic effects. Table 2.4.4 lists the configuration of the elements concerned.

Table 2.4.4. The ground electronic configuration of some elements of the fifth and sixth periods

| Period | Group |  |  |  |  |  |
| :--- | :--- | :--- | :--- | :--- | :--- | :--- |
|  | 5 | 6 | 7 | 8 | 9 | 10 |
| 5th | Nb | Mo | Tc | Ru | Rh | Pd |
|  | $\mathrm{d}^{4} \mathrm{~s}^{1}$ | $\mathrm{~d}^{5} \mathrm{~s}^{1}$ | $\mathrm{~d}^{5} \mathrm{~s}^{2}$ | $\mathrm{~d}^{7} \mathrm{~s}^{1}$ | $\mathrm{~d}^{8} \mathrm{~s}^{1}$ | $\mathrm{~d}^{10} \mathrm{~s}^{0}$ |
| 6th | Ta | W | Re | Os | Ir | Pt |
|  | $\mathrm{d}^{3} \mathrm{~s}^{2}$ | $\mathrm{~d}^{4} \mathrm{~s}^{2}$ | $\mathrm{~d}^{5} \mathrm{~s}^{2}$ | $\mathrm{~d}^{6} \mathrm{~s}^{2}$ | $\mathrm{~d}^{7} \mathrm{~s}^{2}$ | $\mathrm{~d}^{9} \mathrm{~s}^{1}$ |

## (2) Lanthanide contraction

The properties of the elements of the sixth period are influenced by lanthanide contraction: a gradual decrease of the atomic radius with increasing atomic number from La to Lu . The elements of groups 5 to 11 for the fifth and sixth periods have comparable structural parameters. For instance, Nb and Ta, as well as the pair Mo and W, have very similar ionic radii, when they have the same oxidation number. As a result, it is very difficult to separate Nb and Ta, and it is also not easy to separate Mo and W. Similarly, Ag and Au have nearly the same atomic radius, 144 pm . Recent studies of the coordination compounds of $\operatorname{Ag}(\mathrm{I})$ and $\mathrm{Au}(\mathrm{I})$ indicate that the covalent radius of Au is even shorter than that of Ag by about 8 pm . In elementary textbooks the phenomenon of lanthanide contraction is attributed to incomplete shielding of the nucleus by the diffuse 4 f inner subshell. Recent theoretical calculations conclude that lanthanide contraction is the result of both the shielding effect of the 4 f electrons and relativistic effects, with the latter making about $30 \%$ contribution.

## (3) Effect of the $\mathbf{6} \mathbf{s}^{\mathbf{2}}$ inert pair

In the group 13 triad gallium/indium/thallium, the experimental energy separations of the $\left(n s^{2} n \mathrm{p}^{1}\right)^{2} \mathrm{P}$ and $\left(n \mathrm{~s}^{1} n \mathrm{p}^{2}\right)^{2} \mathrm{P}$ states are $4.7,4.3$, and 5.7 eV , respectively. The unusually large energy separation in Tl is another manifestation of the relativistic stabilization of the 6 s orbital. Also, whereas the ionic radius of $\mathrm{Tl}^{+}(150 \mathrm{pm})$ is larger than that of $\mathrm{In}^{+}(140 \mathrm{pm})$, the average of the second and third ionization energies, $1 / 2\left(I_{2}+I_{3}\right)$, of $\mathrm{Tl}\left(4.848 \times 10^{3} \mathrm{~kJ} \mathrm{~mol}^{-1}\right)$ is larger than that of $\operatorname{In}\left(4.524 \times 10^{3} \mathrm{~kJ} \mathrm{~mol}^{-1}\right)$. In other words, even through $\mathrm{Tl}^{+}$ is larger than $\mathrm{In}^{+}$, the 6 s electrons of $\mathrm{Tl}^{+}$are more difficult to detach. Hence Tl is predominantly monovalent as well as trivalent, whereas Ga and In are both trivalent. The same kind of reasoning is valid for Pb and Bi , which tend to favor the lower oxidation states $\mathrm{Pb}^{2+}$ and $\mathrm{Bi}^{3+}$, respectively, with the $6 \mathrm{~s}^{2}$ electron pair remaining intact.

## (4) Comparison between gold and mercury

Elements Au and Hg differ by only one electron, with the following configurations:

$$
\begin{aligned}
& { }_{79} \mathrm{Au}:[\mathrm{Xe}] 4 \mathrm{f}^{14} 5 \mathrm{~d}^{10} 6 \mathrm{~s}^{1} ; \\
& 80 \mathrm{Hg}:[\mathrm{Xe}] 4 \mathrm{f}^{14} 5 \mathrm{~d}^{10} 6 \mathrm{~s}^{2} .
\end{aligned}
$$

## Fundamentals of Bonding Theory

Because of the contraction and stabilization of the 6 s orbital, the outermost, or valence, shell of Au is formed by both the 5 d and 6 s orbitals. Indeed, electronically, Au is halogen-like, with one electron missing from the pseudo noble gas (closed subshell) configuration. Hence, similar to the existence of halogen $\mathrm{X}_{2}$ molecule, gold also forms the covalent $\mathrm{Au}_{2}$ molecule. In addition, gold also forms ionic compounds such as RbAu and CsAu , in which the $\mathrm{Au}^{-}$anion has the pseudo noble gas electronic configuration.

Mercury, with filled 5d and 6s subshells, also has the pseudo noble gas configuration. In the gas phase, Hg exists as a monatomic "molecule." From Fig. 2.4.1, Hg has an $I_{1}$ value similar to those of noble gases; it occupies a maximum position in the $I_{1}$ curve. The interaction between mercury atoms is of the van der Waals type. Hence, Hg and Au have some notably different properties:

|  | Hg | Au |
| :--- | :---: | :---: |
| Density $\left(\mathrm{g} \mathrm{cm}^{-3}\right)$ | 13.53 | 19.32 |
| Melting point $\left({ }^{\circ} \mathrm{C}\right)$ | -39 | 1064 |
| $\Delta H_{\text {fusion }}\left(\mathrm{kJ} \mathrm{mol}^{-1}\right)$ | 2.30 | 12.8 |
| Conductivity $\left(\mathrm{kS} \mathrm{m}^{-1}\right)$ | 10.4 | 426 |

Finally, it should be mentioned that mercury forms the cation $\mathrm{Hg}_{2}^{2+}$ (as in $\mathrm{Hg}_{2} \mathrm{Cl}_{2}$ ), which is isoelectronic to $\mathrm{Au}_{2}$.

## (5) Melting points of the metals

The variation of the melting points of the transition metals, as well as those of the alkali metals and alkali earth metals of the same period, are displayed in Fig. 2.4.6. It is seen that the uppermost curve (that for the elements of the sixth period) starts from Cs , increasing steadily and reaching a maximum at W . Beyond W, the curve starts to decrease and reach the minimum at Hg at the end. It is believed that this trend is the result of the relativistic effects.

In view of the previously discussed contraction and stabilization of the 6 s orbital, the valence shell of the elements of the sixth period consists of one s and five d orbitals. In the metallic state, the six valence orbitals of each atom overlap effectively with the six valence orbitals of the other atoms. For a metal with $N$ atoms, with a total of $6 N$ valence orbitals, $3 N$ of the molecular orbitals are bonding. The energies of these bonding orbitals are very close to each other, forming a bonding band in the process. The remaining $3 N$ molecular orbitals are antibonding. These antibonding molecular orbitals are also with energies very close to each other and they form an antibonding energy band. It should be noted that the overlap between the valence orbital is very effective, due to the high symmetry of the coordination, which is essentially the closest packed situation. As a result, there are only bonding and antibonding energy bands, and there are no nonbonding energy bands.

As we go across the period, we feed electrons to the molecular orbitals, starting from the bonding orbitals. As the bonding energy band starts to fill, the metallic bond becomes stronger and stronger. At W, with six electrons per atom, all the bonding molecular orbitals are filled, which leads to the strongest metallic bond and highest melting point. Once we go beyond W , the antibonding

molecular orbitals start to fill, weakening the metallic bond in the process. Hence the melting point starts to decrease once we get to Re . At the end, at Hg , with 12 valence electrons per atom, all the bonding and antibonding molecular orbitals are fully occupied. There is no net bonding effect, as in the case of noble gases. Hence Hg has the lowest melting point. A similar situation exists for the elements of the two previous periods. However, the variation is less dramatic. This is because the relativistic effects are most prominent for the elements of the sixth period.

The variation of other physical properties such as hardness and conductivity of the metals may be analyzed in a similar manner.

## (6) Noble gas compounds of gold

Relativity plays an important role in stabilizing elusive species such as $\mathrm{XeAuXe}{ }^{+}$(a structural analog of the $\mathrm{ClAuCl}^{+}$anion), which have been observed experimentally by mass spectroscopy. A theoretical study of Pyykkö has shown that about half of the bonding energy in $\mathrm{AuXe}^{+}$arises from relativistic effects. A nice example that illustrates the importance of relativistic effects in the stabilization of gold compounds is $\left[\mathrm{AuXe}_{4}^{2+}\right]\left[\mathrm{Sb}_{2} \mathrm{~F}_{11}^{-}\right]_{2}$, the first bulk compound with covalent bonding between a noble gas and a noble metal. Crystals of this compound remain stable up to $-40^{\circ} \mathrm{C}$. The dark red tetraxenonogold(II) cation $\left[\mathrm{AuXe}_{4}\right]^{2+}$ has a square-planar configuration with an average $\mathrm{Au}-\mathrm{Xe}$ bond distance of 274 pm . In $\left[\mathrm{AuXe}_{4}\right]^{2+}$, xenon functions as a $\sigma$ donor toward $\mathrm{Au}^{2+}$, and calculation shows that a positive charge of about +0.4 resides on

Fig. 2.4.6.
Melting points of the elements.
each ligand atom. The $\mathrm{Xe}-\mathrm{Au}$ bond in $\left[\mathrm{AuXe}_{4}\right]^{2+}$ may be contrasted with the $\mathrm{Xe}-\mathrm{F}$ bond in $\mathrm{XeF}_{4}$, in which a charge transfer of electrons occurs from xenon to fluorine.

## Covalent Bonding in Molecules

After a discussion on atomic structure, we now consider the electronic structure in molecules. It is clear that, whatever theory is chosen to treat this problem, it must be able to answer "Why do molecules form at all?" For instance, when two H atoms collide, the $\mathrm{H}_{2}$ molecule is formed. However, when two He atoms are brought together, no $\mathrm{He}_{2}$ is formed.

One way to answer the aforementioned question is "Two atoms form a molecule because the energy of the whole is lower than the sum of the energies of its parts." So the theory we need should bring about a decrease in energy when a molecule is formed by two atoms. As in the case of an atom, the energy of a molecule can also be calculated using quantum mechanical methods. In this chapter, we first use the simplest diatomic molecules $\mathrm{H}_{2}^{+}$and $\mathrm{H}_{2}$ as examples to illustrate the basic concepts of chemical bonding. Then we will turn to other more complicated molecules.

### 3.1 The hydrogen molecular ion: bonding and antibonding molecular orbitals

### 3.1.1 The variational method

To apply the variational method, we first need to have a trial function. When the system under study is a molecule composed of $n$ atoms, the trial function, which is to become a molecular orbital, is a linear combination of atomic orbitals (LCAO):

$$
\psi=c_{1} \phi_{1}+c_{2} \phi_{2}+\cdots+c_{n} \phi_{n},
$$

where $\phi_{1}, \phi_{2}, \ldots, \phi_{n}$ are known atomic functions, and the coefficients $c_{1}, c_{2}, \ldots, c_{n}$ are parameters to be optimized. In the following we use the simplest LCAO to illustrate the variational method:

$$
\begin{equation*}
\psi=c_{1} \phi_{1}+c_{2} \phi_{2} . \tag{3.1.2}
\end{equation*}
$$

## Fundamentals of Bonding Theory

The energy of this wavefunction is

$$
\begin{align*}
E & =\frac{\int\left(c_{1} \phi_{1}+c_{2} \phi_{2}\right) \hat{H}\left(c_{1} \phi_{1}+c_{2} \phi_{2}\right) \mathrm{d} \tau}{\int\left(c_{1} \phi_{1}+c_{2} \phi_{2}\right)^{2} \mathrm{~d} \tau} \\
& =\frac{c_{1}^{2} \int \phi_{1} \hat{H} \phi_{1} \mathrm{~d} \tau+2 c_{1} c_{2} \int \phi_{1} \hat{H} \phi_{2} \mathrm{~d} \tau+c_{2}^{2} \int \phi_{2} \hat{H} \phi_{2} \mathrm{~d} \tau}{c_{1}^{2} \int \phi_{1}^{2} \mathrm{~d} \tau+2 c_{1} c_{2} \int \phi_{1} \phi_{2}+c_{2}^{2} \int \phi_{2}^{2} \mathrm{~d} \tau} \\
& =\frac{c_{1}^{2} H_{11}+2 c_{1} c_{2} H_{12}+c_{2}^{2} H_{22}}{c_{1}^{2} S_{11}+2 c_{1} c_{2} S_{12}+c_{2}^{2} S_{22}}, \tag{3.1.3}
\end{align*}
$$

where we have made use of the Hermitian property of $\hat{H}$

$$
\begin{equation*}
\int \phi_{1} \hat{H} \phi_{2} \mathrm{~d} \tau=\int \phi_{2} \hat{H} \phi_{1} \mathrm{~d} \tau \tag{3.1.4}
\end{equation*}
$$

and also introduced the notation

$$
\begin{equation*}
H_{i j}=\int \phi_{i} \hat{H} \phi_{j} \mathrm{~d} \tau \tag{3.1.5}
\end{equation*}
$$

and

$$
\begin{equation*}
S_{i j}=\int \phi_{i} \phi_{j} \mathrm{~d} \tau \tag{3.1.6}
\end{equation*}
$$

To obtain the minimum energy of the system, we set

$$
\begin{equation*}
\left(\partial E / \partial c_{1}\right)=0 \tag{3.1.7}
\end{equation*}
$$

and

$$
\begin{equation*}
\left(\partial E / \partial c_{2}\right)=0 \tag{3.1.8}
\end{equation*}
$$

Applying eqs. (3.1.7) and (3.1.8) to eq. (3.1.3), we obtain

$$
\left\{\begin{align*}
\left(H_{11}-E S_{11}\right) c_{1}+\left(H_{12}-E S_{12}\right) c_{2}=0  \tag{3.1.9}\\
\left(H_{12}-E S_{12}\right) c_{1}+\left(H_{22}-E S_{22}\right) c_{2}=0
\end{align*}\right.
$$

These equations are called secular equations. Clearly, $c_{1}=c_{2}=0$ is a solution of eq. (3.1.9). But it is a meaningless solution, as $\psi$ becomes zero. In order for $c_{1}$ and $c_{2}$ to be non-vanishing, we need to have

$$
\left|\begin{array}{cc}
H_{11}-E S_{11} & H_{12}-E S_{12}  \tag{3.1.10}\\
H_{12}-E S_{12} & H_{22}-E S_{22}
\end{array}\right|=0
$$

This is known as a secular determinant, where the only unknown is $E$. The remaining quantities in the determinant, $H_{i j}$ and $S_{i j}$, may be evaluated readily according to their definitions given in eqs. (3.1.5) and (3.1.6) and using the
known functions $\phi_{i}$ and $\phi_{j}$. Upon obtaining $E$ from eq. (3.1.10), we can substitute $E$ into eq. (3.1.9) to solve for $c_{1}$ and $c_{2}$. Since there are two roots of $E$ from the secular determinant, there are also two corresponding sets of coefficients, which lead to two molecular orbitals.

If our trial function has the form given in eq. (3.1.1), the corresponding secular determinant has the dimensions $n \times n$ :

$$
\left|\begin{array}{cccc}
H_{11}-E S_{11} & H_{12}-E S_{12} & \cdots & H_{1 n}-E S_{1 n}  \tag{3.1.11}\\
H_{12}-E S_{12} & H_{22}-E S_{22} & \ldots & H_{2 n}-E S_{2 n} \\
\vdots & \vdots & \vdots & \vdots \\
H_{1 n}-E S_{1 n} & H_{2 n}-E S_{2 n} & \cdots & H_{n n}-E S_{n n}
\end{array}\right|=0 .
$$

There are now $n$ roots of $E$. Substituting each $E$ into the secular equations

$$
\left\{\begin{array}{c}
\left(H_{11}-E S_{11}\right) c_{1}+\left(H_{12}-E S_{12}\right) c_{2}+\ldots+\left(H_{1 n}-E S_{1 n}\right) c_{n}=0  \tag{3.1.12}\\
\left(H_{12}-E S_{12}\right) c_{1}+\left(H_{22}-E S_{22}\right) c_{2}+\ldots+\left(H_{2 n}-E S_{2 n}\right) c_{n}=0 \\
\vdots \\
\left(H_{1 n}-E S_{1 n}\right) c_{1}+\left(H_{2 n}-E S_{2 n}\right) c_{2}+\ldots+\left(H_{n n}-E S_{n n}\right) c_{n}=0
\end{array}\right.
$$

we get a set of $n$ coefficients. In other words, there are altogether $n$ sets of coefficients, or $n$ molecular orbitals. To briefly summarize at this point, starting with $n$ atomic orbitals $\phi_{i}(i=1,2, \ldots, n)$ in eq. (3.1.1), we can construct $n$ independent molecular orbitals using the variational method.

### 3.1.2 The hydrogen molecular ion: energy consideration

Now we consider the simplest molecular system, namely the hydrogen molecular ion $\mathrm{H}_{2}^{+}$. The Schrödinger equation for $\mathrm{H}_{2}^{+}$, in a.u., is

$$
\begin{equation*}
\left[-\frac{1}{2} \nabla^{2}-\left(1 / r_{a}\right)-\left(1 / r_{b}\right)+\left(1 / r_{a b}\right)\right] \psi=E \psi \tag{3.1.13}
\end{equation*}
$$

where $r_{a}, r_{b}$, and $r_{a b}$ (treated as a constant for the time being) are defined in Fig. 3.1.1.

When the nuclei are infinitely apart and the electron is on atom $a$, we have

$$
\begin{equation*}
\psi=1 \mathrm{~s}_{a}=\left[1 /(\pi)^{1 / 2}\right] \mathrm{e}^{-r_{a}}=\psi_{a} \tag{3.1.14}
\end{equation*}
$$

Similarly, when the electron resides on atom $b$ instead, we have

$$
\begin{equation*}
\psi=1 \mathrm{~s}_{b}=\left[1 /(\pi)^{1 / 2}\right] \mathrm{e}^{-r_{b}}=\psi_{b} \tag{3.1.15}
\end{equation*}
$$

If the two nuclei are allowed to come together, it is reasonable to expect that the "molecular orbital" $\psi_{\text {MO }}$ would be some kind of combination of atomic functions (3.1.14) and (3.1.15). This is the basis of the LCAO approximation for describing the chemical bonding in molecular systems. Thus we now have

$$
\begin{equation*}
\psi_{\mathrm{MO}}=c_{1} \psi_{a}+c_{2} \psi_{b} \tag{3.1.16}
\end{equation*}
$$

Fig. 3.1.1.
The coordinate system of $\mathrm{H}_{2}^{+}$.

Fig. 3.1.2.
The overlap integral $S_{a b}=\int\left(1 \mathrm{~s}_{a}\right)\left(1 \mathrm{~s}_{b}\right) \mathrm{d} \tau$, as represented by the shaded volume.

where coefficients $c_{1}$ and $c_{2}$ are to be determined by the variational method. To do that, we need to solve the secular determinant for $E$ :

$$
\left|\begin{array}{ll}
H_{a a}-E S_{a a} & H_{a b}-E S_{a b}  \tag{3.1.17}\\
H_{a b}-E S_{a b} & H_{b b}-E S_{b b}
\end{array}\right|=0 .
$$

The solution of $E$ involves the evaluation of six integrals: $S_{a a}, S_{b b}, S_{a b}, H_{a a}, H_{b b}$, and $H_{a b}$. From the normalization relationship, we have

$$
\begin{equation*}
S_{a a}=\int\left|1 \mathrm{~s}_{a}\right|^{2} \mathrm{~d} \tau=S_{b b}=\int\left|1 \mathrm{~s}_{b}\right|^{2} \mathrm{~d} \tau=1 \tag{3.1.18}
\end{equation*}
$$

In other words, $S_{a a}$ and $S_{b b}$ are simply normalization integrals.
Integral $S_{a b}$ is called the overlap integral. Physically it represents the common volume of the two atomic orbitals. A pictorial representation of $S_{a b}$ is given in Fig. 3.1.2. It is clear that $S_{a b}$ varies with $r_{a b}$, the internuclear distance: when $r_{a b}=0, S_{a b}=1$; when $r_{a b} \rightarrow \infty, S_{a b} \rightarrow 0$. Mathematically, it can be shown that, in a.u.,

$$
\begin{equation*}
S_{a b}=\int\left(1 \mathrm{~s}_{a}\right)\left(1 \mathrm{~s}_{b}\right) \mathrm{d} \tau=\left[1+r_{a b}+\left(\frac{r_{a b}^{2}}{3}\right)\right] \mathrm{e}^{-r_{a b}} \tag{3.1.19}
\end{equation*}
$$

Overlap integral $S_{a b}$ is often used as a measure of the strength of the chemical bond: the bond is strong if $S_{a b}$ is large, while the bond is weak if $S_{a b}$ is small.

Now we deal with the integrals involving Hamiltonian operator $\hat{H}$, in a.u.,

$$
\begin{align*}
H_{a a}=H_{b b} & =\int\left(1 \mathrm{~s}_{a}\right)\left[-\frac{1}{2} \nabla^{2}-\frac{1}{r_{a}}-\frac{1}{r_{b}}+\frac{1}{r_{a b}}\right]\left(1 \mathrm{~s}_{a}\right) \mathrm{d} \tau \\
& =E_{1 \mathrm{~s}}+\frac{1}{r_{a b}}+J, \tag{3.1.20}
\end{align*}
$$

where

$$
\begin{align*}
J & =\int\left(1 \mathrm{~s}_{a}\right) \frac{1}{r_{b}}\left(1 \mathrm{~s}_{a}\right) \mathrm{d} \tau=\int\left(1 \mathrm{~s}_{b}\right) \frac{1}{r_{a}}\left(1 \mathrm{~s}_{b}\right) \mathrm{d} \tau \\
& =-\frac{1}{r_{a b}}+\left(1+\frac{1}{r_{a b}}\right) \mathrm{e}^{-2 r_{a b}} . \tag{3.1.21}
\end{align*}
$$

So

$$
\begin{align*}
H_{a a} & =H_{b b}=-\frac{1}{2}+\left(1+\frac{1}{r_{a b}}\right) \exp \left[-2 r_{a b}\right]  \tag{3.1.22}\\
H_{a b} & =\int\left(1 \mathrm{~s}_{a}\right)\left[-\frac{1}{2} \nabla^{2}-\frac{1}{r_{a}}-\frac{1}{r_{b}}+\frac{1}{r_{a b}}\right]\left(1 \mathrm{~s}_{b}\right) \mathrm{d} \tau \\
& =S_{a b}\left(E_{1 \mathrm{~s}}+\frac{1}{r_{a b}}\right)+K \tag{3.1.23}
\end{align*}
$$

where

$$
\begin{equation*}
K=-\left(1+r_{a b}\right) \mathrm{e}^{-r_{a b}} . \tag{3.1.24}
\end{equation*}
$$

So

$$
\begin{align*}
H_{a b} & =\left(\frac{r_{a b}^{2}}{3}+r_{a b}+1\right) \exp \left[-r_{a b}\right] \cdot\left(\frac{1}{r_{a b}}-\frac{1}{2}\right)-\left(r_{a b}+1\right) \mathrm{e}^{-r_{a b}} \\
& =-\left(\frac{r_{a b}^{2}}{6}+\frac{7}{6} r_{a b}+\frac{1}{2}-\frac{1}{r_{a b}}\right) \mathrm{e}^{-r_{a b}} . \tag{3.1.25}
\end{align*}
$$

Thus $H_{a a}, H_{b b}$, and $H_{a b}$ are dependent on $r_{a b}$ as well. Note that the $S_{a b}$ integrals are dimensionless, while the $H$ integrals have the energy unit. Also, all $H$ integrals are negative.

Expanding secular determinant (3.1.17), we have

$$
\begin{equation*}
\left(H_{a a}-E\right)^{2}-\left(H_{a b}-E S_{a b}\right)^{2}=0 \tag{3.1.26}
\end{equation*}
$$

which leads to roots

$$
\begin{equation*}
E_{S}=\frac{H_{a a}+H_{a b}}{1+S_{a b}}=-\frac{1}{2}+\frac{1}{r_{a b}}-\frac{1+r_{a b}\left(r_{a b}+1\right) \mathrm{e}^{-r_{a b}}-\left(r_{a b}+1\right) \mathrm{e}^{-2 r_{a b}}}{r_{a b}\left[1+\mathrm{e}^{-r_{a b}}\left(\frac{r_{a b}^{2}}{3}+r_{a b}+1\right)\right]} \tag{3.1.27}
\end{equation*}
$$

and

$$
\begin{equation*}
E_{A}=\frac{H_{a a}-H_{a b}}{1-S_{a b}}=-\frac{1}{2}+\frac{1}{r_{a b}}-\frac{1-r_{a b}\left(r_{a b}+1\right) \mathrm{e}^{-r_{a b}}-\left(r_{a b}+1\right) \mathrm{e}^{-2 r_{a b}}}{r_{a b}\left[1-\mathrm{e}^{-r_{a b}}\left(\frac{r_{a b}^{2}}{3}+r_{a b}+1\right)\right]} \tag{3.1.28}
\end{equation*}
$$

with

$$
E_{S}<E_{A}
$$

If we minimize $E_{S}$ by setting $\mathrm{d} E_{S} / \mathrm{d} r_{a b}=0$, we get the optimal bond length

$$
\begin{equation*}
r_{e}=2.494 \text { a.u. }=131.9 \mathrm{pm} \tag{3.1.29}
\end{equation*}
$$

Experimentally, the internuclear separation in $\mathrm{H}_{2}^{+}$is 2 a.u. or 105.8 pm . When $r_{a b}=2.494$ a.u., $S_{a b}=0.460$ (a rather large value for $S_{a b}$ ). If we substitute $r_{a b}=2.494$ a.u. into eq. (3.1.27), we get

$$
\begin{equation*}
E_{S}=\left[-\frac{1}{2}+\left(\frac{1}{r_{a b}}\right)-0.466\right] \text { a.u. } \tag{3.1.30}
\end{equation*}
$$

The electronic dissociation energy $\left(D_{\mathrm{e}}\right)$ of $\mathrm{H}_{2}^{+}$is

$$
\begin{align*}
D_{\mathrm{e}} & =E(H)-E_{S}\left(H_{2}^{+}\right) \\
& =\{-1 / 2-[-1 / 2+(1 / 2.494)-0.466]\} \text { a.u. } \\
& =0.065 \text { a.u. }=1.77 \mathrm{eV} . \tag{3.1.31}
\end{align*}
$$

This is only in fair agreement with the experimental value of 2.79 eV for $D_{\mathrm{e}}$. An improvement in the calculation can be made if we replace the nuclear charge $Z$ in $1 s_{a}$ and $1 s_{b}$ by the effective nuclear charge $Z_{\text {eff }}$ as a parameter. With $Z_{\text {eff }}=1.239$, we have $D_{\mathrm{e}}=2.34 \mathrm{eV}$ and $r_{\mathrm{e}}=106 \mathrm{pm}$.

If we plot the $E_{S}$ and $E_{A}$, as given in eqs. (3.1.27) and (3.1.28), against $r_{a b}$, we get the curves shown in Fig. 3.1.3. These are called potential energy curves. In the figure, $r_{\mathrm{e}}$ is the equilibrium bond length, and $D_{\mathrm{e}}$ is the electronic dissociation energy. It should be noted that molecular vibration exists even at 0 K , so that it does not require all of $D_{\mathrm{e}}$ to dissociate the molecule. Rather, the dissociation energy $D_{0}$, as shown in Fig. 3.1.3, will suffice. The difference between $D_{\mathrm{e}}$ and $D_{0}$ is the zero-point vibrational energy (ZPVE) of the molecule.

Returning to the hydrogen molecular ion, we see that the energy of the system, $E\left(\mathrm{H}_{2}^{+}\right)$, is lower than $E(\mathrm{H})+E\left(\mathrm{H}^{+}\right)$. In other words, the quantum mechanical results "predict" a stable $\mathrm{H}_{2}^{+}$species.

### 3.1.3 The hydrogen molecular ion: wavefunctions

Upon obtaining the energies of the molecular orbitals by solving the secular determinant [eq. (3.1.17)], we are now ready to proceed to determine the coefficients $c_{1}$ and $c_{2}$ of eq. (3.1.16). To do this we need to solve the secular equations

$$
\left\{\begin{array}{l}
\left(H_{a a}-E\right) c_{1}+\left(H_{a b}-E S_{a b}\right) c_{2}=0  \tag{3.1.32}\\
\left(H_{a b}-E S_{a b}\right) c_{1}+\left(H_{b b}-E\right) c_{2}=0
\end{array}\right.
$$

When $E=E_{\mathrm{S}}=\left(H_{a a}+H_{a b}\right) /\left(1+S_{a b}\right)$, we have $c_{1}=c_{2}$, or

$$
\begin{equation*}
\psi_{\mathrm{S}}=c_{1}\left(\psi_{a}+\psi_{b}\right) \equiv c_{1}\left(1 \mathrm{~s}_{a}+1 \mathrm{~s}_{b}\right) . \tag{3.1.33}
\end{equation*}
$$

Upon normalization, $\psi_{\mathrm{S}}$ becomes

$$
\begin{equation*}
\psi_{\mathrm{S}}=\left(2+2 S_{a b}\right)^{-1 / 2}\left(1 \mathrm{~s}_{a}+1 \mathrm{~s}_{b}\right) \tag{3.1.34}
\end{equation*}
$$

Wavefunction $\psi_{\mathrm{S}}$ is called a bonding orbital, as its energy is lower than that of its constituent atomic orbitals (c.f. Fig. 3.1.3).

When $E=E_{\mathrm{A}}=\left(H_{a a}-H_{a b}\right) /\left(1-S_{a b}\right)$, upon substituting into eq. (3.1.32), we obtain $c_{1}=-c_{2}$, or

$$
\begin{equation*}
\psi_{\mathrm{A}}=c_{1}\left(\psi_{a}-\psi_{b}\right)=c_{1}\left(1 \mathrm{~s}_{a}-1 \mathrm{~s}_{b}\right) \tag{3.1.35}
\end{equation*}
$$

Upon normalization, $\psi_{A}$ becomes

$$
\begin{equation*}
\psi_{\mathrm{A}}=\left(2-2 S_{a b}\right)^{-1 / 2}\left(1 \mathrm{~s}_{a}-1 \mathrm{~s}_{b}\right) \tag{3.1.36}
\end{equation*}
$$

Wavefunction $\psi_{\mathrm{A}}$ is called an antibonding molecular orbital, as its energy is higher than that of its constituent atomic orbitals.

The more detailed energy diagram in Fig. 3.1.3 can be simplified to that shown in Fig. 3.1.4, where we see that atomic orbitals $1 \mathrm{~s}_{a}$ and $1 \mathrm{~s}_{b}$ are combined to form two molecular orbitals $\psi_{\mathrm{S}}$ (to be called $\sigma_{1 \mathrm{~S}}$ later) and $\psi_{\mathrm{A}}$ (to be called $\left.\sigma_{1 \mathrm{~s}}^{*}\right)$. Also, $\sigma_{1 \mathrm{~s}}$ with energy lower than those of atomic orbitals is a bonding orbital; $\sigma_{1 \mathrm{~s}}^{*}$ with energy higher than those of atomic orbitals is an antibonding orbitals. The ground electronic configuration for $\mathrm{H}_{2}^{+}$is thus $\left(\sigma_{1 \mathrm{~s}}\right)^{1}$.

An important point regarding the energy level diagram in Fig. 3.1.4 is that, when a bonding and an antibonding molecular orbital are formed by two atomic orbitals, the antibonding effect (the energy difference between 1 s and $\sigma_{1 \mathrm{~s}}^{*}$ ) is greater than the bonding effect (the energy difference between 1 s and $\sigma_{1 \mathrm{~s}}$ ). This is not difficult to see if we examine the expressions for $E_{\mathrm{S}}$ and $E_{\mathrm{A}}$ given in eqs. (3.1.27) and (3.1.28). The denominators for $E_{\mathrm{S}}$ and $E_{\mathrm{A}}$ are $1+S_{a b}$ and $1-S_{a b}$, respectively. Recall that $0<S_{a b}<1$. So $1+S_{a b}>1$ and $1-S_{a b}<1$ and this leads to the result that the bonding effect is smaller than the antibonding effect. If we ignore the overlap of the atomic orbitals by setting $S_{a b}=0$, the bonding effect would be the same as the antibonding effect.

Now we examine the bonding orbital $\sigma_{1 \mathrm{~s}}$ and antibonding orbital $\sigma_{1 \mathrm{~s}}^{*}$ as well as their probability density functions $\left|\sigma_{1 \mathrm{~s}}\right|^{2}$ and $\left|\sigma_{1 \mathrm{~s}}^{*}\right|^{2}$. A schematic representation of $\sigma_{1 \mathrm{~s}}$ is shown in Fig. 3.1.5(a). In this combination of two 1s orbitals, electron density accumulates in the internuclear region. Also, $\sigma_{1 \mathrm{~s}}$ has cylindrical symmetry around the internuclear axis.

Fig. 3.1.4.
A simplified energy level diagram for $\mathrm{H}_{2}^{+}$.

Fig. 3.1.5.
Molecular orbitals of $\mathrm{H}_{2}^{+}$: (a) $\sigma_{1 \mathrm{~s}}$, (b) $\sigma_{1 \mathrm{~s}}^{*}$.

Fig. 3.1.6.
Probability density distribution of $\mathrm{H}_{2}^{+}$ plotted along the internuclear axis: (a) $\left|\sigma_{1 s}\right|^{2}$, (b) $\left|\sigma_{1 s}^{*}\right|^{2}$.

(a)

(b)

In Fig. 3.1.5(b), a schematic drawing for $\sigma_{1 \mathrm{~s}}^{*}$ is shown. It is seen that this combination of 1 s orbitals has no charge accumulation between the nuclei. Indeed, in the nodal plane there is zero probability of finding an electron. As in the case of $\sigma_{1 \mathrm{~s}}$, the $\sigma_{1 \mathrm{~s}}^{*}$ orbital also has cylindrical symmetry around the molecular axis.

The accumulation of charge density between the nuclei in $\sigma_{1 \mathrm{~s}}$ is clearly seen when we consider the probability density function $\left|\sigma_{1 s}\right|^{2}$ :

$$
\begin{align*}
\left|\sigma_{1 \mathrm{~s}}\right|^{2} & =\left|1 \mathrm{~s}_{a}+1 \mathrm{~s}_{b}\right|^{2} \\
& =\left|1 \mathrm{~s}_{a}\right|^{2}+2\left|1 \mathrm{~s}_{a}\right|\left|1 \mathrm{~s}_{b}\right|+\left|1 \mathrm{~s}_{b}\right|^{2} \tag{3.1.37}
\end{align*}
$$

When we plot this function along the internuclear axis, Fig. 3.1.6(a) is obtained. In this figure, the build-up of charge density between the nuclei is obvious.

For the antibonding orbital $\sigma_{1 \mathrm{~s}}^{*}$, we have the probability density function

$$
\begin{align*}
\left|\sigma_{1 \mathrm{~s}}^{*}\right|^{2} & =\left|1 \mathrm{~s}_{a}-1 \mathrm{~s}_{b}\right|^{2} \\
& =\left|1 \mathrm{~s}_{a}\right|^{2}-2\left|1 \mathrm{~s}_{a}\right|\left|1 \mathrm{~s}_{b}\right|+\left|1 \mathrm{~s}_{b}\right|^{2} \tag{3.1.38}
\end{align*}
$$

If we plot $\left|\sigma_{1 \mathrm{~s}}^{*}\right|^{2}$ along the internuclear axis, we get Fig. 3.1.6(b). Now there is a clear deficiency of charge density between the nuclei.

### 3.1.4 Essentials of molecular orbital theory

In sections 3.1.2 and 3.1.3, we use the example of $\mathrm{H}_{2}^{+}$to illustrate the molecular orbital theory. In particular, we note the following:
(1) Since molecular orbitals are linear combinations of atomic orbitals, it follows that $n$ atomic orbitals will generate $n$ molecular orbitals.
(2) If we have $n$ atomic orbitals forming $n$ molecular orbitals, "usually" half of the molecular orbitals are bonding, while the other half are antibonding. However, this condition does not always hold. For instance, if we have three atomic orbitals to form three molecular orbitals, obviously half of the latter cannot be bonding. Also, there is an additional type that we have not yet considered: nonbonding molecular orbitals, which by definition neither gains nor loses stability (or energy).
(3) Bonding molecular orbitals have two characteristics: its energy is lower than those of the constituent atomic orbitals and there is a concentration of charge density between the nuclei.

Table 3.1.1. Molecular orbital theory applied to $\mathrm{H}_{2}^{+}, \mathrm{H}_{2}, \mathrm{He}_{2}^{+}$, and $\mathrm{He}_{2}$

| Molecule Configuration | Bond energy <br> $\left(\mathrm{kJ} \mathrm{mol}^{-1}\right)$ | Bond length Remark <br> $(\mathrm{pm})$ |  |  |
| :--- | :---: | :---: | :---: | :---: |
| $\mathrm{H}_{2}^{+}$ | $\sigma_{1 \mathrm{~s}}^{1}$ | 255 | 106 | The bond is formed by one bonding <br> electron. <br> There are now two bonding electrons. <br> Hence the bond is stronger and shorter <br> than that in $\mathrm{H}_{2}^{+}$. |
| $\mathrm{He}_{2}^{+}$ | $\sigma_{1 \mathrm{~s}}^{2}$ | 431 | 74 | 108 |
| $\mathrm{He}_{2}^{2} \sigma_{1 \mathrm{~s}}^{* 1}$ | 251 | $\mathrm{H}_{2}^{+}$, since antibonding effect is greater <br> than bonding effect. <br> The gain of energy by the bonding <br> electrons is more than offset by the <br> antibonding electrons. Hence there is <br> no bond in He |  |  |

(4) On the other hand, the energy of an antibonding molecular orbital is higher than those of the constituent atomic orbitals. Also, the wavefunction of an antibonding orbital has one or more nodes between the nuclei. Hence there is a deficiency of charge density between the nuclei.

To conclude this section, we apply the energy level diagram in Fig. 3.1.4 to four simple molecules having one to four electrons. The results are summarized in Table 3.1.1.

Examining Table 3.1.1, we see that our simple treatment is able to rationalize, at least semi-quantitatively, the formation of $\mathrm{H}_{2}$ and the non-existence of $\mathrm{He}_{2}$.

### 3.2 The hydrogen molecule: molecular orbital and valence bond treatments

### 3.2.1 Molecular orbital theory for $\mathrm{H}_{2}$

In our previous discussions on $\mathrm{H}_{2}^{+}$, we saw that the lone electron occupies the $\sigma_{1 s}$ molecular orbital:

$$
\begin{equation*}
\sigma_{1 \mathrm{~s}}=\left(2+2 S_{a b}\right)^{-1 / 2}\left(1 \mathrm{~s}_{a}+1 \mathrm{~s}_{b}\right) \tag{3.2.1}
\end{equation*}
$$

The molecular orbital theory was first introduced by F. Hund (of the Hund's rule fame) and R. S. Mullikan, with the latter winning the Nobel Prize in chemistry in 1966. Since $\sigma_{1 \mathrm{~s}}$ can accommodate two electrons, in molecular orbital theory, the wavefunction for $\mathrm{H}_{2}$ is

$$
\begin{align*}
\psi(1,2)= & \sigma_{1 \mathrm{~s}}(1) \sigma_{1 \mathrm{~s}}(2) \\
= & \left(2+2 S_{a b}\right)^{-1 / 2}\left[1 \mathrm{~s}_{a}(1)+1 \mathrm{~s}_{b}(1)\right] \\
& \times\left(2+2 S_{a b}\right)^{-1 / 2}\left[1 \mathrm{~s}_{a}(2)+1 \mathrm{~s}_{b}(2)\right] . \tag{3.2.2}
\end{align*}
$$

From this function, we can see that both electrons in $\mathrm{H}_{2}$ reside in the ellipsoidal $\sigma_{1 \mathrm{~s}}$ orbital. This situation is similar to that of the helium atom, where both

## Fundamentals of Bonding Theory

electrons reside in the spherical 1 s orbital, with wavefunction $1 \mathrm{~s}(1) 1 \mathrm{~s}(2)$. It is important to appreciate that, in $\sigma_{1 \mathrm{~s}}$, the identity of the atomic orbital is lost. This is the essential tenet of molecular orbital theory.

When we use eq. (3.2.2) to determine the energy of $\mathrm{H}_{2}$, we obtain $D_{\mathrm{e}}=260$ $\mathrm{kJ} \mathrm{mol}^{-1}$ and $r_{\mathrm{e}}=85 \mathrm{pm}$, while the experimental results are $458 \mathrm{~kJ} \mathrm{~mol}^{-1}$ and 74 pm , respectively. If we vary the nuclear charge, we obtain $Z_{\text {eff }}=1.197$, $D_{\mathrm{e}}=337 \mathrm{~kJ} \mathrm{~mol}^{-1}$, and $r_{\mathrm{e}}=73 \mathrm{pm}$. So while the quantitative results may only be called fair, we do get a stable $\mathrm{H}_{2}$ molecule.

### 3.2.2 Valence bond treatment of $\mathrm{H}_{2}$

Historically, molecular orbital theory was preceded by an alternative and successful description of the bonding in $\mathrm{H}_{2}$. In 1927, W. Heitler and F. London proposed the valence bond theory, in which each electron resides in an atomic orbital. In other words, in this model, the identity of the atomic orbital is preserved. There are two ways in which the two electrons in $\mathrm{H}_{2}$ can be accommodated in the pair of 1 s atomic orbitals:
(a) Electron 1 in a 1 s orbital centered at nucleus $a$ and electron 2 in a 1 s orbital centered at nucleus $b$. Mathematically:

$$
\begin{equation*}
\psi_{\mathrm{I}}(1,2)=1 \mathrm{~s}_{a}(1) 1 \mathrm{~s}_{b}(2) \tag{3.2.3}
\end{equation*}
$$

(b) Electron 1 in orbital $1 \mathrm{~s}_{b}$ and electron 2 in $1 \mathrm{~s}_{a}$, or,

$$
\begin{equation*}
\psi_{\mathrm{II}}(1,2)=1 \mathrm{~s}_{b}(1) 1 \mathrm{~s}_{a}(2) \tag{3.2.4}
\end{equation*}
$$

The valence bond wavefunction for $\mathrm{H}_{2}$ is simply a linear combination of $\psi_{\mathrm{I}}$ and $\psi_{\text {II }}$ :

$$
\begin{align*}
\psi(1,2) & =c_{\mathrm{I}} \psi_{\mathrm{I}}+c_{\mathrm{II}} \psi_{\mathrm{II}} \\
& =c_{\mathrm{I}} 1 \mathrm{~s}_{a}(1) 1 \mathrm{~s}_{b}(2)+c_{\mathrm{II}} 1 \mathrm{~s}_{b}(1) 1 \mathrm{~s}_{a}(2), \tag{3.2.5}
\end{align*}
$$

where the coefficients $c_{\mathrm{I}}$ and $c_{\mathrm{II}}$ are to be determined by the variational method. To do that, we once again need to solve a secular determinant:

$$
\left|\begin{array}{ll}
H_{I I}-E S_{I I} & H_{\text {III }}-E S_{\text {III }}  \tag{3.2.6}\\
H_{\text {III }}-E S_{\text {III }} & H_{\text {IIII }}-E S_{\text {IIII }}
\end{array}\right|=0,
$$

Upon solving for $E$, we substitute $E$ into the following secular equations to obtain coefficient $c_{\mathrm{I}}$ and $c_{\mathrm{II}}$ :

$$
\left\{\begin{array}{l}
\left(H_{\mathrm{II}}-E S_{\mathrm{II}}\right) c_{\mathrm{I}}+\left(H_{\mathrm{III}}-E S_{\mathrm{III}}\right) c_{\mathrm{II}}=0  \tag{3.2.7}\\
\left(H_{\mathrm{III}}-E S_{\mathrm{III}}\right) c_{\mathrm{I}}+\left(H_{\mathrm{IIII}}-E S_{\mathrm{IIII}}\right) c_{\mathrm{II}}=0
\end{array} .\right.
$$

With $H_{\text {II }}=H_{\text {IIII }}$ and $S_{\text {II }}=S_{\text {IIII }}$, the roots of eq. (3.2.6) are

$$
\begin{align*}
& E_{+}=\left(H_{\mathrm{II}}+H_{\mathrm{III}}\right) /\left(1+S_{\mathrm{III}}\right),  \tag{3.2.8}\\
& E_{-}=\left(H_{\mathrm{II}}-H_{\mathrm{III}}\right) /\left(1-S_{\mathrm{III}}\right) . \tag{3.2.9}
\end{align*}
$$

A diagram illustrating the various distances in $\mathrm{H}_{2}$ is shown in Fig. 3.2.1. The Hamiltonian operator for this system, in a.u., is

$$
\begin{equation*}
\hat{H}=-\frac{1}{2} \nabla_{1}^{2}-\frac{1}{2} \nabla_{2}^{2}-\frac{1}{r_{a 1}}-\frac{1}{r_{b 1}}-\frac{1}{r_{a 2}}-\frac{1}{r_{b 2}}+\frac{1}{r_{12}}+\frac{1}{r_{a b}} . \tag{3.2.10}
\end{equation*}
$$

In the following, we evaluate the various $H_{i j}$ and $S_{i j}$ integrals:

$$
\begin{align*}
& S_{\mathrm{II}}=S_{\mathrm{IIII}}=\iint 1 \mathrm{~s}_{a}(1) 1 \mathrm{~s}_{b}(2) \cdot 1 \mathrm{~s}_{a}(1) 1 \mathrm{~s}_{b}(2) \mathrm{d} \tau_{1} \mathrm{~d} \tau_{2} \\
& =\int\left|1 \mathrm{~s}_{a}(1)\right|^{2} \mathrm{~d} \tau_{1} \cdot \int\left|1 \mathrm{~s}_{b}(2)\right|^{2} \mathrm{~d} \tau_{2}=1  \tag{3.2.11}\\
& S_{\mathrm{III}}=\iint 1 \mathrm{~s}_{a}(1) 1 \mathrm{~s}_{b}(2) \cdot 1 \mathrm{~s}_{b}(1) 1 \mathrm{~s}_{a}(2) \mathrm{d} \tau_{1} \mathrm{~d} \tau_{2} \\
& =\int 1 \mathrm{~s}_{a}(1) 1 \mathrm{~s}_{b}(1) \mathrm{d} \tau_{1} \cdot \int 1 \mathrm{~s}_{a}(2) 1 \mathrm{~s}_{b}(2) \mathrm{d} \tau_{2} \\
& =S_{a b}^{2} \tag{3.2.12}
\end{align*}
$$

where $S_{a b}$ is simply the overlap integral introduced in the treatment of $\mathrm{H}_{2}^{+}$. Meanwhile,

$$
\begin{align*}
H_{\text {II }} & =H_{\text {IIII }}=\iint 1 \mathrm{~s}_{a}(1) 1 \mathrm{~s}_{b}(2) \hat{H} 1 \mathrm{~s}_{a}(1) 1 \mathrm{~s}_{b}(2) \mathrm{d} \tau_{1} \mathrm{~d} \tau_{2} \\
& =2 E_{1 \mathrm{~s}}+\frac{1}{r_{a b}}+J_{1}-2 J_{2} \tag{3.2.13}
\end{align*}
$$

where $J_{1}$ and $J_{2}$ are called Coulomb integrals:

$$
\begin{align*}
J_{1} & =\iint \frac{1}{r_{12}}\left|1 \mathrm{~s}_{a}(1) 1 \mathrm{~s}_{b}(2)\right|^{2} \mathrm{~d} \tau_{1} \mathrm{~d} \tau_{2},  \tag{3.2.14}\\
J_{2} & =\iint \frac{1}{r_{a 2}}\left|1 \mathrm{~s}_{a}(1) 1 \mathrm{~s}_{b}(2)\right|^{2} \mathrm{~d} \tau_{1} \mathrm{~d} \tau_{2} \\
& =\iint \frac{1}{r_{b 1}}\left|1 \mathrm{~s}_{a}(1) 1 \mathrm{~s}_{b}(2)\right|^{2} \mathrm{~d} \tau_{1} \mathrm{~d} \tau_{2} . \tag{3.2.15}
\end{align*}
$$

Finally,

$$
\begin{align*}
H_{\mathrm{III}} & =\iint 1 \mathrm{~s}_{a}(1) 1 \mathrm{~s}_{b}(2) \hat{H} 1 \mathrm{~s}_{b}(1) 1 \mathrm{~s}_{a}(2) \mathrm{d} \tau_{1} \mathrm{~d} \tau_{2} \\
& =2 E_{1 s} S_{a b}^{2}+\frac{S_{a b}^{2}}{r_{a b}}+K_{1}-2 K_{2} \tag{3.2.16}
\end{align*}
$$

## Fundamentals of Bonding Theory

where $K_{1}$ and $K_{2}$ are called resonance integrals:

$$
\begin{align*}
K_{1} & =\iint \frac{1}{r_{12}}\left|1 \mathrm{~s}_{a}(1) 1 \mathrm{~s}_{b}(2) 1 \mathrm{~s}_{b}(1) 1 \mathrm{~s}_{a}(2)\right| \mathrm{d} \tau_{1} \mathrm{~d} \tau_{2},  \tag{3.2.17}\\
K_{2} & =\iint \frac{1}{r_{a 1}}\left|1 \mathrm{~s}_{a}(1) 1 \mathrm{~s}_{b}(2) 1 \mathrm{~s}_{b}(1) 1 \mathrm{~s}_{a}(2)\right| \mathrm{d} \tau_{1} \mathrm{~d} \tau_{2} \\
& =\iint \frac{1}{r_{b 1}}\left|1 \mathrm{~s}_{a}(1) 1 \mathrm{~s}_{b}(2) 1 \mathrm{~s}_{b}(1) 1 \mathrm{~s}_{a}(2)\right| \mathrm{d} \tau_{1} \mathrm{~d} \tau_{2} . \tag{3.2.18}
\end{align*}
$$

Substituting $H_{i j}$ and $S_{i j}$ into eqs. (3.2.8) and (3.2.9), we obtain

$$
\begin{align*}
& E_{+}=2 E_{1 \mathrm{~s}}+\frac{1}{r_{a b}}+\frac{J_{1}-2 J_{2}+K_{1}-2 K_{2}}{1+S_{a b}^{2}}  \tag{3.2.19}\\
& E_{-}=2 E_{1 \mathrm{~s}}+\frac{1}{r_{a b}}+\frac{J_{1}-2 J_{2}-K_{1}+2 K_{2}}{1-S_{a b}^{2}} \tag{3.2.20}
\end{align*}
$$

Note the integrals $J_{1}, J_{2}, K_{1}$, and $K_{2}$ are all functions of $r_{a b}$.
When we plot $E_{+}$and $E_{-}$against $r_{a b}$, we get the energy curves shown in Fig. 3.2.2. So, once again, the valence bond treatment yields a stable $\mathrm{H}_{2}$ molecule, even though the quantitative results do not match exactly the experimental data.

Upon substituting $E_{+}$into eq. (3.2.7), we get $c_{\mathrm{I}}=c_{\mathrm{II}}$. After normalization, the wavefunction becomes

$$
\begin{equation*}
\psi_{+}=\left(2+2 S_{a b}^{2}\right)^{-1 / 2}\left[1 \mathrm{~s}_{a}(1) 1 \mathrm{~s}_{b}(2)+1 \mathrm{~s}_{b}(1) 1 \mathrm{~s}_{a}(2)\right] . \tag{3.2.21}
\end{equation*}
$$

Also, with $E_{-}$, we get $c_{\mathrm{I}}=-c_{\mathrm{II}}$. After normalization, the wavefunction becomes:

$$
\begin{equation*}
\psi_{-}=\left(2-2 S_{a b}^{2}\right)^{-1 / 2}\left[1 \mathrm{~s}_{a}(1) 1 \mathrm{~s}_{b}(2)-1 \mathrm{~s}_{b}(1) 1 \mathrm{~s}_{a}(2)\right] . \tag{3.2.22}
\end{equation*}
$$

After a simple valence bond treatment of $\mathrm{H}_{2}$, we now proceed to study the excited states of $\mathrm{H}_{2}$. Through this discussion, we will recognize that the molecular orbital and valence bond treatments, after modification, can bring about the same quantitative results.

Fig. 3.2.2.
Valence bond energies $E_{+}$and $E_{-}$ plotted as functions of $r_{a b}$.

### 3.2.3 Equivalence of the molecular orbital and valence bond models

As discussed previously, the bonding molecular orbital of $\mathrm{H}_{2}$ is

$$
\begin{equation*}
\sigma_{1 \mathrm{~s}}=\left(2+2 S_{a b}\right)^{-1 / 2}\left(1 \mathrm{~s}_{a}+1 \mathrm{~s}_{b}\right) \tag{3.2.23}
\end{equation*}
$$

and the antibonding molecular orbital has the form

$$
\begin{equation*}
\sigma_{1 \mathrm{~s}}^{*}=\left(2-2 S_{a b}\right)^{-1 / 2}\left(1 \mathrm{~s}_{a}-1 \mathrm{~s}_{b}\right) . \tag{3.2.24}
\end{equation*}
$$

The ground configuration of $\mathrm{H}_{2}$ is $\sigma_{1 \mathrm{~s}}^{2}$, with the (unnormalized) wavefunction

$$
\begin{equation*}
\psi_{1}\left(\sigma_{1 \mathrm{~s}}^{2}\right)=\left[1 \mathrm{~s}_{a}(1)+1 \mathrm{~s}_{b}(1)\right] \times\left[1 \mathrm{~s}_{a}(2)+1 \mathrm{~s}_{b}(2)\right] . \tag{3.2.25}
\end{equation*}
$$

Upon adding the spin part, the total wavefunction for the ground state of $\mathrm{H}_{2}$ is

$$
\begin{align*}
\psi_{1}\left(\sigma_{1 \mathrm{~s}}^{2}\right) & =\left[1 \mathrm{~s}_{a}(1)+1 \mathrm{~s}_{b}(1)\right]\left[1 \mathrm{~s}_{a}(2)+1 \mathrm{~s}_{b}(2)\right][\alpha(1) \beta(2)-\beta(1) \alpha(2)] \\
& =\left|\begin{array}{ll}
\sigma_{1 \mathrm{~s}} \alpha(1) & \sigma_{1 \mathrm{~s}} \beta(1) \\
\sigma_{1 \mathrm{~s}} \alpha(2) & \sigma_{1 \mathrm{~s}} \beta(2)
\end{array}\right| \tag{3.2.26}
\end{align*}
$$

Clearly, this is a spin singlet state.
Similarly, the excited configuration $\sigma_{1 \mathrm{~s}}^{* 2}$ has the wavefunction

$$
\begin{align*}
\psi_{2}\left(\sigma_{1 \mathrm{~s}}^{* 2}\right) & =\left[1 \mathrm{~s}_{a}(1)-1 \mathrm{~s}_{b}(1)\right]\left[1 \mathrm{~s}_{a}(2)-1 \mathrm{~s}_{b}(2)\right][\alpha(1) \beta(2)-\beta(1) \alpha(2)] \\
& =\left|\begin{array}{ll}
\sigma_{1 s}^{*} \alpha(1) & \sigma_{1 s}^{*} \beta(1) \\
\sigma_{1 \mathrm{~s}}^{*} \alpha(2) & \sigma_{1 \mathrm{~s}}^{*} \beta(2)
\end{array}\right| \tag{3.2.27}
\end{align*}
$$

This is also a spin singlet state. Furthermore, this is a repulsive state; i.e., it is not a bound state.

For the excited configuration $\sigma_{1 \mathrm{~s}}^{1} \sigma_{1 \mathrm{~s}}^{* 1}$, there are two states, one singlet and one triplet. This situation is similar to that found in the excited configuration $1 \mathrm{~s}^{1} 2 \mathrm{~s}^{1}$ of the helium atom. The singlet and triplet wavefunctions for these excited configurations are:
$\psi_{3}\left(\sigma_{1 \mathrm{~s}}^{1} \sigma_{1 \mathrm{~s}}^{* 1} ; S=0\right)=\left[\sigma_{1 \mathrm{~s}}(1) \sigma_{1 \mathrm{~s}}^{*}(2)+\sigma_{1 \mathrm{~s}}(2) \sigma_{1 \mathrm{~s}}^{*}(1)\right][\alpha(1) \beta(2)-\beta(1) \alpha(2)]$
$\psi_{4}\left(\sigma_{1 \mathrm{~s}}^{1} \sigma_{1 \mathrm{~s}}^{* 1} ; S=1\right)=\left[\sigma_{1 \mathrm{~s}}(1) \sigma_{1 \mathrm{~s}}^{*}(2)-\sigma_{1 \mathrm{~s}}(2) \sigma_{1 \mathrm{~s}}^{*}(1)\right]\left\{\begin{array}{c}{[\alpha(1) \beta(2)+\beta(1) \alpha(2)]} \\ \alpha(1) \alpha(2) . \\ \beta(1) \beta(2)\end{array}\right.$

On the other hand, the (un-normalized) ground ( $\psi_{+}$) and excited ( $\psi_{-}$) state valence bond wavefunctions are

$$
\begin{align*}
& \psi_{+}=1 \mathrm{~s}_{a}(1) 1 \mathrm{~s}_{b}(2)+1 \mathrm{~s}_{b}(1) 1 \mathrm{~s}_{a}(2)  \tag{3.2.30}\\
& \psi_{-}=1 \mathrm{~s}_{a}(1) 1 \mathrm{~s}_{b}(2)-1 \mathrm{~s}_{b}(1) 1 \mathrm{~s}_{a}(2) \tag{3.2.31}
\end{align*}
$$

## Fundamentals of Bonding Theory

Expanding the wavefunction in eq. (3.2.25), we get

$$
\begin{align*}
\psi_{1}\left(\sigma_{1 \mathrm{~s}}^{2}\right) & =\left[1 \mathrm{~s}_{a}(1) 1 \mathrm{~s}_{b}(2)+1 \mathrm{~s}_{b}(1) 1 \mathrm{~s}_{a}(2)\right]+\left[1 \mathrm{~s}_{a}(1) 1 \mathrm{~s}_{a}(2)+1 \mathrm{~s}_{b}(1) 1 \mathrm{~s}_{b}(2)\right] \\
& =\psi_{+}+\psi_{\mathrm{i}}, \tag{3.2.32}
\end{align*}
$$

where

$$
\begin{equation*}
\psi_{\mathrm{i}}=1 \mathrm{~s}_{a}(1) 1 \mathrm{~s}_{a}(2)+1 \mathrm{~s}_{b}(1) 1 \mathrm{~s}_{b}(2) \tag{3.2.33}
\end{equation*}
$$

Wavefunction $\psi_{\mathrm{i}}$ refers to the situation where both electrons are on nucleus $a$ or nucleus $b$, i.e., ionic structures. Now it is obvious that the valence bond wavefunction $\psi_{+}$considers only covalent structure, while the molecular orbital wavefunction $\psi_{1}$ has an equal mixture of covalent and ionic contributions. Similarly, expanding the wavefunction in eq. (3.2.27) yields

$$
\begin{align*}
\psi_{2}\left(\sigma_{1 \mathrm{~s}}^{* 2}\right) & =-\left[1 \mathrm{~s}_{a}(1) 1 \mathrm{~s}_{b}(2)+1 \mathrm{~s}_{b}(1) 1 \mathrm{~s}_{a}(2)\right]+\left[1 \mathrm{~s}_{a}(1) 1 \mathrm{~s}_{a}(2)+1 \mathrm{~s}_{b}(1) 1 \mathrm{~s}_{b}(2)\right] \\
& =-\psi_{+}+\psi_{\mathrm{i}} \tag{3.2.34}
\end{align*}
$$

So the wavefunction for the excited configuration $\sigma_{1 \mathrm{~s}}^{* 2}$ is also an equal mixture of covalent and ionic parts, except now that the linear combination coefficients have different signs.

Solving eqs. (3.2.32) and (3.2.34) for $\psi_{+}$, we get

$$
\begin{equation*}
\psi_{+}=\psi_{1}-\psi_{2} \tag{3.2.35}
\end{equation*}
$$

So, put another way, the valence bond wavefunctions for the ground state of $\mathrm{H}_{2}$ has equal contributions from configurations $\sigma_{1 \mathrm{~s}}^{2}$ and $\sigma_{1 \mathrm{~s}}^{* 2}$, and the combination coefficients have different signs. Such a wavefunction, which employs a mixture of configurations to describe the electronic state of an atom or molecule, is called a configuration interaction (CI) wavefunction.

It is obvious that the deficiency of $\psi_{+}$is that it does not take ionic contributions ( $\psi_{\mathrm{i}}$ ) into account. Conversely, $\psi_{1}$ suffers from too much (50\%) contribution from the ionic structures. To get the wavefunction with optimal ionic contribution, we set

$$
\begin{equation*}
\psi_{+}^{\prime}=c_{+} \psi_{+}+c_{\mathrm{i}} \psi_{\mathrm{i}} \tag{3.2.36}
\end{equation*}
$$

where coefficient $c_{+}$and $c_{\mathrm{i}}$ are to be determined through the following $2 \times 2$ secular determinant and the associated secular equations:

$$
\begin{align*}
& \left|\begin{array}{cc}
H_{++}-E S_{++} & H_{+\mathrm{i}}-E S_{+\mathrm{i}} \\
H_{+\mathrm{i}}-E S_{+\mathrm{i}} & H_{\mathrm{ii}}-E S_{\mathrm{ii}}
\end{array}\right|=0  \tag{3.2.37}\\
& \left\{\begin{array}{c}
\left(H_{++}-E S_{++}\right) c_{+}+\left(H_{+\mathrm{i}}-E S_{+\mathrm{i}}\right) c_{\mathrm{i}}=0 \\
\left(H_{+\mathrm{i}}-E S_{+\mathrm{i}}\right) c_{+}+\left(H_{\mathrm{ii}}-E S_{\mathrm{ii}}\right) c_{\mathrm{i}}=0
\end{array}\right. \tag{3.2.38}
\end{align*}
$$

The result of this optimization process is $c_{\mathrm{i}} / c_{+}=0.16$. In other words, the optimal wavefunction has ionic and covalent contributions in the ratio of about 1:6. Such a dominance of covalent character is expected for a molecule such as $\mathrm{H}_{2}$.

Table 3.2.1. Optimized dissociation energies and equilibrium bond lengths from trial wavefunctions for $\mathrm{H}_{2}$ with adjustable parameters

| Trial wavefunction | $D_{\mathrm{e}}\left(\mathrm{kJ} \mathrm{mol}^{-1}\right)$ | $r_{\mathrm{e}}(\mathrm{pm})$ |
| :---: | :---: | :---: |
| $\left[1 \mathrm{~s}_{a}(1)+1 \mathrm{~s}_{b}(1)\right]\left[1 \mathrm{~s}_{a}(2)+1 \mathrm{~s}_{b}(2)\right]$, eq. (3.2.1); $Z=1$ | 260.0 | 85.2 |
| $\left[1 \mathrm{~s}_{a}(1)+1 \mathrm{~s}_{b}(1)\right]\left[1 \mathrm{~s}_{a}(2)+1 \mathrm{~s}_{b}(2)\right]$, eq. (3.2.1); $Z_{\text {eff }}=1.197$ | 336.5 | 73.0 |
| $1 \mathrm{~s}_{a}(1) 1 \mathrm{~s}_{b}(2)+1 \mathrm{~s}_{b}(1) 1 \mathrm{~s}_{a}(2)$, eq. (3.2.30); $Z=1$ | 304.5 | 86.8 |
| $1 \mathrm{~s}_{a}(1) 1 \mathrm{~s}_{b}(2)+1 \mathrm{~s}_{b}(1) 1 \mathrm{~s}_{a}(2)$, eq. (3.2.30); $Z_{\text {eff }}=1.166$ | 364.9 | 74.6 |
| $\begin{aligned} & c\left[1 \mathrm{~s}_{a}(1) 1 \mathrm{~s}_{b}(2)+1 \mathrm{~s}_{b}(1) 1 \mathrm{~s}_{a}(2)\right]+\left[1 \mathrm{~s}_{a}(1) 1 \mathrm{~s}_{a}(2)+1 \mathrm{~s}_{b}(1) 1 \mathrm{~s}_{b}(2)\right], \\ & \text { eqs. }(3.2 .30),(3.2 .33) \text {, and (3.2.36); } Z=1 \text { and } c=6.322 \end{aligned}$ | 311.6 | 88.4 |
| $\begin{gathered} c\left[1 \mathrm{~s}_{a}(1) 1 \mathrm{~s}_{b}(2)+1 \mathrm{~s}_{b}(1) 1 \mathrm{~s}_{a}(2)\right]+\left[1 \mathrm{~s}_{a}(1) 1 \mathrm{~s}_{a}(2)+1 \mathrm{~s}_{b}(1) 1 \mathrm{~s}_{b}(2)\right], \\ \text { eqs. }(3.2 .30),(3.2 .33) \text {, and }(3.2 .36) ; Z_{\text {eff }}=1.194 \text { and } c=3.78 \end{gathered}$ | 388.4 | 75.6 |
| $\phi_{a}(1) \phi_{b}(2)+\phi_{b}(1) \phi_{a}(2), \phi=1 \mathrm{~s}+\lambda 2 p_{z}$ (a "polarized" atomic function); $Z_{\text {eff }}(1 \mathrm{~s})=Z_{\text {eff }}(2 \mathrm{p})=1.190, \lambda=0.105$ | 389.8 | 74.9 |
| $\begin{gathered} c\left[\phi_{a}(1) \phi_{b}(2)+\phi_{b}(1) \phi_{a}(2)\right]+\left[1 \mathrm{~s}_{a}(1) 1 \mathrm{~s}_{a}(2)+1 \mathrm{~s}_{b}(1) 1 \mathrm{~s}_{b}(2)\right] \\ \quad \phi=1 \mathrm{~s}+\lambda 2 \mathrm{p}_{z} ; Z_{\mathrm{eff}}(1 \mathrm{~s})=Z_{\mathrm{eff}}(2 \mathrm{p})=1.190, c=5.7, \lambda=0.07 \end{gathered}$ | 397.7 | 74.6 |
| Four-parameter function by Hirschfelder and Linnett (1950) | 410.1 | 76.2 |
| Thirteen-term function by James and Coolidge (1933) | 455.7 | 74.1 |
| One hundred-term function by Kołos and Wolniewicz (1968) | 458.1 | 74.1 |
| Experimental | 458.1 | 74.1 |

Similarly, we can also improve $\psi_{1}$ by mixing in an optimal amount of $\psi_{2}$ :

$$
\begin{equation*}
\psi_{1}^{\prime}=c_{1} \psi_{1}+c_{2} \psi_{2} \tag{3.2.39}
\end{equation*}
$$

The optimal $c_{2} / c_{1}$ ratio is -0.73 . More importantly, the improved valence bond wavefunction $\psi_{+}^{\prime}$ and the improved molecular orbital wavefunction $\psi_{1}^{\prime}$ are one and the same, thus showing these two approaches can lead to identical quantitative results.

Table 3.2.1 summarizes the results of various approximate wavefunctions for the hydrogen molecule. This list is by no means complete, but it does show that, as the level of sophistication of the trial function increases, the calculated dissociation energy and bond distance approach closer to the experimental values. In 1968, W. Kołos and L. Wolniewicz used a 100 -term function to obtain results essentially identical to the experimental data. So the variational treatment of the hydrogen molecule is now a closed topic.

### 3.3 Diatomic molecules

After the treatments of $\mathrm{H}_{2}^{+}$and $\mathrm{H}_{2}$, we are ready to take on other diatomic molecules. Before we do that, we first state two criteria governing the formation of molecular orbitals:
(1) For two atomic orbitals $\phi_{a}$ and $\phi_{b}$ to form a bonding and antibonding molecular orbitals, $\phi_{a}$ and $\phi_{b}$ must have a non-zero overlap, i.e.,

$$
\begin{equation*}
S_{a b}=\int \phi_{a} \phi_{b} \mathrm{~d} \tau \neq 0 \tag{3.3.1}
\end{equation*}
$$

Furthermore, for $S_{a b} \neq 0, \phi_{a}$ and $\phi_{b}$ must have the same symmetry. In Fig. 3.3.1, we can see that there is net overlap in the left and middle cases,

Fig. 3.3.1.
Non-zero overlap in the two cases shown on the left and in the middle, and zero overlap in the case shown on the right.

while $S_{a b}$ vanishes in the case shown on right. The concept of symmetry will be studied more fully in Chapters 6 and 7, when the topic of group theory is taken up.
(2) The second criterion is the energy factor: for $\phi_{a}$ and $\phi_{b}$ to have significant bonding (and antibonding) effect, they should have similar energies. This is why, in our treatments of $\mathrm{H}_{2}$ and $\mathrm{H}_{2}^{+}$, we are only concerned with the interaction between two 1s orbitals. We ignore the interaction between, say, the 1 s orbital on $\mathrm{H}_{a}$ and the 2s orbital on $\mathrm{H}_{b}$. These two atomic orbitals do have non-zero overlap between them. But these orbitals do not bond (or interact) effectively because they have very different energies.

### 3.3.1 Homonuclear diatomic molecules

Now we proceed to discuss homonuclear diatomics with 2 s and 2 p valence orbitals. Starting from these atomic orbitals, we will make (additive and subtractive) combinations of them to form molecular orbitals. In addition, we also need to know the energy ordering of these molecular orbitals.

We first consider the 2 s orbitals. As in the cases of $\mathrm{H}_{2}^{+}$and $\mathrm{H}_{2}$, the combination of $\left(2 \mathrm{~s}_{a}+2 \mathrm{~s}_{b}\right)$ leads to a concentration of charge between the nuclei. Hence it is a $\sigma$ bonding orbital and is called $\sigma_{\mathrm{s}}$. On the other hand, the $\left(2 \mathrm{~s}_{a}-2 \mathrm{~s}_{b}\right)$ combination has a nodal plane between the nuclei and there is a charge deficiency in this region. Hence this is a $\sigma$ antibonding orbital, which is designated as $\sigma_{\mathrm{s}}^{*}$.

For the 2 p orbitals, there are two types of overlap. We first note that the two $\mathrm{p}_{z}$ orbitals both lie along the internuclear axis (conventionally designated as the $z$ axis), while the $\mathrm{p}_{x}$ and $\mathrm{p}_{y}$ orbitals are perpendicular to this axis. Once again, $2 \mathrm{p}_{z a}+2 \mathrm{p}_{z b}$ leads to a bonding orbital called $\sigma_{z}$, while the combination $2 \mathrm{p}_{z a}-2 \mathrm{p}_{z b}$ is an antibonding molecular orbital called $\sigma_{z}^{*}$. It is seen that these two molecular orbitals also have cylindrical symmetry around the internuclear axis. So both of them are $\sigma$ orbitals.

The overlap between the $2 \mathrm{p}_{x a}$ and $2 \mathrm{p}_{x b}$ orbitals occurs in two regions, which have the same size and shape but carry opposite signs: one above the $y z$ plane and the other below it. As there is no longer cylindrical symmetry around the nuclear axis, the molecular orbital is not a $\sigma$ type. Rather, it is called a $\pi_{x}$ orbital, which is characterized by a change in sign across the $y z$ plane (a nodal plane). In an analogous manner, the combination $2 \mathrm{p}_{x a}-2 \mathrm{p}_{x b}$ leads to the antibonding $\pi_{x}^{*}$ orbital, which is composed of four lobes of alternating signs partitioned by two nodal planes. Similarly, there are the corresponding bonding $\pi_{y}\left(2 \mathrm{p}_{y a}+2 \mathrm{p}_{y b}\right)$ and antibonding $\pi_{y}^{*}\left(2 \mathrm{p}_{y a}-2 \mathrm{p}_{y b}\right)$ molecular orbitals.

Before we proceed to discuss the energy order of these molecular orbitals, it is important to note that the $2 \mathrm{p}_{x}$ orbital on atom $a$ has zero overlap with either $2 \mathrm{p}_{y}$ or $2 \mathrm{p}_{z}$ on atom $b$; in other words, the pair of orbitals do not have compatible symmetry. Therefore, among the six 2 p orbitals on the two atoms, $2 \mathrm{p}_{x a}$ interacts only with $2 \mathrm{p}_{x b}, 2 \mathrm{p}_{y a}$ with $2 \mathrm{p}_{y b}$, and $2 \mathrm{p}_{z a}$ with $2 \mathrm{p}_{z b}$. Furthermore, the $\pi_{x}$ and $\pi_{y}$ orbitals have the same energy; i.e., they are doubly degenerate. Similarly, the $\pi_{x}^{*}$ and $\pi_{y}^{*}$ orbitals compose another degenerate set at a higher energy.

To summarize briefly at this point: referring to Fig. 3.3.2, we have started with eight atomic orbitals (one 2 s and three 2 p orbitals on each atom) and have constructed eight molecular orbitals, $\sigma_{2 \mathrm{~s}}, \sigma_{2 \mathrm{~s}}^{*}, \sigma_{z}, \sigma_{z}^{*}, \pi_{x}, \pi_{x}^{*}, \pi_{y}$, and $\pi_{y}^{*}$. The relative energies of these molecular orbitals can be determined from experiments such as spectroscopic measurements or from calculations. For homonuclear diatomics, there are two energy level schemes, as shown in Fig. 3.3.2.

In each scheme, the eight molecular orbitals form six energy levels and can accommodate up to 16 electrons. The scheme on the right is applicable to atoms whose $2 s-2 p$ energy difference is small, while the scheme on the left is for atoms with a large $2 s-2 p$ energy gap. (Recall, from Fig. 3.3.1, s orbitals can overlap with p orbitals to form $\sigma$ molecular orbitals. Whether this interaction is important depends on the energy difference between the interacting atomic orbitals.)

The experimental $2 \mathrm{~s}-2 \mathrm{p}$ energy differences of the elements of the second period are summarized in Table 3.3.1. It can be readily seen that $O$ and $F$ have the largest $2 \mathrm{~s}-2 \mathrm{p}$ gap. Hence the energy ordering shown on the left side of Fig. 3.3.2 is applicable to $\mathrm{O}_{2}$ and $\mathrm{F}_{2}$. On the other hand, the energy scheme on the right side of Fig. 3.3.2 is applicable for $\mathrm{Li}_{2}, \mathrm{Be}_{2}, \mathrm{~B}_{2}, \mathrm{C}_{2}$, and $\mathrm{N}_{2}$. Furthermore, the only difference between the two scheme is the relative ordering of the $\sigma_{z}$ and

Fig. 3.3.2.
The shapes and energy ordering of the molecular orbitals for homonuclear diatomic molecules. The scheme on the left is applicable to $\mathrm{O}_{2}$ and $\mathrm{F}_{2}$, while that on the right is applicable to other diatomics of the same period.

Table 3.3.1. The $2 \mathrm{~s}-2 \mathrm{p}$ energy gap of the second-row elements

| Element | Li | Be | B | C | N | O | F |
| :--- | :---: | :---: | ---: | ---: | ---: | :---: | :---: |
| $-E_{2 \mathrm{~s}}(\mathrm{eV})$ | 5.39 | 9.32 | 12.9 | 16.6 | 20.3 | 28.5 | 37.8 |
| $-E_{2 \mathrm{p}}(\mathrm{eV})$ | 3.54 | 6.59 | 8.3 | 11.3 | 14.5 | 13.6 | 17.4 |
| $E_{2 \mathrm{p}}-E_{2 \mathrm{~s}}(\mathrm{eV})$ | 1.85 | 2.73 | 4.6 | 5.3 | 5.8 | 14.9 | 20.4 |

degenerate $\left(\pi_{x}, \pi_{y}\right)$ levels. For $\mathrm{O}_{2}$ and $\mathrm{F}_{2}$, there is no significant $\mathrm{s}-\mathrm{p}$ mixing, due to the larger $2 \mathrm{~s}-2$ p energy gaps of O and F . On the other hand, for the remaining homonuclear diatomics of the same period, through s-p mixing, the molecular orbitals are no longer called $\sigma_{\mathrm{s}}, \sigma_{\mathrm{s}}^{*}, \sigma_{z}, \sigma_{z}^{*}$, etc. Instead they are now called $\sigma_{\mathrm{g}}$, $\sigma_{\mathrm{u}}$, etc., where g indicates centrosymmetry and u indicates antisymmetry with respect to the molecular center.

Table 3.3.2. Electronic configurations and structural parameters of homonuclear diatomic molecules of the second period

| $\mathrm{X}_{2}$ | Electronic configuration | Bond length (pm) | Bonding energy ( $\mathrm{kJ} \mathrm{mol}^{-1}$ ) | Bond order |
| :---: | :---: | :---: | :---: | :---: |
| $\mathrm{Li}_{2}$ | $1 \sigma_{\mathrm{g}}^{2}$ | 267.2 | 110.0 | 1 |
| $\mathrm{Be}_{2}$ | $1 \sigma_{\mathrm{g}}^{2} 1 \sigma_{\mathrm{u}}^{2}$ | - | - | 0 |
| $\mathrm{B}_{2}$ | $1 \sigma_{\mathrm{g}}^{2} 1 \sigma_{\mathrm{u}}^{2} 1 \pi_{\mathrm{u}}^{2}$ | 158.9 | 274.1 | 1 |
| $\mathrm{C}_{2}$ | $1 \sigma_{\mathrm{g}}^{2} 1 \sigma_{\mathrm{u}}^{2} 1 \pi_{\mathrm{u}}^{4}$ | 124.25 | 602 | 2 |
| $\mathrm{C}_{2}^{2-}$ | $1 \sigma_{\mathrm{g}}^{2} 1 \sigma_{\mathrm{u}}^{2} 1 \pi_{\mathrm{u}}^{4} 2 \sigma_{\mathrm{g}}^{2}$ | 120 | - | 3 |
| $\mathrm{N}_{2}$ | $1 \sigma_{\mathrm{g}}^{2} 1 \sigma_{\mathrm{u}}^{2} 1 \pi_{\mathrm{u}}^{4} 2 \sigma_{\mathrm{g}}^{2}$ | 109.76 | 941.69 | 3 |
| $\mathrm{N}_{2}^{+}$ | $1 \sigma_{\mathrm{g}}^{2} 1 \sigma_{\mathrm{u}}^{2} 1 \pi_{\mathrm{u}}^{4} 2 \sigma_{\mathrm{g}}^{1}$ | 111.6 | 842.15 | $2^{1 / 2}$ |
| $\mathrm{N}_{2}^{2-}$ | $\sigma_{\mathrm{s}}^{2} \sigma_{\mathrm{s}}^{* 2} \sigma_{z}^{2} \pi_{x}^{2} \pi_{y}^{2} \pi_{x}^{* 1} \pi_{y}^{* 1}$ | 122.4 | - | 2 |
| $\mathrm{O}_{2}$ | $\sigma_{\mathrm{s}}^{2} \sigma_{\mathrm{s}}^{* 2} \sigma_{z}^{2} \pi_{x}^{2} \pi_{y}^{2} \pi_{x}^{* 1} \pi_{y}^{* 1}$ | 120.74 | 493.54 | 2 |
| $\mathrm{O}_{2}^{+}$ | $\sigma_{\mathrm{s}}^{2} \sigma_{\mathrm{s}}^{* 2} \sigma_{z}^{2} \pi_{x}^{2} \pi_{y}^{2} \pi_{x}^{* 1}$ | 112.27 | 626 | $2^{1 / 2}$ |
| $\mathrm{O}_{2}^{-}$ | $\sigma_{\mathrm{s}}^{2} \sigma_{\mathrm{s}}^{* 2} \sigma_{z}^{2} \pi_{x}^{2} \pi_{y}^{2} \pi_{x}^{* 2} \pi_{y}^{* 1}$ | 126 | 392.9 | $1^{1 / 2}$ |
| $\mathrm{O}_{2}^{2-}$ | $\sigma_{\mathrm{s}}^{2} \sigma_{\mathrm{s}}^{* 2} \sigma_{z}^{2} \pi_{x}^{2} \pi_{y}^{2} \pi_{x}^{* 2} \pi_{y}^{* 2}$ | 149 | 138 | 1 |
| $\mathrm{F}_{2}$ | $\sigma_{\mathrm{s}}^{2} \sigma_{\mathrm{s}}^{* 2} \sigma_{z}^{2} \pi_{x}^{2} \pi_{y}^{2} \pi_{x}^{* 2} \pi_{y}^{* 2}$ | 141.7 | 155 | 1 |

Table 3.3.2 summarizes the various properties of second-row homonuclear diatomic molecules. In the last column of the table, we list the "bond order" between atoms A and B in the molecule AB. Simply put, the bond order is a number that gives an indication of its strength relative to that of a two-electron single bond. Thus the bond order of $\mathrm{H}_{2}^{+}\left(\sigma_{1 \mathrm{~s}}^{1}\right)$ is $1 / 2$, while that of $\mathrm{H}_{2}\left(\sigma_{1 \mathrm{~s}}^{2}\right)$ is 1 . For a system with antibonding electrons, we take the simplistic view that one antibonding electron "cancels out" one bonding electron. Thus the bond orders in $\mathrm{He}_{2}^{+}\left(\sigma_{1 \mathrm{~s}}^{2} \sigma_{1 \mathrm{~s}}^{* 1}\right)$ and $\mathrm{He}_{2}\left(\sigma_{1 \mathrm{~s}}^{2} \sigma_{1 \mathrm{~s}}^{* 2}\right)$ are $1 / 2$ and 0 , respectively, and helium is not expected to form a diatomic molecule.

Some interesting points are noted from the results given in Table 3.3.2:
(1) The bond in $\mathrm{Li}_{2}$ is longer and weaker than that in $\mathrm{H}_{2}\left(74 \mathrm{pm} ; 431 \mathrm{~kJ} \mathrm{~mol}^{-1}\right)$. This is because the bond in $\mathrm{Li}_{2}$ is formed by 2 s valence electrons that lie outside filled 1 s atomic orbitals.
(2) The diatomic molecule $\mathrm{Be}_{2}$ is unstable; the ground state is a repulsive state. As in $\mathrm{He}_{2}$, the stabilization gained by the bonding electrons is more than offset by the destabilizing antibonding electrons.
(3) The bond in $\mathrm{B}_{2}$ is stronger than that in $\mathrm{Li}_{2}$ because B has a smaller atomic radius than Li . Also, $\mathrm{B}_{2}$ has two unpaired electrons in the $1 \pi_{\mathrm{u}}$ orbital and is hence a paramagnetic species.
(4) The bond length and bond energy in $\mathrm{C}_{2}$ are compatible with the double bond predicted by molecular orbital theory. It is noted that the $2 \sigma_{\mathrm{g}}$ orbital is only slightly higher in energy than $1 \pi_{\mathrm{u}}$. Indeed, $\mathrm{C}_{2}$ absorbs light in the visible region at $19,300 \mathrm{~cm}^{-1}$. This corresponds to exciting an electron from the $1 \pi_{\mathrm{u}}$ molecular orbital to the $2 \sigma_{\mathrm{g}}$ orbital. This is a fairly small excitation energy for a diatomic molecule, since electronic excitations for other diatomics are usually observed in the ultraviolet region.
(5) The bond in $\mathrm{N}_{2}$ is a triple bond, in agreement with the Lewis structure $: \mathrm{N} \equiv \mathrm{N}$ : of this molecule. We now can see that the lone pairs in the Lewis structure correspond to the $1 \sigma_{\mathrm{g}}^{2}$ and $1 \sigma_{\mathrm{u}}^{2}$ electrons; the two pairs of bonding and antibonding electrons result in no net bonding. The three bonds in the Lewis structure correspond to the $1 \pi_{\mathrm{u}}^{4}$ and $2 \sigma_{\mathrm{g}}^{2}$ electrons in molecular orbital theory. The electronic excitation from the $2 \sigma_{\mathrm{g}}$ orbital to $1 \pi_{\mathrm{g}}$ orbital occurs at around $70,000 \mathrm{~cm}^{-1}$ in the vacuum ultraviolet region. The experimental energy ordering of the molecular orbitals for the $\mathrm{N}_{2}$ molecule is shown in Fig. 3.3.3(a). Upon losing one electron to form $\mathrm{N}_{2}^{+}$, there is not much change in bond length, as the electron is from a weakly bonding $2 \sigma_{\mathrm{g}}$ orbital. In a recently determined crystal structure of $\mathrm{SrN}_{2}$, the bond length found for the diazenide anion $\left(\mathrm{N}_{2}^{2-}\right)$ is compatible with the theoretical bond order of 2 .
(6) Molecular orbital theory predicts that $\mathrm{O}_{2}$ is paramagnetic, in agreement with experiment. Note that the Lewis structure of $\mathrm{O}_{2}$ does not indicate that it has two unpaired electrons, even through it does imply the presence of a double bond. In fact, the prediction/confirmation of paramagnetism in $\mathrm{O}_{2}$ was one of the early successes of molecular orbital theory. Also, the ions $\mathrm{O}_{2}^{+}$ (dioxygen cation), $\mathrm{O}_{2}^{-}$(superoxide anion), and $\mathrm{O}_{2}^{2-}$ (peroxide anion) have bond orders $2^{1 / 2}, 1^{1 / 2}$, and 1 , respectively. The experimental energy levels of the molecular orbital for the $\mathrm{O}_{2}$ molecule are shown in Fig . 3.3.3(b).
(7) Fluorine $\mathrm{F}_{2}$, is isoelectronic with $\mathrm{O}_{2}^{2-}$. Hence they have similar bond lengths as well as similar bond energies. Finally, molecular orbital theory

Fig. 3.3.3.
Energy level diagrams for $\mathrm{N}_{2}$ and $\mathrm{O}_{2}$.
predicts that the ground electronic configuration of $\mathrm{Ne}_{2}$ (with two more electrons than $\mathrm{F}_{2}$ ) leads to a repulsive state. So far there is no experimental evidence for the existence of $\mathrm{Ne}_{2}$, in agreement with molecular orbital results.

### 3.3.2 Heteronuclear diatomic molecules

## (1) The hydrogen fluoride molecule

Before discussing heteronuclear diatomic XY , where both X and Y are secondrow atoms, we first take HF as an example for detailed molecular orbital treatment. Since the H 1s orbital (with energy -13.6 eV ) and F $2 \mathrm{p}(-17.4 \mathrm{eV}$ ) have similar energies, while that of $\mathrm{F} 2 \mathrm{~s}(-37.8 \mathrm{eV})$ is much lower, we only need to consider the interaction between H 1s and F 2p orbitals.

If we take the internuclear axis as the $z$ axis, it is clear that the $\mathrm{F} 2 \mathrm{p}_{z}$ and the H 1 s orbital overlap. The bonding orbital (called $\sigma_{z}$ ) is represent by the combination

$$
\begin{equation*}
\sigma_{z}=c_{1}[1 \mathrm{~s}(\mathrm{H})]+c_{2}\left[2 \mathrm{p}_{z}(\mathrm{~F})\right] . \tag{3.3.2}
\end{equation*}
$$

The coefficients $c_{1}$ and $c_{2}$ give the relative contributions of the H 1 s and $\mathrm{F} 2 \mathrm{p}_{z}$ orbitals to the $\sigma_{z}$ orbital. Unlike the case of homonuclear diatomics, these coefficients are no longer equal, since the interacting atomic orbitals have different energies.

As we know, bonding electrons are "pulled" toward the more electronegative atom, which has the more stable valence orbitals. Therefore, in eq. (3.3.2), $c_{2}$ is greater than $c_{1}$; i.e., the $\mathrm{F} 2 \mathrm{p}_{z}$ contributes more than H 1 s to the bonding molecular orbital $\sigma_{z}$. It is always true that the atomic orbital on the more electronegative atom contributes more to the bonding molecular orbital.

The antibonding orbital (called $\sigma_{z}^{*}$ ) between F $2 \mathrm{p}_{z}$ and H 1s orbitals has the form

$$
\begin{equation*}
\sigma_{z}^{*}=c_{3}[1 \mathrm{~s}(\mathrm{H})]-c_{4}\left[2 \mathrm{p}_{z}(\mathrm{~F})\right] . \tag{3.3.3}
\end{equation*}
$$

Since most of the $2 \mathrm{p}_{z}$ orbital on F is "used up" in the formation of $\sigma_{z}$, it is now clear that, in $\sigma_{z}^{*}, c_{3}>c_{4}$. In other words, the atomic orbital on the more electropositive atom always contributes more to the antibonding molecular orbital.

The F $2 \mathrm{p}_{x}$ and $\mathrm{F} 2 \mathrm{p}_{y}$ orbitals are suitable for forming $\pi$ molecular orbitals. However, in the HF molecule, the hydrogen 1s orbital does not have the proper symmetry to overlap with the $\mathrm{F} 2 \mathrm{p}_{x}$ or $\mathrm{F} 2 \mathrm{p}_{y}$ orbital. Thus, the $\mathrm{F} 2 \mathrm{p}_{x}$ and $\mathrm{F} 2 \mathrm{p}_{y}$ orbitals are nonbonding orbitals. By definition, a nonbonding molecular orbital in a diatomic molecule is simply an atomic orbital on one of the atoms; it gains or loses no stability (or energy) and its charge density is localized at the atom where the aforementioned atomic orbital originates.

The energy level diagram for HF is shown in Fig. 3.3.4. By the dotted lines, we can see that $\sigma_{z}$ is formed by the H 1 s and F 2 p ( $2 \mathrm{p}_{z}$ in this case) orbitals. Since the energy of $\sigma_{z}$ is closer to that of F 2 p than that of H 1 s , it is clear the F 2 p orbital contributes more to the $\sigma_{z}$ orbital. On the other hand, the H

Fig. 3.3.4.
Energy level diagram of HF.

1 s contributes more to the $\sigma_{z}^{*}$ orbital. Also, the degenerate nonbonding $\pi_{x}^{n}$ and $\pi_{y}^{n}$ orbitals are formed solely by $\mathrm{F} 2 \mathrm{p}_{x}$ and $\mathrm{F} 2 \mathrm{p}_{y}$ orbitals, respectively, without any energy change.

From the energy level diagram in Fig. 3.3.4, it follows naturally that the ground configuration of HF is $2 \mathrm{~s}^{2} \sigma_{z}^{2}\left(\pi_{x}^{n}=\pi_{y}^{n}\right)^{4}$. Among the four pairs of electron in this molecule, only the pair in $\sigma_{z}$ is shared by H and F , while the other three pairs are localized at $F$. This bonding picture is in total agreement with the Lewis formula:

Since the two electrons in $\sigma_{z}$ are not equally shared by H and F , it would be of interest to determine the charge separation in this molecule. This information is furnished by the experimentally determined dipole moment, $6.06 \times 10^{-30}$ C m, of the molecule. Also, the electrons are closer to F than to H ; i.e., the negative end of the dipole points toward $F$.

The H-F bond length is 91.7 pm . If the lone electron of H is transferred to F , giving rise to the ionic structure $\mathrm{H}^{+} \mathrm{F}^{-}$, the dipole moment would be

$$
\left(91.7 \times 10^{-12} \mathrm{~m}\right) \times\left(1.60 \times 10^{-19} \mathrm{C}\right)=1.47 \times 10^{-29} \mathrm{C} \mathrm{~m}
$$

Hence we see that the electron of H is only partially transferred to F . The ionic percentage of the HF may be estimated to be

$$
\frac{6.06 \times 10^{-30} \mathrm{C} \mathrm{~m}}{1.47 \times 10^{-29} \mathrm{C} \mathrm{~m}} \times 100 \%=41 \%
$$

## (2) Heteronuclear diatomic molecules of the second-row elements

Now we describe the bonding in a general diatomic molecule XY, where both X and Y are second-row elements and Y is more electronegative than X . The molecular orbital energy level diagram is shown in Fig. 3.3.5. The $\sigma$ and $\pi$ bonding and antibonding orbitals are formed in the same manner as for $\mathrm{X}_{2}$, but the coefficients of the orbitals on Y are larger than those on X for the bonding orbitals, and the converse holds for the antibonding orbitals. In other words, the electrons in bonding orbitals are more likely to be found near the more electronegative atom Y , while the electrons in the antibonding orbitals are more likely to be near the more electropositive atom X. In Fig. 3.3.5, the molecular orbitals no longer carry the subscripts $u$ and $g$, since there is no center of symmetry in XY.

The bonding properties of several representative diatomics are discussed below.
(a) BN (with eight valence electrons): This paramagnetic molecule has the ground configuration of $1 \sigma^{2} 1 \sigma^{* 2} 1 \pi^{3} 2 \sigma^{1}$, with two unpaired electrons. For this system, the $2 \sigma$ orbital energy is higher than that of $1 \pi$ by about the same energy required to pair two electrons. In any event, the bond order is 2. The bond lengths of $\mathrm{C}_{2}$ and BN are 124.4 and 128 pm , respectively. The

Fig. 3.3.5.
Energy level diagram of a heteronuclear diatomic molecule.

Fig. 3.3.6.
Energy level diagrams of CO and NO.

bond energy of BN is $385 \mathrm{~kJ} \mathrm{~mol}^{-1}$, suspiciously low compared with 602 $\mathrm{kJ} \mathrm{mol}^{-1}$ for $\mathrm{C}_{2}$. Clearly more experimental work is required in this case.
(b) $\mathrm{BO}, \mathrm{CN}$, and $\mathrm{CO}^{+}$(with nine valence electrons): The electronic configuration for these molecules is $1 \sigma^{2} 1 \sigma^{* 2} 1 \pi^{4} 2 \sigma^{1}$, with bond order $2^{1 / 2}$. They all have bond lengths shorter than $\mathrm{BN}\left(\right.$ or $\mathrm{C}_{2}$ ), 120 pm for $\mathrm{BO}, 117 \mathrm{pm}$ for CN , and 112 pm for $\mathrm{CO}^{+}$. Also, they have fairly similar bond energies: 800, 787 , and $805 \mathrm{~kJ} \mathrm{~mol}^{-1}$ for $\mathrm{BO}, \mathrm{CN}$, and $\mathrm{CO}^{+}$, respectively, all of which are greater than that of $\mathrm{C}_{2}$.
(c) $\mathrm{NO}^{+}, \mathrm{CO}$, and $\mathrm{CN}^{-}$(with ten valence electrons): Here the electronic configuration is $1 \sigma^{2} 1 \sigma^{* 2} 1 \pi^{4} 2 \sigma^{2}$, with a bond order of 3 . They have similar bond lengths: 106,113 , and 114 pm for $\mathrm{NO}^{+}, \mathrm{CO}$, and $\mathrm{CN}^{-}$, respectively. The bond energy of carbon monoxide $\left(1070 \mathrm{~kJ} \mathrm{~mol}^{-1}\right)$ is slightly greater than that of $\mathrm{N}_{2}\left(941 \mathrm{~kJ} \mathrm{~mol}^{-1}\right)$. The energy level diagram for CO is shown in Fig. 3.3.6(a).
(d) NO (with eleven valence electrons): The ground electronic configuration is $1 \sigma^{2} 2 \sigma^{* 2} 1 \pi^{4} 2 \sigma_{z}^{2} 1 \pi^{* 1}$ and the bond order is $2^{1 / 2}$. The bond length of NO, 115 pm , is longer than those of both CO and $\mathrm{NO}^{+}$. Its bond dissociation energy, $627.5 \mathrm{~kJ} \mathrm{~mol}^{-1}$, is considerably less than those of CO and $\mathrm{N}_{2}$. The importance of NO in both chemistry and biochemistry will be discussed
in detail in Section 14.2. The energy level diagram for NO is shown in Fig. 3.3.6(b).

### 3.4 Linear triatomic molecules and spn hybridization schemes

In this section, we first discuss the bonding in two linear triatomic molecules: $\mathrm{BeH}_{2}$ with only $\sigma$ bonds and $\mathrm{CO}_{2}$ with both $\sigma$ and $\pi$ bonds. Then we go on to treat other polyatomic molecules with the hybridization theory. Next we discuss the derivation of a self-consistent set of covalent radii for the atoms. Finally, we study the bonding and reactivity of conjugated polyenes by applying Hückel molecular orbital theory.

### 3.4.1 Beryllium hydride, $\mathrm{BeH}_{2}$

The molecular orbitals of this molecule are formed by the 2 s and 2 p orbitals of Be and the 1s orbitals of $\mathrm{H}_{a}$ and $\mathrm{H}_{b}$. Here we take the molecular axis in $\mathrm{BeH}_{2}$ as the $z$ axis, as shown in Fig. 3.4.1.

To form the molecular orbitals for polyatomic molecules $\mathrm{AX}_{n}$, we first carry out linear combinations of the orbitals on X and then match them, taking into account their symmetry characteristics, with the atomic orbitals on the central atom A .

For our simple example of $\mathrm{BeH}_{2}$, the valence orbitals on $\mathrm{H}_{a}$ and $\mathrm{H}_{b}, 1 \mathrm{~s}_{a}$ and $1 \mathrm{~s}_{b}$, can form only two linear (and independent) combinations: $1 \mathrm{~s}_{a}+1 \mathrm{~s}_{b}$ and $1 \mathrm{~s}_{a}-1 \mathrm{~s}_{b}$. We can see that combination $1 \mathrm{~s}_{a}+1 \mathrm{~s}_{b}$ matches in symmetry with the Be 2s orbital. Hence they can form both bonding and antibonding molecular orbitals:

$$
\begin{align*}
& \sigma_{\mathrm{s}}=c_{1} 2 \mathrm{~s}(\mathrm{Be})+c_{2}\left(1 \mathrm{~s}_{a}+1 \mathrm{~s}_{b}\right),  \tag{3.4.1}\\
& c_{2}>c_{1}  \tag{3.4.2}\\
& \sigma_{\mathrm{s}}^{*}=c_{1}^{\prime} 2 \mathrm{~s}(\mathrm{Be})-c_{2}^{\prime}\left(1 \mathrm{~s}_{a}+1 \mathrm{~s}_{b}\right),
\end{align*} \quad c_{1}^{\prime}>c_{2}^{\prime} .
$$

The relative magnitudes of coefficients $c_{1}$ and $c_{2}$, as well as those of $c_{1}^{\prime}$ and $c_{2}^{\prime}$, are determined by the relative electronegatives of the atoms concerned, which are reflected by the relative energies of the atomic orbitals.

Similarly, the combination $1 \mathrm{~s}_{a}-1 \mathrm{~s}_{b}$ has a net overlap with the $2 \mathrm{p}_{z}$ orbital of Be. They form bonding and antibonding molecular orbitals in the following manner:

$$
\begin{array}{cc}
\sigma_{z}=c_{3} 2 \mathrm{p}_{z}(\mathrm{Be})+c_{4}\left(1 \mathrm{~s}_{a}-1 \mathrm{~s}_{b}\right), & c_{4}>c_{3} \\
\sigma_{z}^{*}=c_{3}^{\prime} 2 \mathrm{p}_{z}(\mathrm{Be})-c_{4}^{\prime}\left(1 \mathrm{~s}_{a}-1 \mathrm{~s}_{b}\right), & c_{3}^{\prime}>c_{4}^{\prime} . \tag{3.4.4}
\end{array}
$$

Finally, the $2 \mathrm{p}_{x}$ and $2 \mathrm{p}_{y}$ orbitals on Be are not symmetry-compatible with the $1 \mathrm{~s}_{a}$ or $1 \mathrm{~s}_{b}$ orbitals (or their linear combinations). Hence they are nonbonding orbitals:

$$
\left\{\begin{array}{l}
\pi_{x}^{n}=2 \mathrm{p}_{x}(\mathrm{Be})  \tag{3.4.5}\\
\pi_{y}^{n}=2 \mathrm{p}_{y}(\mathrm{Be})
\end{array}\right.
$$

Fig. 3.4.1.
Coordinate system for $\mathrm{BeH}_{2}$.

Table 3.4.1. Summary of the formation of the molecular orbitals in $\mathrm{BeH}_{2}$

| Orbital on Be | Orbitals on H | Molecular orbitals |
| :--- | :---: | :--- |
| 2 s | $(2)^{-1 / 2}\left(1 \mathrm{~s}_{a}+1 \mathrm{~s}_{b}\right)$ | $\sigma_{\mathrm{s}}, \sigma_{\mathrm{s}}^{*}$ |
| $2 \mathrm{p}_{z}$ | $(2)^{-1 / 2}\left(1 \mathrm{~s}_{a}-1 \mathrm{~s}_{b}\right)$ | $\sigma_{z}, \sigma_{z}^{*}$ |
| $\begin{cases}2 \mathrm{p}_{x} & - \\ 2 \mathrm{p}_{y} & -\end{cases}$ | $\pi_{x}^{n}$ |  |
| $\pi_{y}^{n}$ |  |  |

There are totally six molecular orbitals ( $\sigma_{\mathrm{s}}, \sigma_{\mathrm{s}}^{*}, \sigma_{z}, \sigma_{z}^{*}, \pi_{x}^{n}$, and $\pi_{y}^{n}$ ) formed by the six atomic orbitals ( 2 s and 2 p orbitals on Be and 1 s orbitals on the hydrogens). Note that the $\sigma$ molecular orbitals have cylindrical symmetry around the molecular axis, while the nonbonding $\pi$ orbitals do not. Another important characteristic of these orbitals is that they are "delocalized" in nature. For example, an electron occupying the $\sigma_{\mathrm{s}}$ orbital has its density spread over all three atoms. Table 3.4.1 summarizes the way the molecular orbitals of $\mathrm{BeH}_{2}$ are formed by the atomic orbitals on Be and H , where the linear combinations of H orbitals are normalized.

The energy level diagram for $\mathrm{BeH}_{2}$, shown in Fig. 3.4.2, is constructed as follows. The 2 s and 2 p of Be are shown on the left of the diagram, while the 1 s orbitals of the hydrogens are shown on the right. Note that the H 1 s orbitals are placed lower than either the Be 2 p or Be 2 s orbitals. This is because Be is more electropositive than H . The molecular orbitals-bonding, antibonding, and nonbonding-are placed in the middle of the diagram. As usual, the bonding orbitals have lower energy than the constituent atomic orbitals, and correspondingly the antibonding orbitals are of higher energy. The nonbonding orbitals have the same energy as their parent atomic orbitals. After constructing the energy level diagram, we place the four valence electrons of $\mathrm{BeH}_{2}$ in the two lowest molecular orbitals, leading to a ground electronic configuration of $\sigma_{\mathrm{s}}^{2} \sigma_{z}^{2}$. In this description, the two electron-pair bonds are spread over all these atoms. The delocalization of electrons is an important feature of the molecular orbital model.

Concluding the molecular orbital treatment of $\mathrm{BeH}_{2}$, we can see that the two (filled) bonding molecular orbitals $\sigma_{\mathrm{s}}$ and $\sigma_{z}$ have different shapes and different energies. This is contrary to our intuition for $\mathrm{BeH}_{2}$ : we expect the two bonds in $\mathrm{BeH}_{2}$ to be identical (in shape as well as in stability) to each other. In any event, this is the picture provided by the molecular orbital model.

### 3.4.2 Hybridization scheme for linear triatomic molecules

If we prefer to describe the bonding of a polyatomic molecule using localized two-center, two-electron ( $2 c-2 e$ ) bonds, we can turn to the hybridization theory, which is an integral part of the valence bond method. In this model, for $\mathrm{AX}_{n}$ systems, we linearly combine the atomic orbitals on atom A in such a way that the resultant combinations (called hybrid orbitals) point toward the X atoms. For our $\mathrm{BeH}_{2}$ molecule in hand, two equivalent, colinear hybrid orbitals are constructed from the 2 s and $2 \mathrm{p}_{z}$ orbitals on Be , which can overlap with the two 1 s hydrogen orbitals to form two $\mathrm{Be}-\mathrm{H}$ single bonds. (The $2 \mathrm{p}_{x}$ and $2 \mathrm{p}_{y}$
(a)

(b)

(c)

orbitals do not take part in the hybridization scheme, otherwise the resultant hybrid orbitals would not point directly at the hydrogens.) If we combine the 2 s and $2 \mathrm{p}_{z}$ orbitals in the following manner:

$$
\begin{align*}
& h_{1}=(2)^{-1 / 2}\left(2 \mathrm{~s}+2 \mathrm{p}_{z}\right),  \tag{3.4.6}\\
& h_{2}=(2)^{-1 / 2}\left(2 \mathrm{~s}-2 \mathrm{p}_{z}\right), \tag{3.4.7}
\end{align*}
$$

the hybrid orbitals $h_{1}$ and $h_{2}$ would overlap nicely with the 1s orbitals on $\mathrm{H}_{a}$ and $\mathrm{H}_{b}$, respectively, as shown in Fig. 3.4.3.

The two bonding orbitals in $\mathrm{BeH}_{2}$ have the wavefunctions

$$
\begin{array}{ll}
\psi_{1}=c_{5} h_{1}+c_{6} 1 \mathrm{~s}_{a}, & c_{6}>c_{5} \\
\psi_{2}=c_{5} h_{2}+c_{6} 1 \mathrm{~s}_{b}, & c_{6}>c_{5} . \tag{3.4.9}
\end{array}
$$

So now we have two equivalent bonding orbitals $\psi_{1}$ and $\psi_{2}$ with the same energy. Moreover, $\psi_{1}$ and $\psi_{2}$ are localized orbitals: $\psi_{1}$ is localized between $\operatorname{Be}$ and $\mathrm{H}_{a}$ and $\psi_{2}$ between Be and $\mathrm{H}_{b}$. They are $2 c-2 e$ bonds.

### 3.4.3 Carbon dioxide, $\mathrm{CO}_{2}$

Carbon dioxide is a linear molecule with both $\sigma$ and $\pi$ bonds. The coordinate system chosen for $\mathrm{CO}_{2}$ is shown in Fig. 3.4.4. Once again, the molecular axis is taken to be the $z$ axis. The atomic orbitals taking part in the bonding of this molecule are the 2 s and 2 p orbitals on C and the 2 p orbitals on O . There are a total of ten atomic orbitals and they will form ten molecular orbitals.

The $\sigma$ orbitals in $\mathrm{CO}_{2}$ are very similar to those in $\mathrm{BeH}_{2}$. The only difference is that the oxygens make use of their $2 p_{z}$ orbitals instead of the 1 s orbitals used

## Fig. 3.4.3.

The formation of the two sp hybrid orbitals in $\mathrm{BeH}_{2}[(\mathrm{a})$ and (b)] and the two equivalent bonds in $\mathrm{BeH}_{2}$ (c).

Fig. 3.4.4.
The coordinate system of $\mathrm{CO}_{2}$.

## (a)

(b)

by the hydrogens in $\mathrm{BeH}_{2}$. The $\sigma$ orbitals thus have the wavefunctions

$$
\begin{align*}
\sigma_{\mathrm{s}} & =c_{7} 2 \mathrm{~s}(\mathrm{C})+c_{8}\left[2 \mathrm{p}_{z}(a)+2 \mathrm{p}_{z}(b)\right], & & c_{7}>c_{8}  \tag{3.4.10}\\
\sigma_{\mathrm{s}}^{*} & =c_{7}^{\prime} 2 \mathrm{~s}(\mathrm{C})-c_{8}^{\prime}\left[2 \mathrm{p}_{z}(a)+2 \mathrm{p}_{z}(b)\right], & & c_{8}^{\prime}>c_{7}^{\prime}  \tag{3.4.11}\\
\sigma_{z} & =c_{9} 2 \mathrm{p}_{z}(\mathrm{C})+c_{10}\left[2 \mathrm{p}_{z}(a)+2 \mathrm{p}_{z}(b)\right], & & c_{10}>c_{9}  \tag{3.4.12}\\
\sigma_{z}^{*} & =c_{9}^{\prime} 2 \mathrm{p}_{z}(\mathrm{C})-c_{10}^{\prime}\left[2 \mathrm{p}_{z}(a)+2 \mathrm{p}_{z}(b)\right], & & c_{9}^{\prime}>c_{10}^{\prime} . \tag{3.4.13}
\end{align*}
$$

The $\pi$ molecular orbitals are made up of the $2 \mathrm{p}_{x}$ and $2 \mathrm{p}_{y}$ orbitals of the three atoms. Let's take the $2 \mathrm{p}_{x}$ orbitals first. The two $2 \mathrm{p}_{x}$ orbitals can be combined in two ways:

$$
\begin{align*}
& 2 \mathrm{p}_{x}(a)+2 \mathrm{p}_{x}(b)  \tag{3.4.14}\\
& 2 \mathrm{p}_{x}(a)-2 \mathrm{p}_{x}(b) \tag{3.4.15}
\end{align*}
$$

Combination (3.4.14) overlaps with the $\mathrm{C} 2 \mathrm{p}_{x}$ orbital as shown in Fig. 3.4.5(a). Since, for our linear molecule, the $x$ and $y$ axes are equivalent (and not uniquely defined), we can readily write down the following $\pi$ bonding and antibonding molecular orbitals:

$$
\begin{align*}
\pi_{x}=c_{11} 2 \mathrm{p}_{x}(\mathrm{C})+c_{12}\left[2 \mathrm{p}_{x}(a)+2 \mathrm{p}_{x}(b)\right], & c_{12}>c_{11}  \tag{3.4.16}\\
\pi_{x}^{*}=c_{11}^{\prime} 2 \mathrm{p}_{x}(\mathrm{C})-c_{12}^{\prime}\left[2 \mathrm{p}_{x}(a)+2 \mathrm{p}_{x}(b)\right], & c_{11}^{\prime}>c_{12}^{\prime}  \tag{3.4.17}\\
\pi_{y}=c_{11} 2 \mathrm{p}_{y}(\mathrm{C})+c_{12}\left[2 \mathrm{p}_{y}(a)+2 \mathrm{p}_{y}(b)\right], & c_{12}>c_{11}  \tag{3.4.18}\\
\pi_{y}^{*}=c_{11}^{\prime} 2 \mathrm{p}_{y}(\mathrm{C})-c_{12}^{\prime}\left[2 \mathrm{p}_{x}(a)+2 \mathrm{p}_{x}(b)\right], & c_{11}^{\prime}>c_{12}^{\prime} \tag{3.4.19}
\end{align*}
$$

On the other hand, combination (3.4.15) has zero overlap with the $\mathrm{C} 2 \mathrm{p}_{x}$ orbital [Fig. 3.4.5(b)] and is therefore a nonbonding orbital. Indeed, we have two equivalent nonbonding orbitals:

$$
\begin{align*}
& \pi_{x}^{n}=2 \mathrm{p}_{x}(a)-2 \mathrm{p}_{x}(b)  \tag{3.4.20}\\
& \pi_{y}^{n}=2 \mathrm{p}_{y}(a)-2 \mathrm{p}_{y}(b) . \tag{3.4.21}
\end{align*}
$$

As previously mentioned, ten molecular orbitals are formed. Table 3.4.2 summarizes the formation of the molecular orbitals in $\mathrm{CO}_{2}$, where the linear combinations of O orbitals are normalized. Note that all bonding and antibonding orbitals spread over all three atoms, while the nonbonding orbitals have no participation from C orbitals.

Table 3.4.2. Summary of the formation of the molecular orbitals in $\mathrm{CO}_{2}$

| Orbital on C | Orbitals on $\mathrm{O}^{*}$ | Molecular orbitals |
| :--- | :---: | :---: |
| 2 s | $(2)^{1 / 2}\left(z_{a}+z_{b}\right)$ | $\sigma_{\mathrm{s}}, \sigma_{\mathrm{s}}^{*}$ |
| $2 \mathrm{p}_{z}$ | $(2)^{1 / 2}\left(z_{a}-z_{b}\right)$ | $\sigma_{z}, \sigma_{z}^{*}$ |
| $2 \mathrm{p}_{x}$ | $\left\{\begin{array}{l}(2)^{1 / 2}\left(x_{a}+x_{b}\right) \\ 2 \mathrm{p}_{y}\end{array}\right.$ | $\left\{\begin{array}{l}\pi_{x} / 2 \\ (2)^{1 / 2}\left(y_{a}+y_{b}\right) \\ (2)^{1 / 2}\left(y_{a}-x_{b}\right)\end{array}\right.$ |
| $\pi_{x}^{*}$ |  |  |\(\quad\left\{\begin{array}{l}\pi_{y} \pi_{y}^{*} <br>

\pi_{y}\end{array}\right.\)

* Here $x_{a}$ represents $2 \mathrm{p}_{x}(a)$, Similar abbreviations are also used to designate other orbitals on the oxygen atoms.

The energy level diagram for $\mathrm{CO}_{2}$ is shown in Fig. 3.4.6. Note that the oxygen 2 p orbitals are more stable than their corresponding orbitals on carbon. The 16 valence electrons in $\mathrm{CO}_{2}$ occupy the orbitals as shown in Fig. 3.4.6 and the ground configuration for $\mathrm{CO}_{2}$ is

$$
2 \mathrm{~s}_{a}^{2} 2 \mathrm{~s}_{b}^{2} \sigma_{\mathrm{s}}^{2} \sigma_{z}^{2}\left(\pi_{x}=\pi_{y}\right)^{4}\left(\pi_{x}^{n}=\pi_{y}^{n}\right)^{4} .
$$

So there are two $\sigma$ bonds, two $\pi$ bonds, and four nonbonding electron pairs localized on the oxygen atoms.

In the valence bond or hybridization model for $\mathrm{CO}_{2}$, we have two resonance (or canonical) structures, as shown in Fig. 3.4.7. In both structures, the two $\sigma$ bonds are formed by the sp hybrids on carbon with the $2 \mathrm{p}_{z}$ orbitals on the oxygens. In the left resonance structure, the $\pi$ bonds are formed by the $2 \mathrm{p}_{x}$ orbitals on C and $\mathrm{O}_{a}$ and the $2 \mathrm{p}_{y}$ orbitals on C and $\mathrm{O}_{b}$. In the other structure, the $\pi$ bonds are formed by the $2 \mathrm{p}_{x}$ orbitals on C and $\mathrm{O}_{b}$ and the $2 \mathrm{p}_{y}$ orbitals on C and $\mathrm{O}_{a}$. The "real" structure is a resonance hybrid of these two extremes. In effect, once again, we get two $\sigma$ bonds, two $\pi$ bonds, and four "lone pairs" on the two oxygens. This description is in total agreement with the molecular orbital picture. The only difference is that electron delocalization in $\mathrm{CO}_{2}$ is

Fig. 3.4.6.
Energy level diagram of $\mathrm{CO}_{2}$.

Fig. 3.4.7.
The resonance structures of $\mathrm{CO}_{2}$.

Fig. 3.4.8.
A coordinate system for the $\mathrm{sp}^{2}$ hybrid orbitals.
inherent in the molecular orbital model, whereas description according to the valence-bond hybridization scheme requires the concept of resonance between two canonical structures.

### 3.4.4 The $\mathrm{sp}^{n}(\mathrm{n}=1-3)$ hybrid orbitals

## (1) The sp hybridization scheme

Recalling from Section 3.4.1, we use the s orbital and the $\mathrm{p}_{z}$ orbital to form two equivalent hybrid orbitals, one pointing in the $+z$ direction and the other in the $-z$ direction. These two orbitals are called sp hybrids, since they are formed by one $s$ and one p orbital. The wavefunctions of the sp hybrid orbitals are given by eqs. (3.4.6) and (3.4.7). In matrix form the wavefunction are

$$
\left|\begin{array}{l}
h_{1}  \tag{3.4.22}\\
h_{2}
\end{array}\right|=\left|\begin{array}{rr}
1 /(2)^{1 / 2} & 1 /(2)^{1 / 2} \\
1 /(2)^{1 / 2} & -1 /(2)^{1 / 2}
\end{array}\right|\left|\begin{array}{l}
\mathrm{s} \\
\mathrm{p}_{z}
\end{array}\right|=\left|\begin{array}{ll}
a & b \\
c & d
\end{array}\right|\left|\begin{array}{l}
\mathrm{s} \\
\mathrm{p}_{z}
\end{array}\right|
$$

We now use this $2 \times 2$ coefficient matrix to illustrate the relationships among the coefficients:
(a) Since each atomic orbital is "used up" in the construction of the hybrids, $a^{2}+c^{2}=1$ and $b^{2}+d^{2}=1$
(b) Since each hybrids is normalized, $a^{2}+b^{2}=1$ and $c^{2}+d^{2}=1$.
(c) Since hybrids are orthogonal to each other, $a c+b d=0$.

## (2) The $\mathbf{s p}^{2}$ hybridization scheme

If we use the s orbital and the $\mathrm{p}_{x}$ and $\mathrm{p}_{y}$ orbitals to form three equivalent orbitals $h_{1}, h_{2}$, and $h_{3}$, these orbitals are called $\mathrm{sp}^{2}$ hybrids. Furthermore, they lie in the $x y$ plane and form $120^{\circ}$ angles between them. Now the hybrids have the wavefunctions

$$
\left|\begin{array}{l}
h_{1}  \tag{3.4.23}\\
h_{2} \\
h_{3}
\end{array}\right|=\left|\begin{array}{lll}
a & b & c \\
d & e & f \\
g & j & k
\end{array}\right|\left|\begin{array}{l}
\mathrm{s} \\
\mathrm{p}_{x} \\
\mathrm{p}_{y}
\end{array}\right| .
$$

If the three hybrids have the orientations as shown in Fig. 3.4.8, we then get the following results for the coefficients. Since the s orbital is (equally) split among the three equivalent hybrids,

$$
\begin{gather*}
a^{2}=d^{2}=g^{2}=1 / 3,  \tag{3.4.24}\\
a=d=g=1 /(3)^{1 / 2} \tag{3.4.25}
\end{gather*}
$$

(a) Since $h_{1}$ lies on the $x$ axis, $\mathrm{p}_{y}$ cannot contribute to $h_{1}$,

$$
\begin{equation*}
c=0 . \tag{3.4.26}
\end{equation*}
$$

(b) Relation $a^{2}+b^{2}+c^{2}=1$ leads to

$$
\begin{equation*}
b=\left(\frac{2}{3}\right)^{1 / 2} \tag{3.4.27}
\end{equation*}
$$

(c) Orbital $\mathrm{p}_{x}$ contributes equally to $h_{2}$ and $h_{3}$ and $b^{2}+e^{2}+j^{2}=1$. Hence

$$
\begin{equation*}
e=j=-\left(\frac{1}{6}\right)^{1 / 2} \tag{3.4.28}
\end{equation*}
$$

Note that both $e$ and $j$ are negative because $h_{2}$ and $h_{3}$ project on the $-x$ direction.
(d) Orbital $\mathrm{p}_{y}$ contributes equally to $h_{2}$ and $h_{3}$ (but $f>0$ and $k<0$ ) and $c^{2}+f^{2}+k^{2}=1$. Hence

$$
\begin{align*}
f & =1 /(2)^{1 / 2}  \tag{3.4.29}\\
k & =-1 /(2)^{1 / 2} \tag{3.4.30}
\end{align*}
$$

Collecting all the coefficients, we have

$$
\left|\begin{array}{l}
h_{1}  \tag{3.4.31}\\
h_{2} \\
h_{3}
\end{array}\right|=\left|\begin{array}{ccc}
1 /(3)^{1 / 2} & (2 / 3)^{1 / 2} & 0 \\
1 /(3)^{1 / 2} & -1 /(6)^{1 / 2} & 1 /(2)^{1 / 2} \\
1 /(3)^{1 / 2} & -1 /(6)^{1 / 2} & -1 /(2)^{1 / 2}
\end{array}\right|\left|\begin{array}{c}
\mathrm{s} \\
\mathrm{p}_{x} \\
\mathrm{p}_{y}
\end{array}\right| .
$$

The correctness of these coefficients can be checked in many ways. For example,

$$
\begin{equation*}
a d+b e+c f=\frac{1}{(3)^{1 / 2}} \frac{1}{(3)^{1 / 2}}+\left(\frac{2}{3}\right)^{1 / 2}\left(-\frac{1}{(6)^{1 / 2}}\right)+0\left[-\frac{1}{(2)^{1 / 2}}\right]=0 . \tag{3.4.32}
\end{equation*}
$$

Also, the angle $\theta$ between $h_{2}$ and the $+y$ axis can be calculated:

$$
\begin{equation*}
\theta=\tan ^{-1}\left[(6)^{-1 / 2} /(2)^{-1 / 2}\right]=\tan ^{-1}(3)^{-1 / 2}=30^{\circ} . \tag{3.4.33}
\end{equation*}
$$

To confirm that $h_{1}, h_{2}$, and $h_{3}$ are equivalent to each other, we can calculate their hybridization indices and see that they are identical. The hybridization index $n$ of a hybrid orbital is defined as

$$
\begin{equation*}
m=\frac{\text { total p orbital population }}{\text { total s orbital population }}=\frac{\sum \mid \mathrm{p} \text { orbital coefficients }\left.\right|^{2}}{\mid \mathrm{s} \text { orbital coefficients }\left.\right|^{2}} . \tag{3.4.34}
\end{equation*}
$$

## Fundamentals of Bonding Theory

For $h_{1}, h_{2}$, and $h_{3}$ given in eq. (3.4.31), $n=2$. Hence they are called $\mathrm{sp}^{2}$ hybrids. The two hybrid orbitals in $\mathrm{BeH}_{2}$ [eq. (3.4.22)] have $n=1$. So they are sp hybrids.

A molecule whose bonding can be readily rationalized by the $\mathrm{sp}^{2}$ hybridization scheme is $\mathrm{BF}_{3}$. As indicated by the Lewis formulas shown below, there are three canonical strructures, each with three $\sigma$ bonds, one $\pi$ bond, and eight lone pairs on the F atoms. The three $\sigma$ bonds are formed by the overlap of the $\mathrm{sp}^{2}$ hybrids (formed by $2 \mathrm{~s}, 2 \mathrm{p}_{x}$, and $2 \mathrm{p}_{y}$ ) on B with the $2 \mathrm{p}_{z}$ orbital on each F atom, while the $\pi$ bond is formed by the $2 \mathrm{p}_{z}$ orbital on B and the $2 \mathrm{p}_{x}$ orbital on one of the F atoms. This description is in accord with the experimental FBF bond angles of $120^{\circ}$. Also, it may be concluded that the bond order for the $\mathrm{B}-\mathrm{F}$ bonds in $\mathrm{BF}_{3}$ is $1^{1 / 3}$.

## (3) The $\mathbf{s p}^{3}$ hybridization scheme

Now we take up the construction of the $\mathrm{sp}^{3}$ hybrid orbitals. It is well known that the angle between two $\mathrm{sp}^{3}$ hybrids is about $109^{\circ}$. With the aid of Fig. 3.4.9, this angle can now be calculated exactly:

$$
\theta=\cos ^{-1}\left(-\frac{1}{3}\right) \sim 109^{\circ} 28^{\prime} 16^{\prime \prime}
$$

If the four hybrids $h_{1}, h_{2}, h_{3}$, and $h_{4}$ points to atoms $a, b, c$, and $d$, respectively, as shown in Fig. 3.4.9, it can be readily shown that

$$
\left|\begin{array}{l}
h_{1}  \tag{3.4.35}\\
h_{2} \\
h_{3} \\
h_{4}
\end{array}\right|=\left|\begin{array}{rrrr}
1 / 2 & 1 / 2 & 1 / 2 & 1 / 2 \\
1 / 2 & -1 / 2 & -1 / 2 & 1 / 2 \\
1 / 2 & 1 / 2 & -1 / 2 & -1 / 2 \\
1 / 2 & -1 / 2 & 1 / 2 & -1 / 2
\end{array}\right|\left|\begin{array}{l}
\mathrm{s} \\
\mathrm{p}_{x} \\
\mathrm{p}_{y} \\
\mathrm{p}_{z}
\end{array}\right|
$$

If we adopt the coordinates system in Fig. 3.4.10 for the four $\mathrm{sp}^{3}$ hybrids, we can readily get

$$
\left|\begin{array}{l}
h_{1}  \tag{3.4.36}\\
h_{2} \\
h_{3} \\
h_{4}
\end{array}\right|=\left|\begin{array}{cccc}
1 / 2 & (3 / 2)^{1 / 2} & 0 & 0 \\
1 / 2 & -1 /\left[2(3)^{1 / 2}\right] & 0 & (2 / 3)^{1 / 2} \\
1 / 2 & -1 /\left[2(3)^{1 / 2}\right] & 1 /(2)^{1 / 2} & -1 /(6)^{1 / 2} \\
1 / 2 & -1 /\left[2(3)^{1 / 2}\right] & -1 /(2)^{1 / 2} & -1 /(6)^{1 / 2}
\end{array}\right|\left|\begin{array}{c}
\mathrm{s} \\
\mathrm{p}_{x} \\
\mathrm{p}_{y} \\
\mathrm{p}_{z}
\end{array}\right|
$$

Fig. 3.4.10.
The "original" (1931) Pauling coordinate system for the $\mathrm{sp}^{3}$ hybrids.
Fig. 3.4.9.
The angle formed by two $\mathrm{sp}^{3}$ hybrids.

It can be easily checked that the hybrids given in either eq. (3.4.35) or eq. (3.4.36) are $\mathrm{sp}^{3}$ hybrids; i.e., their hybridization index (population ratio of p orbitals and s orbital) is 3 . The four $\mathrm{sp}^{3}$ hybrids of C are directed toward the corners of a tetrahedron and suitable for forming four localized bonding orbitals with four hydrogen 1 s orbitals. Such a bonding picture for $\mathrm{CH}_{4}$ is familiar to all chemistry students.

Another sp ${ }^{3}$ hybridized system is the sulfate anion $\mathrm{SO}_{4}^{2-}$, in which the four oxygen atoms are also arranged in a tetrahedral manner. However, in addition to the four $\sigma$ bonds, this anion also has two $\pi$ bonds:

It is clear that there are six equivalent resonance structures for $\mathrm{SO}_{4}^{2-}$. Hence the bond order of $\mathrm{S}-\mathrm{O}$ bonds in $\mathrm{SO}_{4}^{2-}$ is $1^{1 / 2}$.

## (4) Inequivalent hybrid orbitals

We conclude this section by discussing systems where there are two types of hybrid orbitals. One such example is $\mathrm{NH}_{3}$, where there are three equivalent bond hybrids and one lone pair hybrid. Another example is the water molecule. As shown in Fig. 3.4.11, hybrids $h_{1}$ and $h_{2}$ are lone pairs orbitals, while hybrids $h_{3}$ and $h_{4}$ are used to form bonding orbitals with hydrogen 1 s orbitals. If we let the coefficient for the s orbital in $h_{1}$ be $(a / 2)^{1 / 2}$, the other coefficients for all hybrids can be expressed in terms of $a$ :

$$
\left.\left|\begin{array}{l}
h_{1}  \tag{3.4.37}\\
h_{2} \\
h_{3} \\
h_{4}
\end{array}\right|=\left|\begin{array}{cccc|}
(a / 2)^{1 / 2} & 1 /(2)^{1 / 2} & {[(1-a) / 2]^{1 / 2}} & 0 \\
(a / 2)^{1 / 2} & -1 /(2)^{1 / 2} & {[(1-a) / 2]^{1 / 2}} & 0 \\
{[(1-a) / 2]^{1 / 2}} & 0 & -(a / 2)^{1 / 2} & 1 /(2)^{1 / 2} \\
{[(1-a) / 2]^{1 / 2}} & 0 & -(a / 2)^{1 / 2} & 1 /(2)^{1 / 2}
\end{array}\right| \begin{array}{|c}
\mathrm{s} \\
\mathrm{p}_{x} \\
\mathrm{p}_{y}
\end{array} \right\rvert\,
$$

Now we can derive a relationship between angles $\alpha$ (formed by $h_{1}$ and $h_{2}$ ) and $\beta$ (formed by $h_{3}$ and $h_{4}$ ):

$$
\begin{align*}
& \cot \left(\frac{\alpha}{2}\right)=\frac{[(1-a) / 2]^{1 / 2}}{(1 / 2)^{1 / 2}}=(1-a)^{1 / 2}  \tag{3.4.38}\\
& \cot \left(\frac{\beta}{2}\right)=\frac{(a / 2)^{1 / 2}}{(1 / 2)^{1 / 2}}=a^{1 / 2} \tag{3.4.39}
\end{align*}
$$

Combining eqs. (3.4.38) and (3.4.39),

$$
\begin{equation*}
\cot ^{2}\left(\frac{\alpha}{2}\right)+\cot ^{2}\left(\frac{\beta}{2}\right)=1 \tag{3.4.40}
\end{equation*}
$$

Fig. 3.4.11.
Hybrids $h_{1}$ and $h_{2}$ are for lone pairs, and $h_{3}$ and $h_{4}$ are for bonded pairs.

For $\mathrm{H}_{2} \mathrm{O},<\mathrm{HOH}=\beta=104.5^{\circ}$. Now we can calculate the angle formed by the two lone pairs:

$$
\begin{equation*}
\alpha=115.4^{\circ} \tag{3.4.41}
\end{equation*}
$$

The angle between lone pairs is larger than that between two bonded pairs, in agreement with the VSEPR (valence-shell electron-pair repulsion) theory.

Now we derive a relationship between the hybridization index of a bonded pair $\left(n_{\mathrm{b}}\right)$ with that of a lone pair $\left(n_{\ell}\right)$ :

$$
\begin{aligned}
n_{\ell} & =n_{1}=n_{2}=\frac{[1 / 2+(1-a) / 2]}{(a / 2)} \\
& =\frac{(2-a)}{a}
\end{aligned}
$$

or

$$
\begin{equation*}
a=\frac{2}{\left(n_{\ell}+1\right)} \tag{3.4.42}
\end{equation*}
$$

or

$$
\begin{equation*}
a=\frac{\left(n_{\mathrm{b}}-1\right)}{\left(n_{\mathrm{b}}+1\right)} \tag{3.4.43}
\end{equation*}
$$

Combining eqs. (3.4.42) and (3.4.43) we can obtain a relationship between $n_{\ell}$ and $n_{\mathrm{b}}$ :

$$
\begin{equation*}
n_{\mathrm{b}}=\frac{\left(n_{\ell}+3\right)}{\left(n_{\ell}-1\right)} \tag{3.4.44}
\end{equation*}
$$

Finally, we relate bond angle $\beta$ with parameter $a$ :

$$
\begin{align*}
\cos \beta & =\cos ^{2}\left(\frac{\beta}{2}\right)-\sin ^{2}\left(\frac{\beta}{2}\right) \\
& =\left[\frac{a}{2} /\left(\frac{1}{2}+\frac{a}{2}\right)\right]-\left[\frac{1}{2} /\left(\frac{1}{2}+\frac{a}{2}\right)\right]=\frac{(a-1)}{(a+1)} \tag{3.4.45}
\end{align*}
$$

With eq. (3.4.43), we get

$$
\begin{equation*}
\cos \beta=-1 / n_{\mathrm{b}}, \text { or } n_{\mathrm{b}}=-\sec \beta \tag{3.4.46}
\end{equation*}
$$

For water, $\beta=104.5^{\circ}, n_{\mathrm{b}}=3.994, n_{\ell}=2.336, a=0.600$.
It should be noted that, in this treatment, it is assumed that bonded hybrids $h_{3}$ and $h_{4}$ point directly at the hydrogens. In other words, the $\mathrm{O}-\mathrm{H}$ bonds are "straight," not "bent."

### 3.4.5 Covalent radii

A covalent bond is formed through the overlap of the atomic orbitals on two atoms. All atoms have their structural characteristics; the bond length and bond energy of a covalent bond between two atoms are manifestations of these characteristics. Based on a large quantity of structural data, it is found that there is a certain amount of constancy for the lengths of the single bonds formed between atoms A and B. This kind of constancy also exists for the lengths of the double bonds and triple bonds formed between the same two atoms. From these structural data chemists arrive at the concept of a covalent radius for each element. It is expected that the length of bond $\mathrm{A}-\mathrm{B}$ is approximately the sum of covalent radii for elements A and B.

The covalent radius of a given element is determined in the following manner. Experimentally, the single bonds formed by the overlap of $\mathrm{sp}^{3}$ hybrids in C (diamond), $\mathrm{Si}, \mathrm{Ge}, \mathrm{Sn}$ (gray tin) have lengths 154, 235, 245, and 281 pm , respectively. Hence the covalent radii for the single bonds of these elements are $77,117,122$, and 140 pm , respectively. From the average length of $\mathrm{C}-\mathrm{O}$ single bonds, the single-bond covalent radius for O can be determined to be 74 pm . Table 3.4.3 lists the covalent radii of the main group elements.

Different authors sometimes give slightly different covalent radii for the same element; this is particularly true for alkali metals and alkali earth metals. Such a variation arises from the following factors:
(a) Atoms A and B have different electronegativities and the bonds they form are polar, having a certain amount of ionic character.
(b) The bond length usually varies with coordination number. It is often that the higher the coordination number, the longer the bonds.
(c) The length of a bond is also influenced by the nature of the neighboring atoms or group.

As pointed out in Sections 14.3.3 and 14.3.4, the length of a $\mathrm{C}-\mathrm{C}$ single bond ranges from 136 to 164 pm . Hence the data given in Table 3.4.3 are for reference

Table 3.4.3. The covalent radii, in picometers (pm), of main group elements

| Single bond | H |  |  |  |  |  |  |  |  |
| :--- | :--- | :--- | :--- | :--- | :--- | :--- | :--- | :--- | :--- |
|  | 37 |  |  |  | B | C | N | O | F |
|  | Li | Be |  |  | 88 | 77 | 74 | 74 | Ne |
|  | 134 | 111 |  |  | Al | Si | P | S | Cl |
|  | Na | Mg |  |  | Ar |  |  |  |  |
|  | 154 | 136 |  |  | 125 | 117 | 110 | 102 | 99 |

only. The bond lengths arising from these covalent radii should not be taken as very accurate structural data.

### 3.5 Hückel molecular orbital theory for conjugated polyenes

In this section, we first study the $\pi$ bonding in conjugated polyenes by means of the Hückel molecular orbital theory. Then we will see how the wavefunctions obtained control the course of the reaction for these molecules.

### 3.5.1 Hückel molecular orbital theory and its application to ethylene and butadiene

A schematic energy level diagram for conjugated polyenes is shown in Fig. 3.5.1. It is obvious that the chemical and physical properties of these compounds are mostly controlled by the orbitals within the dotted lines; i.e., the $\pi$ and $\pi^{*}$ molecular orbitals, as well as the nonbonding orbitals, if there are any. Hence, to study the electronic structure of these systems, as a first approximation, we can ignore the $\sigma$ and $\sigma^{*}$ orbitals and concentrate on the $\pi$ and $\pi^{*}$ orbitals.

In conjugated polyenes, each carbon atom contributes one p orbital and one electron to the $\pi$ bonding of the system, as illustrated in Fig. 3.5.2. So the $\pi$ molecular orbitals have the general form

$$
\begin{align*}
\psi & =\sum c_{i} \phi_{i} \\
& =c_{1} \phi_{1}+c_{2} \phi_{2}+\ldots+c_{n} \phi_{n} \tag{3.5.1}
\end{align*}
$$

The values of the coefficient $c_{i}$ can be determined "variationally"; i.e., they are varied until the total energy reaches a minimum. The energies of the molecular orbitals are obtained by solving for values of $E$ in the secular determinant:

$$
\left|\begin{array}{cccc}
H_{11}-E S_{11} & H_{12}-E S_{12} & \ldots & H_{1 n}-E S_{1 n}  \tag{3.5.2}\\
H_{12}-E S_{12} & H_{22}-E S_{22} & \ldots & H_{2 n}-E S_{2 n} \\
\vdots & \vdots & & \vdots \\
H_{1 n}-E S_{1 n} & H_{2 n}-E S_{2 n} & \ldots & H_{n n}-E S_{n n}
\end{array}\right|=0
$$

Different methods of approximation means different ways of calculating integrals $H_{i j}$ and $S_{i j}$. The Hückel approximation, first proposed by German physicist E. Hückel, is very likely to be simplest:
(1) $S_{i j}=\int \phi_{i} \phi_{j} \mathrm{~d} \tau= \begin{cases}0, & \text { if } i \neq j, \\ 1, & \text { if } i=j .\end{cases}$

That is, there is no overlap between orbitals on different atoms. Note that this drastic approximation violates the basic bonding principle: To form a bond there must an overlap of orbitals.
(2) $H_{i i}=\int \phi_{i} \hat{H} \phi_{i} \mathrm{~d} \tau=\alpha$.
$H_{i i}$ is called the Coulomb integral and is assumed to be the same for each atom. Also, $\alpha<0$.
(3) $H_{i j}=\int \phi_{i} H \phi_{j} \mathrm{~d} \tau=\beta$ if $\phi_{i}$ and $\phi_{j}$ are neighboring atomic orbitals.
$H_{i j}$ is called the resonance integral. Also, $\beta<0$.
(4) $H_{i j}=0$ if $\phi_{i}$ and $\phi_{j}$ are not neighboring atomic orbitals.

In other words, the interaction between non-neighboring orbitals is ignored.
After solving for $E$ ( $n$ of them in all) in eq. (3.5.2), we can then substitute each $E$ in the following secular equations to determine the values of coefficient $c_{i}$ :

$$
\left\{\begin{array}{l}
\left(H_{11}-E S_{11}\right) c_{1}+\left(H_{12}-E S_{12}\right) c_{2}+\ldots+\left(H_{1 n}-E S_{1 n}\right) c_{n}=0  \tag{3.5.3}\\
\left(H_{12}-E S_{12}\right) c_{1}+\left(H_{22}-E S_{22}\right) c_{2}+\ldots+\left(H_{2 n}-E S_{2 n}\right) c_{n}=0 \\
\vdots \quad \vdots \\
\vdots \\
\left(H_{1 n}-E S_{1 n}\right) c_{1}+\left(H_{2 n}-E S_{2 n}\right) c_{2}+\ldots+\left(H_{n n}-E S_{n n}\right) c_{n}=0
\end{array} .\right.
$$

Now we apply this approximation to the $\pi$ system of a few polyenes.

## (1) Ethylene

The two atomic orbitals participating in $\pi$ bonding are shown in Fig. 3.5.3. The secular determinant has the form

$$
\left|\begin{array}{cc}
\alpha-E & \beta  \tag{3.5.4}\\
\beta & \alpha-E
\end{array}\right|=\left|\begin{array}{cc}
x & 1 \\
1 & x
\end{array}\right|=0
$$

with $x=(\alpha-E) / \beta$. Solving eq. (3.5.4) leads to $x= \pm 1$, or

$$
\begin{align*}
& E_{1}=\alpha+\beta=E(\pi)  \tag{3.5.5}\\
& E_{2}=\alpha-\beta=E\left(\pi^{*}\right) \tag{3.5.6}
\end{align*}
$$

Substituting $E_{1}$ and $E_{2}$ into the equations

$$
\left\{\begin{array}{l}
(\alpha-E) c_{1}+\beta c_{2}=0  \tag{3.5.7}\\
\beta c_{1}+(\alpha-E) c_{2}=0
\end{array}\right.
$$

we can obtain the molecular orbital wavefunctions:
When $E=E_{1}$, we have $c_{1}=c_{2}$, or

$$
\begin{equation*}
\psi_{1}=\psi(\pi)=(2)^{-1 / 2}\left(\phi_{1}+\phi_{2}\right) \tag{3.5.8}
\end{equation*}
$$

When $E=E_{2}$, we have $c_{1}=-c_{2}$, or

$$
\begin{equation*}
\psi_{2}=\psi\left(\pi^{*}\right)=(2)^{-1 / 2}\left(\phi_{1}-\phi_{2}\right) \tag{3.5.9}
\end{equation*}
$$

The two $\pi$ electrons in ethylene occupy the $\psi(\pi)$ orbital. Hence the energy for a $\pi$ bond in the Hückel model is

$$
\begin{equation*}
E_{\pi}=2 \alpha+2 \beta \tag{3.5.10}
\end{equation*}
$$

The energy level diagram for the $\pi$ orbitals in ethylene is very simple and shown in Fig. 3.5.4. Note that in this approximation the bonding effect is equal to the antibonding effect. This arises from ignoring the overlap.

Fig. 3.5.3.
The atomic orbitals for $\pi$ bonding in ethylene.

Fig. 3.5.4.

Fig. 3.5.6.
The $\pi$ and $\pi^{*}$ molecular orbitals of butadiene.

## Fundamentals of Bonding Theory

## (2) Butadiene

Now we proceed to use the same method to treat a higher homolog of ethylene, namely butadiene. The atomic orbitals taking part in the $\pi$ bonding of this molecule is shown in Fig. 3.5.5. For this system, the secular determinant is

$$
\left|\begin{array}{cccc}
\alpha-E & \beta & 0 & 0  \tag{3.5.11}\\
\beta & \alpha-E & \beta & 0 \\
0 & \beta & \alpha-E & \beta \\
0 & 0 & \beta & \alpha-E
\end{array}\right|=\left|\begin{array}{cccc}
x & 1 & 0 & 0 \\
1 & x & 1 & 0 \\
0 & 1 & x & 1 \\
0 & 0 & 1 & x
\end{array}\right|=0
$$

where, again, $x=(\alpha-E) / \beta$. Expanding this determinant, we get

$$
x^{4}-3 x^{2}+1=0
$$

or

$$
\begin{equation*}
x=\left[ \pm(5)^{1 / 2} \pm 1\right] / 2= \pm 1.618, \pm 0.618 \tag{3.5.12}
\end{equation*}
$$

The energies and the wavefunctions are tabulated in Table 3.5.1. The wavefunctions are shown pictorially in Fig. 3.5.6. Note that as the number of nodes in a wavefunction increases, so does the energy associated with the wavefunction.

Table 3.5.1. The Hückel energies and wavefunction of the $\pi$ molecular orbitals of butadiene

| $x$ | Energy | Wavefunction |
| ---: | :---: | :--- |
| 1.618 | $E_{4}=\alpha-1.618 \beta$ | $\psi_{4}\left(\pi^{*}\right)=0.372 \phi_{1}-0.602 \phi_{2}+0.602 \phi_{3}-0.372 \phi_{4}$ |
| 0.618 | $E_{3}=\alpha-0.618 \beta$ | $\psi_{3}\left(\pi^{*}\right)=0.602 \phi_{1}-0.372 \phi_{2}-0.372 \phi_{3}+0.602 \phi_{4}$ |
| -0.618 | $E_{2}=\alpha+0.618 \beta$ | $\psi_{2}(\pi)=0.602 \phi_{1}+0.372 \phi_{2}-0.372 \phi_{3}-0.602 \phi_{4}$ |
| -1.618 | $E_{1}=\alpha+1.618 \beta$ | $\psi_{1}(\pi)=0.372 \phi_{1}+0.602 \phi_{2}+0.602 \phi_{3}+0.372 \phi_{4}$ |

Since the first two orbitals ( $\psi_{1}$ and $\psi_{2}$ ) are filled,

$$
\begin{equation*}
E_{\pi}=2(\alpha+1.618 \beta)+2(\alpha+0.618 \beta)=4 \alpha+4.472 \beta \tag{3.5.13}
\end{equation*}
$$

If the two $\pi$ bonds in butadiene were localized, they would have energy $2(2 \alpha+2 \beta)=4 \alpha+4 \beta$. Hence, by allowing the four $\pi$ electrons to delocalize over the entire molecular skeleton, there is a gain in stability, which is called delocalization energy (DE). For butadiene,

$$
\begin{align*}
\mathrm{DE} & =4 \alpha+4.472 \beta-(4 \alpha+4 \beta) \\
& =0.472 \beta<0 \tag{3.5.14}
\end{align*}
$$

By combining high-level ab initio calculations with high-resolution infrared spectroscopy, the equilibrium bond lengths in $s$-trans-butadiene have been determined to an unprecedented precision of 0.1 pm . The values found for the pair of $\pi$-electron delocalized double bonds and the delocalized central single bond are 133.8 and 135.4 pm , respectively. The data provide definitive structural evidence that validates the fundamental concepts of $\pi$-electron delocalization, conjugation, and bond alternation in organic chemistry.

### 3.5.2 Predicting the course of a reaction by considering the symmetry of the wavefunction

The molecular orbitals of butadiene, shown in Fig. 3.5.6, can be used to predict, or at least to rationalize, the course of concerted reactions (those which take place in a single step without involvement of intermediates) it would undergo. For instance, experimentally it is known that different cyclization products are obtained from butadiene by heating and upon light irradiation.

In 1965, the American chemists R. B. Woodward and R. Hoffmann ("conservation of orbital symmetry" or Woodward-Hoffmann rules) and Japanese chemist K. Fukui ("frontier orbital theory") proposed theories to explain these results as well as those for other reactions. (Woodward won the Nobel Prize in Chemistry in 1965 for his synthetic work. In 1981, after the death of Woodward, Hoffmann and Fukui shared the same prize for the theories discussed here.)
These theories assert that the pathway of a chemical reaction accessible to a compound is controlled by its highest occupied molecular orbital (HOMO). For the thermal reaction of butadiene, which is commonly called "ground-state chemistry," the HOMO is $\psi_{2}$ and lowest unoccupied molecular orbital (LUMO) is $\psi_{3}$ (Fig. 3.5.6). For the photochemical reaction of butadiene, which is known to be "excited-state chemistry," the HOMO is $\psi_{3}$ (Fig. 3.5.6).

The thermal and photochemical cyclization of a butadiene bearing different substituents at its terminal carbon atoms is represented by eqs. (3.5.15) and (3.5.16), respectively. Note that for a short conjugated polyene consisting of four or six carbon atoms, conformational interconversion between their transoid (or s-trans) and cisoid (or s-cis) forms takes place readily.

For wavefunction $\psi_{2}$, the terminal atomic orbitals $\phi_{1}$ and $\phi_{4}$ have the relative orientations as shown in Fig. 3.5.7. It is evident that a conrotatory process leads to a bonding interaction between $\phi_{1}$ and $\phi_{4}$, while a disrotatory process leads to an antibonding interaction between $\phi_{1}$ and $\phi_{4}$. Clearly the conrotatory process prevails in this case.

Conversely, for wavefunction $\psi_{3}$, the terminal atomic orbitals $\phi_{1}$ and $\phi_{4}$ have the relative orientations shown in Fig. 3.5.8. Here a conrotatory pathway yields an antibonding interaction between the terminal atomic orbitals, while a disrotatory step leads to a stabilizing bonding interaction. Hence the disrotatory process wins out in this case.
To conclude this section, we apply this theory to the cyclization of hexatriene:

Fig. 3.5.7.
Thermal cyclization of butadiene.

Table 3.5.2. The Hückel energies and wavefunctions of the $\pi$ moleular orbitals of hexatriene

| $x$ | Energy | Wavefunction |
| :---: | :---: | :---: |
| 1.802 | $E_{6}=\alpha-1.802 \beta$ | $\psi_{6}=0.232 \phi_{1}-0.418 \phi_{2}+0.521 \phi_{3}-0.521 \phi_{4}+0.418 \phi_{5}-0.232 \phi_{6}$ |
| 1.247 | $E_{5}=\alpha-1.247 \beta$ | $\psi_{5}=0.418 \phi_{1}-0.521 \phi_{2}+0.232 \phi_{3}+0.232 \phi_{4}-0.521 \phi_{5}+0.418 \phi_{6}$ |
| 0.445 | $E_{4}=\alpha-0.445 \beta$ | $\psi_{4}=0.521 \phi_{1}-0.232 \phi_{2}-0.418 \phi_{3}+0.418 \phi_{4}+0.232 \phi_{5}-0.521 \phi_{6}$ |
| -0.445 | $E_{3}=\alpha+0.445 \beta$ | $\psi_{3}=0.521 \phi_{1}+0.232 \phi_{2}-0.418 \phi_{3}-0.418 \phi_{4}+0.232 \phi_{5}+0.521 \phi_{6}$ |
| -1.247 | $E_{2}=\alpha+1.247 \beta$ | $\psi_{2}=0.418 \phi_{1}+0.521 \phi_{2}+0.232 \phi_{3}-0.232 \phi_{4}-0.521 \phi_{5}-0.418 \phi_{6}$ |
| -1.802 | $E_{1}=\alpha+1.802 \beta$ | $\psi_{1}=0.232 \phi_{1}+0.418 \phi_{2}+0.521 \phi_{3}+0.521 \phi_{4}+0.418 \phi_{5}+0.232 \phi_{6}$ |

The secular determinant of hexatriene is

$$
\left|\begin{array}{cccccc}
x & 1 & 0 & 0 & 0 & 0  \tag{3.5.18}\\
1 & x & 1 & 0 & 0 & 0 \\
0 & 1 & x & 1 & 0 & 0 \\
0 & 0 & 1 & x & 1 & 0 \\
0 & 0 & 0 & 1 & x & 1 \\
0 & 0 & 0 & 0 & 1 & x
\end{array}\right|=0, \text { with } x=(\alpha-E) / \beta
$$

The solutions of this determinant, along with the energies and wavefunctions of the $\pi$ molecular orbitals, are summarized in Table 3.5.2. While these wavefunctions are not pictorially shown here, we can readily see that the number of nodes of the wavefunctions increases as their energies increase. Indeed, $\psi_{1}, \psi_{2}, \ldots, \psi_{6}$ have $0,1, \ldots, 5$ nodes, respectively. Also,

$$
\begin{align*}
E_{\pi} & =2(\alpha+1.802 \beta)+2(\alpha+1.247 \beta)+2(\alpha+0.445 \beta) \\
& =6 \alpha+6.988 \beta .  \tag{3.5.19}\\
\mathrm{DE} & =6 \alpha+6.988 \beta-3(2 \alpha+2 \beta) \\
& =0.988 \beta<0 . \tag{3.5.20}
\end{align*}
$$

For the thermal and photochemical cyclization of hexatriene, the controlling HOMO's are $\psi_{3}$ and $\psi_{4}$, respectively. As shown in Fig. 3.5.9, the allowed

Fig. 3.5.8.
Photocyclization of butadiene.

Fig. 3.5.9.
Thermal and photochemical cyclization reactions of hexatriene.

pathway for the thermal reaction is disrotatory. On the other hand, the allowed pathway for the photochemical reaction is conrotatory. These results are just the opposite of those found for the cyclization reactions of butadiene (Figs. 3.5.7 and 3.5.8).

## Chemical Bonding in Condensed Phases

Studies of structural chemistry in the solid state are of particular interest in view of the following justifications:
(a) The majority of the important materials used in modern optical, electronic, and magnetic applications are solids.
(b) Our present understanding of structure-property correlation originates mainly from results obtained in the gaseous and solid states. Based on this foundation, the structure of matter in the liquid phase can be deduced and further investigations then carried out.
(c) Starting from the knowledge of the fixed atomic positions in the solid state of a given compound, new materials can be designed by adding atoms into the lattice or removing atoms from the lattice, and such new materials will have different properties.
(d) The atoms in a solid are bonded together through many types of interactions, the nature of which often determines the properties of the material.

In this chapter, the basic types of chemical bonds existing in condensed phases are discussed. These interactions include ionic bonds, metallic bonds, covalent bonding (band theory), and intermolecular forces. In Chapter 10, the structures of some inorganic crystalline materials will be presented.

### 4.1 Chemical classification of solids

Solids are conveniently classified in terms of the types of chemical bonds that hold the atoms together, as shown in Table 4.1.1. The majority of solids involve

Table 4.1.1. Classification of simple solids

| Class | Example |
| :--- | :--- |
| Ionic | $\mathrm{NaCl}, \mathrm{MgO}, \mathrm{CaF}_{2}, \mathrm{CsCl}$ |
| Covalent | $\mathrm{C}($ diamond $), \mathrm{SiO}_{2}$ (silica) |
| Molecular | $\mathrm{Cl}_{2}, \mathrm{~S}_{8}, \mathrm{HgCl}_{2}$, benzene |
| Metallic | $\mathrm{Na}, \mathrm{Mg}, \mathrm{Fe}, \mathrm{Cu}, \mathrm{Au}$ |

Table 4.1.2. Some examples of complex solids held together by a combination of different bond types

| Bond types involved | Example |
| :--- | :--- |
| Ionic, covalent | $\mathrm{ZnS}, \mathrm{TiO}_{2}$ |
| Ionic, covalent, van der Waals | $\mathrm{CdI}_{2}$ |
| Ionic, metallic | $\mathrm{NbO}, \mathrm{TiO}_{x}(0.75<x<1.25)$ |
| Ionic, covalent, metallic, van der Waals | ZrCl |
| Ionic, covalent, metallic | $\mathrm{K}_{2} \mathrm{Pt}(\mathrm{CN})_{4} \mathrm{Br}_{0.3} \cdot 3 \mathrm{H}_{2} \mathrm{O},\left(\mathrm{SNBr}_{x}\right)_{\infty}(0.25<x<1.5)$ |
| Covalent, metallic, van der Waals | $\mathrm{C}($ graphite $)$ |
| Covalent, hydrogen bond | Ice |
| Ionic, covalent, metallic, van der Waals | $\mathrm{TTF}: \mathrm{TCNQ}, \mathrm{Tl}_{2} \mathrm{RbC}_{60}$ |

TTF, tetrathiafulvalene; TCNQ, tetracyanoquinodimethane.
more complex chemical bonding, and some examples are given in Table 4.1.2. Here the term "metallic" indicates electron delocalization over the entire solid.

In ZnS the transfer of two electrons from the metal atom to the non-metal is incomplete, so that the bond between the formal $\mathrm{Zn}^{2+}$ and $\mathrm{S}^{2-}$ ions has significant covalent character. The same is true for compounds containing metal ions with a high formal charge such as $\mathrm{TiO}_{2}$.

Fig. 4.1.1.
Layer structure in (a) $\mathrm{CdI}_{2}$ and (b) ZrCl .

In the layer structure of $\mathrm{CdI}_{2}$, the iodine atoms belonging to adjacent layers are connected by van der Waals forces (Fig. 4.1.1(a)). The metal atoms in TiO and NbO are in a low oxidation state and the excess electrons can form metalmetal bonds extending in one and two dimensions, which are responsible for the metallic character of these oxides. The sheet structure of ZrCl is composed of four homoatomic layers in the sequence $\cdot . \mathrm{ClZrZrCl} \cdots \mathrm{ClZrZrCl} \cdots$, as shown in Fig. 4.1.1(b). Each Zr has six metal neighbors in the same layer at 342 pm , and three metal neighbors in the next layer at 309 pm , compared to an average distance of 320 pm in $\alpha-\mathrm{Zr}$. There is strong metal-metal bonding in the double Zr layers. Each Zr has three Cl neighbors in the adjacent layer at 263 pm , indicating both covalent and ionic bonding. The $\mathrm{Cl} \cdots \mathrm{Cl}$ inter-sheet distances at $\sim 360 \mathrm{pm}$ are normal van der Waals contacts.

Fig. 4.1.2.
Overlap of $5 \mathrm{~d}_{z^{2}}$ orbitals along a chain of Pt centers in the crystal structure of $\mathrm{K}_{2} \mathrm{Pt}(\mathrm{CN})_{4} \mathrm{Br}_{0.3} \cdot 3 \mathrm{H}_{2} \mathrm{O}$.

Fig. 4.1.3.
Crystal structure of the "molecular metal" TTF:TCNQ.

The partially oxidized complex $\mathrm{K}_{2} \mathrm{Pt}(\mathrm{CN})_{4} \mathrm{Br}_{0.3} \cdot 3 \mathrm{H}_{2} \mathrm{O}$ behaves as a onedimensional conductor, owing to overlap of the platinum $5 \mathrm{~d}_{z^{2}}$ orbitals atoms along a chain composed of stacking of square-planar $\left[\operatorname{Pt}(\mathrm{CN})_{4}\right]^{1.7-}$ units (Fig. 4.1.2).

The $1: 1$ solid adduct of tetrathiafulvalene (TTF) and tetracyanoquinodimethane (TCNQ) is the first-discovered "molecular metal," which consists of alternate stacks each composed of molecules of the same type (Fig. 4.1.3). A charge transfer of 0.69 electron per molecule from the HOMO (mainly $S$ atom's lone pair in character) of TTF to the LUMO of TCNQ results in two partially filled bands, which account for the electrical conductivity of TTF:TCNQ.

A binary compound $\mathrm{A}_{n} \mathrm{~B}_{m}$ consists of atoms of two kind of elements, A and B , and its bond type depends on the average value of the electronegativities of the two elements ( $\bar{\chi}$, mean of $\chi_{\mathrm{A}}$ and $\chi_{\mathrm{B}}$ ), and on the difference of the electronegativities of the two elements $\left(\Delta \chi=\left|\chi_{A}-\chi_{B}\right|\right)$. Figure 4.1.4 shows the distribution of the compounds $\mathrm{A}_{n} \mathrm{~B}_{m}$ in a diagram of the " $\bar{\chi}-\Delta \chi$ " relationship. This diagram may be divided into four regions which correspond to the four bond types: ionic (I), metallic (II), semi-metallic (III), and covalent (IV). For example, the compound $\mathrm{SF}_{4}$ has the following parameters: $\chi_{\mathrm{F}}=4.19, \chi_{\mathrm{S}}=2.59, \bar{\chi}=3.39$, and $\Delta \chi=1.60$, which place the compound in region IV. Thus the bond type of $\mathrm{SF}_{4}$ is covalent. In another example, the parameters of ZrCl are $\chi_{\mathrm{Zr}}=1.32, \chi_{\mathrm{Cl}}=2.87, \bar{\chi}=2.20$, and $\Delta \chi=1.55$, which place the compound on the border of regions I and IV. So the bond in ZrCl is expected to exhibit both ionic and covalent characters.

### 4.2 Ionic bond

### 4.2.1 Ionic size: crystal radii of ions

A set of empirical ionic radii can be derived from the direct measurement of internuclear distances in crystal structures. The additivity of ionic radii is substantiated by the near constancy of the differences in internuclear distances $\Delta r$ between the alkali metal halides, as shown in Table 4.2.1.

By assuming a value for the radius of each single ion (e.g., 140 pm for $\mathrm{O}^{2-}$ and 133 pm for $\mathrm{F}^{-}$), a set of self-consistent ionic radii can be generated. There exist several compilations of ionic radii, and some selected representative values for ions with coordination number 6 are listed in Table 4.2.2.

Some comments on the ionic radii collected in Table 4.2.2 are as follows:
(1) Values of the ionic radii are derived from experimental data, which give the internuclear distances and electron densities, and generally take the distance of contacting neighbor ions to be the sum of the ionic radii of the cation and anion:

$$
\text { Internuclear distance between contacting neighbors }=r_{\text {cation }}+r_{\text {anion }} \text {. }
$$

Thus, a hard sphere model is assumed for the ionic crystal, with ions of opposite charge touching one another in the crystal lattice. Such an approximation means that the assignment of individual radii is somewhat arbitrary. The values listed in Table 4.2.2 are a set of data which assume that the radius of $\mathrm{O}^{2-}$ is 140 pm and that of $\mathrm{F}^{-}$is 133 pm .

Fig. 4.1.4.
Bond types and electronegativities of some binary compounds.

Table 4.2.1. Internuclear distance ( pm ) and their difference in alkali metal halides

(2) The valence state of ions listed in Table 4.2.2 are obtained from the oxidation states of the atoms in the compounds. They are only formal values and they do not indicate the number of transferred electrons. In other words, the bonding type between the atoms is not considered. These radii are effective ionic radii and they can be used for rough estimation of the packing of ions in crystals and other calculations.
(3) There is an increase in size with increasing coordination number and for a given coordination number with increasing $Z$ within a periodic group. In general:

$$
\begin{array}{lcccc}
\text { Coordination number: } & 4 & 6 & 8 & 12 \\
\text { Relative radius: } & 0.94 & 1.00 & 1.03 & 1.12
\end{array}
$$

For cations with high charge the decrease in radii as the coordination number decreases can be quite large. For instance, the radii of $\mathrm{Mn}^{7+}$ in six- and four-coordinate geometry are 46 and 25 pm , respectively. Some effective ionic radii of four-coordinate high-valence cations are listed below:

$$
\begin{array}{llllllllllllllll}
\text { Cation } & \mathrm{B}^{3+} & \mathrm{C}^{4+} & \mathrm{Cr}^{6+} & \mathrm{Mn}^{7+} & \mathrm{Mo}^{6+} & \mathrm{P}^{5+} & \mathrm{Pb}^{4+} & \mathrm{S}^{6+} & \mathrm{Se}^{6+} & \mathrm{Si}^{4+} & \mathrm{Sn}^{4+} & \mathrm{V}^{5+} & \mathrm{W}^{6+} & \mathrm{Zr}^{4+} \\
\text { Radius }(\mathrm{pm}) & 11 & 15 & 26 & 25 & 41 & 17 & 65 & 12 & 28 & 26 & 55 & 35.5 & 42 & 59
\end{array}
$$

(4) The ionic radii are generally irregular, slowly decreasing in size with increasing $Z$ for transition metals of the same charge. Also, the high-spin (HS) ions have larger radii than low-spin (LS) ions of the same species and charge.

Table 4.2.2. Ionic radii (in pm )* with coordination number 6

| Ion | Radius | Ion | Radius | Ion | Radius | Ion | Radius | Ion | Radius |

* Selected from R. D. Shannon. Acta Crystallogr. A32, 751-67 (1976). Notations HS and LS refer to high- and low-spin state, respectively.

Because of the diversity of the chemical bonds, the bond type usually varies with the coordination number, especially for the ions with high valence and low coordination number. Figure 4.2 . 1 shows the relationship between the ionic radii and the number of $d$ electrons in the first series of transition metals.

Fig. 4.2.1.
Relationship between the ionic radii and the number of $d$ electrons of the first series of transition metals. Open circles denote high-spin complexes.

### 4.2.2 Lattice energies of ionic compounds

The lattice energy $U$ of an ionic compound is defined as the energy required to convert one mole of crystalline solid into its component cations and anions in their thermodynamic standard states (non-interacting gaseous ions at standard temperature and pressure). It can be calculated using either the Born-Landé equation

$$
\begin{equation*}
U=\frac{N_{0} A Z_{+} Z_{-} e^{2}}{4 \pi \epsilon_{0} r_{\mathrm{e}}}\left(1-\frac{1}{m}\right) \tag{4.2.1}
\end{equation*}
$$

or the Born-Mayer equation

$$
\begin{equation*}
U=\frac{N_{0} A Z_{+} Z_{-} e^{2}}{4 \pi \epsilon_{0} r_{\mathrm{e}}}\left(1-\frac{\rho}{r_{\mathrm{e}}}\right), \tag{4.2.2}
\end{equation*}
$$

where $N_{0}$ is Avogardro's number, $A$ is the Madelung constant, $Z_{+}$and $Z_{-}$are the charges on the cation and anion, $r_{\mathrm{e}}$ is the equilibrium interionic distance, and $\rho$ is a parameter in the repulsion term $-b \mathrm{e}^{-r / \rho}$, which is found to be nearly constant for most crystals with a value of 34.5 pm , and $m$ is a parameter in the repulsion term $a / r^{m}$ for interionic interaction, which is usualy assigned an integral value of 9 . Table 4.2.3 gives the Madelung constants $A$ for a number of ionic crystals. The values listed refer to the structural type with unit charges ( $Z_{+}=Z_{-}=1$ ) at the ion sites.

Kapustinskii noted that if the Madelung constant $A$ is divided by the number of ions per formula unit for a number of crystal structures, nearly the same value is obtained. Furthermore, as both $A / n$ and $r_{\mathrm{e}}$ increase with the coordination number, their ratio $A / n r_{\mathrm{e}}$ is expected to be approximately the same from one structure to another. Therefore, Kapustinskii proposed that the structure of any ionic solid is energetically equivalent to a hypothetical rock-salt structure and its lattice energy can be calculated using the Madelung constant of NaCl and the appropriate ionic radii for $(6,6)$ coordination.

Table 4.2.3. Madelung constants of selected crystals

| Formula | Space group | Compound name | Coordination mode | Madelung constant |
| :--- | :--- | :--- | :---: | :---: |
| NaCl | $F m \overline{3} m$ | rock salt | $(6,6)$ | 1.7476 |
| CsCl | $P m \overline{3} m$ | cesium chloride | $(8,8)$ | 1.7627 |
| $\beta-\mathrm{ZnS}$ | $F \overline{4} 3 m$ | zinc blende (sphalerite) | $(4,4)$ | 1.6381 |
| $\alpha-\mathrm{ZnS}$ | $P 6 m c$ | wurzite | $(4,4)$ | 1.6413 |
| $\mathrm{CaF}_{2}$ | $F m \overline{3} m$ | fluorite | $(8,4)$ | 2.5194 |
| $\mathrm{Cu}_{2} \mathrm{O}$ | $P n 3 m$ | cuprite | $(6,3)$ | 2.2212 |
| $\mathrm{TiO}_{2}$ | $P 4 / m n m$ | rutile | $(4,2)$ | 2.408 |
| $\mathrm{TiO}_{2}$ | $C 4 / 2 m c$ | anatase | $\beta$-quartz | $(6,4)$ |
| $\beta-\mathrm{SiO}_{2}$ | $P 6_{2} 22$ | corundum |  | 2.400 |
| $\alpha-\mathrm{Al}_{2} \mathrm{O}_{3}$ | $R \overline{3} c$ |  |  | 4.172 |

Substituting $r_{\mathrm{e}}=r_{+}+r_{-}$(in pm), $\rho=34.5 \mathrm{pm}, A=1.7476$, and values for $N_{0}, e$ and $\varepsilon_{0}$ into the Born-Mayer equation gives the Kapustinskii equation:

$$
\begin{equation*}
U=\frac{1.214 \times 10^{5} Z_{+} Z_{-} n}{r_{+}+r_{-}}\left(1-\frac{34.5}{r_{+}+r_{-}}\right) \mathrm{kJ} \mathrm{~mol}^{-1} . \tag{4.2.3}
\end{equation*}
$$

The lattice energies calculated using this equation are compared with those obtained from the Born-Haber cycle in Table 4.2.4.

Table 4.2.4. Lattice energies (in $\mathrm{kJ} \mathrm{mol}^{-1}$ ) of some alkali metal halides and divalent transition metal chalcogenides

| Ionic Compound | Born-Haber | Kapustinskii | Ionic compound | Born-Haber | Kapustinskii |
| :--- | :---: | :---: | :--- | :---: | :---: |
| LiF | 1009 | 952 | CsF | 715 | 713 |
| LiCl | 829 | 803 | CsCl | 640 | 625 |
| LiBr | 789 | 793 | CsBr | 620 | 602 |
| LiI | 734 | 713 | CsI | 587 | 564 |
| NaF | 904 | 885 | MnO | 3812 | 3895 |
| NaCl | 769 | 753 | FeO | 3920 | 3987 |
| NaBr | 736 | 734 | CoO | 3992 | 4046 |
| NaI | 688 | 674 | NiO | 4075 | 4084 |
| KF | 801 | 789 | CuO | 4033 | 4044 |
| KCl | 698 | 681 | ZnO | 3971 | 4142 |
| KBr | 672 | 675 | ZnS (zinc blende) | 3619 | 3322 |
| KI | 632 | 614 | ZnS (wurtzite) | 3602 | 3322 |
| RbF | 768 | 760 | MnS | 3351 | 3247 |
| RbCl | 678 | 662 | MnSe | 3305 | 3083 |
| RbBr | 649 | 626 | ZnSe | 3610 | 3150 |
| RbI | 613 | 590 |  |  |  |

A useful application of the Kapustinskii equation is the prediction of the existence of previously unknown compounds. From Table 4.2.5, it is seen that all dihalides of the alkali metals with the exception of $\mathrm{CsF}_{2}$ are unstable with respect to their formation from the elements. However, $\mathrm{CsF}_{2}$ is unstable with respect to disproportionation: the enthalpy of the reaction $\mathrm{CsF}_{2} \rightarrow \mathrm{CsF}+1 / 2 \mathrm{~F}_{2}$ is $-405 \mathrm{~kJ} \mathrm{~mol}^{-1}$.

Table 4.2.5. Predicted enthalpies of formation (in $\mathrm{kJ} \mathrm{mol}^{-1}$ ) of some metal dihalides and oxides using the Kapustinskii equation

| M | $\mathrm{MF}_{2}$ | $\mathrm{MCl}_{2}$ | $\mathrm{MBr}_{2}$ | $\mathrm{MI}_{2}$ | MO |
| :--- | ---: | ---: | ---: | ---: | ---: |
| Li | - | 4439 | 4581 | 4740 | 4339 |
| Na | 1686 | 2146 | 2230 | 2427 | 2184 |
| K | 435 | 854 | 975 | 1117 | 1017 |
| Rb | 163 | 548 | 661 | - | 787 |
| Cs | -126 | 213 | 318 | 473 | 515 |
| Al | -774 | -272 | -146 | 8 | -230 |
| Cu | -531 | -218 | -142 | -21 | -155 |
| Ag | -205 | 96 | 167 | 282 | 230 |

In cases where the lattice energy is known from the Born-Haber cycle, the Kapustinskii equation can be used to derive the ionic radii of complex anions such as $\mathrm{SO}_{4}{ }^{2-}$ and $\mathrm{PO}_{4}{ }^{3-}$. The values determined in this way are known as thermochemical radii; some values are shown in Table 4.2.6.

Table 4.2.6. Thermochemical radii of polyatomic ions*

| Ion | Radius (pm) | Ion | Radius (pm) | Ion | Radius (pm) | Ion | Radius (pm) |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |

### 4.2.3 Ionic liquids

An ionic liquid is a liquid that consists only of ions. However, this term includes an additional special definition to distinguish it from the classical definition of a molten salt. While a molten salt generally refers to the liquid state of a high-melting salt, such as molten sodium chloride, an ionic liquid exists at much lower temperatures (approx. $<100^{\circ} \mathrm{C}$ ). The most important reported ionic liquids are composed of the following cations and anions:

Cations:

imidazolium ion

pyridinium ion
$\mathrm{R}=\mathrm{R}^{\prime}=$ methyl (MMIM)
$\mathrm{R}=$ methyl, $\mathrm{R}^{\prime}=$ ethyl (EMIM)
$\mathrm{R}=$ methyl, $\mathrm{R}^{\prime}=n$-butyl (BMIN)

ammonium ion

phosphonium ion

Anions: $\mathrm{AlCl}_{4}^{-}, \mathrm{Al}_{2} \mathrm{Cl}_{7}^{-}, \mathrm{BF}_{4}^{-}, \mathrm{Cl}^{-}, \mathrm{AlEtCl}_{3}^{-}, \mathrm{PF}_{6}^{-}, \mathrm{NO}_{3}^{-}, \mathrm{CF}_{3} \mathrm{SO}_{3}^{-}$
The development of ionic liquids has revealed that the ions possess the following structural features:
(1) The ionic radii have large values. The key criterion for the evaluation of an ionic liquid is its melting point. Comparison of the melting points of different chlorides salts, as listed in Table 4.2.7, illustrates the influence of the cation clearly: High melting points are characteristic for alkali metal chlorides, which have small cationic radii, whereas chlorides with suitable large organic cations melt at much lower temperatures. Besides the effect of the cation, an increasing size of anion with the same charge leads to a further decrease in melting point, as shown in Table 4.2.7.
(2) There are weak interactions between the ions in an ionic liquid, but the formation of hydrogen bonds is avoided as far as possible.
(3) In general, the cations and anions of ionic liquids are composed of organic and inorganic components, respectively. The solubility properties of an ionic liquid can be achieved by variation of the alkyl group on the cations and by choice of the counter-anions.

The physical and chemical properties of the ionic liquids that make them interesting as potential solvents and in other applications are listed below.
(1) They are good solvents for a wide range of inorganic and organic materials at low temperature, and usual combinations of reagents can be brought into the same phase. Ionic liquids represent a unique class of new reaction media for transition metal catalysis.
(2) They are often composed of poorly coordinating ions, so they serve as highly polar solvents that do not interfere with the intended chemical reactions.

Table 4.2.7. Melting point of some salts and ionic liquids

| Salt/ionic liquid | $\mathrm{mp}\left({ }^{\circ} \mathrm{C}\right)$ | Salt/ionic liquid | $\mathrm{mp}\left({ }^{\circ} \mathrm{C}\right)$ |
| :--- | :---: | :--- | ---: |
| NaCl | 801 | $[\mathrm{EMIM}] \mathrm{NO}_{2}$ | 55 |
| KCl | 772 | $[\mathrm{EMIM}] \mathrm{NO}_{3}$ | 38 |
| $[\mathrm{MMIM}] \mathrm{Cl}$ | 125 | $[\mathrm{EMIM}] \mathrm{AlCl}_{4}$ | 7 |
| $[\mathrm{EMIM}] \mathrm{Cl}$ | 87 | $[\mathrm{EMIM}] \mathrm{BF}_{4}$ | 6 |
| $[\mathrm{BMIM}] \mathrm{Cl}$ | 65 | $[\mathrm{EMIM}] \mathrm{CF}_{3} \mathrm{SO}_{3}$ | -9 |
| $[\mathrm{BMIM}] \mathrm{CF}_{3} \mathrm{SO}_{3}$ | 16 | $[\mathrm{EMIM}] \mathrm{CF}_{3} \mathrm{CO}_{2}$ | -14 |

## Fundamentals of Bonding Theory

(3) They are immiscible with a number of organic solvents and provide a non-aqueous, polar alternative for two-phase systems. Hydrophobic ionic liquids can also be used as immiscible polar phases with water.
(4) The interacting forces between ions in the ionic liquids are the strong electrostatic Coulombic forces. Ionic liquids have no measurable vapor pressure, and hence they may be used in high-vacuum systems to overcome many contaminant problems. Advantage of their non-volatile nature can be taken to conduct product separation by distillation with prevention of uncontrolled evaporation.

### 4.3 Metallic bonding and band theory

Metallic structure and bonding are characterized by delocalized valence electrons, which are responsible for the high electrical conductivity of metals. This contrasts with ionic and covalent bonding in which the valence electrons are localized on particular atoms or ions and hence are not free to migrate through the solid. The physical data for some solid materials are shown in Table 4.3.1.

The band theory of solids has been developed to account for the electronic properties of materials. Two distinct lines of approach will be described.

### 4.3.1 Chemical approach based on molecular orbital theory

Table 4.3.1. Conductivities of some metals, semiconductors, and insulators

| Category | Material | Conductivity $\left(\Omega^{-1} \mathrm{~m}^{-1}\right)$ | Band gap (eV) |
| :--- | :--- | :---: | :---: |
| Metals | Copper | $6.0 \times 10^{7}$ | 0 |
|  | Sodium | $2.4 \times 10^{7}$ | 0 |
|  | Magnesium | $2.2 \times 10^{7}$ | 0 |
|  | Aluminium | $3.8 \times 10^{7}$ | 0 |
| Zero-band gap semiconductor | Graphite | $2 \times 10^{5}$ | 0 |
| Semiconductors | Silicon | $4 \times 10^{-4}$ | 1.11 |
|  | Germanium | $2.2 \times 10^{-4}$ | 0.67 |
| Insulators | Gallium arsenide | $1.0 \times 10^{-6}$ | 1.42 |
|  | Diamond | $1 \times 10^{-14}$ | 5.47 |
|  | Polythene | $10^{-15}$ |  |

A piece of metal may be regarded as an infinite solid where all the atoms are arranged in a close-packed manner. If a large number of sodium atoms are

Fig. 4.3.1.
The evolution of a band of molecular orbitals as the number of contributing atoms such as Na increases. The shaded part in the band of $N$ atoms indicates its containing electrons.

brought together, the interaction of the 3 s valence orbitals will generate a very closely spaced set of molecular orbitals, as shown in Fig. 4.3.1. It is more appropriate to refer to such molecular orbitals as energy states since each is delocalized over all atoms in the metal, and the entire spectrum of energy states is known as a band.

The energy states in a band are not evenly distributed, and the band structure is better described by a plot of energy $E$ against a density of states function $N(E)$ which represents the number of energy states lying between $E$ and $\delta E$, as shown in Fig. 4.3.2.

The number of states within each band is equal to the total number of orbitals contributed by the atoms. For one mole of metal, a s band will consist of $N_{0}$ states and a 3 p band of $3 N_{0}$ states. These bands will remain distinct if the s-p separation is large, as shown in Fig. 4.3.3(a). However, if the s-p separation is small, the $s$ and $p$ bands overlap extensively and band mixing occurs. This situation, as illustrated in Fig. 4.3.3(b), applies to the alkaline-earth metals and main group metals.

The electronic properties of a solid are closely related to the band structure. The band that contains the electrons of highest energy is called the valence band, and the lowest unoccupied energy levels above them are called the conduction band.

There are four basic types of band structure as shown in Fig. 4.3.3. In (a) the valence band is only partially filled by electrons, and metals such as Na and Cu with a half-filled s band are well described by this diagram. The energy corresponding to the highest occupied state at 0 K is known as the Fermi energy $E_{\mathrm{F}}$.

The alkaline-earth metals and group 12 metals $(\mathrm{Zn}, \mathrm{Cd}, \mathrm{Hg})$ have the right number of electrons to completely fill an s band. However, s-p mixing occurs and the resulting combined band structure remains incompletely filled, as shown in Fig. 4.3.3(b). Hence these elements are also good metallic conductors.

Fig. 4.3.2.
Density of states diagram for the 3 s band of sodium.

Fig. 4.3.3.
Schematic representation of band structure and the primary density of states situations: (a) metal will no overlapping bands, (b) metal with overlapping bands, (c) an insulator, and (d) a semiconductor.

Insulators have a completely filled valence band separated by a large gap from the empty conduction band, as illustrated in Fig. 4.3.3(c). Diamond is an excellent insulator with a band gap of 5.47 eV . Figure 4.3.3(d) shows a situation in which a fully occupied band is separated from a vacant band by a small band gap. This property characterizes a semiconductor, the subject matter of the next section.

### 4.3.2 Semiconductors

Intrinsic semiconductors have a band structure similar to that of insulators, except that the gap is smaller, usually in the range 0.5 to 3 eV . A few electrons may have sufficient thermal energy to be promoted to the empty conduction band. Each electron leaving the valence band not only creates a charge carrier in the conduction band but also leaves behind a hole in the valence band. This hole provides a vacancy which can promote the movement of electrons in the valence band.

The presence of an impurity such as an As or a Ga atom in silicon leads to an occupied level in the band gap just below the conduction band or a vacant level just above the valence band, respectively. Such materials are described as extrinsic semiconductors. The $n$-type semiconductors have extra electrons provided by donor levels, and the $p$-type semiconductors have extra holes originating from the acceptor levels. Band structures of the different types of semiconductors are shown in Fig. 4.3.4.

In solid-state electronic devices, a $p-n$ junction is made by diffusing a dopant of one type into a semiconductor layer of the other type. Electrons migrate from the $n$-type region to the $p$-type region, forming a space charge region where there are no carriers. The unbalanced charge of the ionized impurities causes the bands to bend, as shown in Fig. 4.3.5, until a point is reached where the Fermi levels are equivalent.
A $p-n$ junction can be used to rectify an electric current, that is, to make it much easier to pass in one direction than the other. The depletion of carriers for the junction effectively forms an insulating barrier. If positive potential is applied to the $n$-type side (a situation known as reverse bias), more carriers are removed and the barrier becomes wider. However, under forward bias the $n$-type is made more negative relative to the $p$ side, so that the energy barrier is decreased and the carriers may flow through.

### 4.3.3 Variation of structure types of 4d and 5d transition metals

Calculated relative energies from the density of states curves including the d orbitals have been used to rationalize the changes in metallic structure observed across the 4 d and 5 d transition series, as summarized in Table 4.3.2. To understand the variation of these structures, we first determine the average electronic energy for a model transition metal with body-centered cubic packing (bcp), hexagonal closest packing (hcp), and cubic closest packing (ccp) structures. Then we plot the energy differences of these structures as a function of the number of d electrons. As shown in Fig. 4.3.6, the solid line indicates the energy of bcp minus the energy of ccp (bcp-ccp), and the broken line indicates the energy of hcp minus the energy of ccp (hcp-ccp).

Table 4.3.2. Crystal structure of 4 d and 5 d transition metals

| 4 d element and number of d electrons | Structure | $\Delta E$ |  | 5d element and number of d electrons | Structure | $\Delta E$ |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
|  |  | (hcp - ccp) | (bcp - ccp) |  |  | (hcp - ccp) | (bcp - ccp) |
| Y (1) | hcp | - | + | La (1) | hexagonal | - | + |
| Zr (2) | hcp | - | + | Hf (2) | hcp | - | + |
| Nb (3) | bcp | + | - | Ta (3) | bcp | + | - |
| Mo (4) | bcp | + | - | W (4) | bcp | + | - |
| Tc (5) | hcp | $\sim 0$ | - | $\operatorname{Re}(5)$ | hcp | $\sim 0$ | - |
| Ru (6) | hcp | - | + | Os (6) | hcp | - | + |
| $\mathrm{Rh}(7)$ | ccp | - | + | Ir (7) | ccp | - | + |
| $\mathrm{Pd}(8)$ | ccp | $\sim 0$ | + | $\mathrm{Pt}(8)$ | ccp | $\sim 0$ | + |
| Ag (9) | ccp | + | - | Au (9) | ccp | + | - |
| Cd (10) | hcp | 0 | 0 | $\mathrm{Hg}(10)$ | trigonal | 0 | 0 |

Studying the plots in Fig. 4.3.6, we can see that for d electron counts of 1 and 2, the preferred structure is hcp. For $n=3$ or 4 , the bcp structure is the most stable. These results are in agreement with the observation as listed in Table 4.3.2. For d electron counts of 5 or more, the hcp and ccp structures have comparable energies. However, the hcp structure is correctly predicted to be more stable for metals with six d electrons, and the ccp for later transition elements. These calculations show how the structures of metallic elements are determined by rather subtle differences in the density of states, which in turn are controlled by the different types of bonding interaction present.

## Fig. 4.3.6.

The computed relative energy of bcp ccp (solid line) and hcp - ccp, (broken line) as a function of the number of $d$ electrons.

### 4.3.4 Metallic radii

The metallic radius ( $r_{\text {met }}$ ) is defined as one half of the internuclear distance between neighboring metal atoms in a metallic crystal, and is dependent upon the coordination number (CN). The relative metallic radius for different polymorphs of the same metal varies with CN . When CN decreases, $r_{\text {met }}$ also decreases. The relative $r_{\text {met }}$ values are estimated to be as follows:

| Coordination number: | 12 | 8 | 6 | 4 |
| :--- | :--- | :--- | :--- | :--- |
| Relative radius: | 1.00 | 0.97 | 0.96 | 0.88 |

For example, metallic barium has a bcp lattice with $a=502.5 \mathrm{pm}$ (Table 10.3.2). From these results, the metallic radius of Ba atom can be calculated:

$$
\begin{array}{ll}
r_{\text {met }}(\mathrm{CN}=8) & =217.6 \mathrm{pm}, \\
r_{\text {met }}(\mathrm{CN}=12) & =224.3 \mathrm{pm} .
\end{array}
$$

The values of $r_{\text {met }}$ listed in Table 4.3.3 refer to 12-coordinate metal centers. Since not all metals actually adopt structures with equivalent 12-coordinate atoms such as the ccp structure, the $r_{\text {met }}$ values are estimated from the experimental values. For the hcp structure, there are two sets of six-coordinate atoms, which are not exactly equivalent to each other. In such circumstances, we usually adopt the average value of the two sets. Gallium possesses a complex structure in which each atom has one neighbor at 244 pm , two at 270 pm , two at 273 pm , and two at 279 pm , and its $r_{\text {met }}$ can be estimated as 141 pm .

The metallic radii may be used to define the relative sizes of atoms, which has implications for their structural and chemical properties. For example, going down a given group in the Periodic Table, the metallic radii of the

elements increase, the first ionization energies generally decrease, and the electronegativities also decrease.

### 4.3.5 Melting and boiling points and standard enthalpies of atomization of the metallic elements

Table 4.3.4 lists the melting and boiling points and enthalpies of atomization $\left(\Delta H_{\mathrm{at}}^{\circ}\right)$ of the metallic elements. These data show that, in general, these properties are closely correlated. The $\Delta H_{\mathrm{at}}^{\circ}$ values reflect the strength of the metal-metal bonds in their metallic structures. For example, the sixth row elements show an overall increase in $\Delta H_{\mathrm{at}}^{\circ}$ from Cs to W and then there is a marked decrease from W to Hg . Because of the relativistic effects on the sixth row elements (which have been discussed in section 2.4), the energies of 6 s and 5 d orbitals are very similar. Hence, for a metal containing $N$ atoms, there are 6 N valence orbitals. The band structure of the metal corresponds to an infinite set of delocalized molecular orbitals which extend throughout the structure. Half of these closely spaced orbitals are bonding ( $3 N$ orbitals) and half are antibonding ( 3 N orbitals). If the bands of molecular orbitals are filled in the aufbau fashion, the $\Delta H_{\text {at }}^{\circ}$ values should increase from a low initial value for $\mathrm{d}^{0} \mathrm{~s}^{1}$ (metal Cs) to a maximum at $\mathrm{d}^{5} \mathrm{~s}^{1}$ (metal W ), and a minimum for the completely filled shell $\mathrm{d}^{10} \mathrm{~s}^{2}$ (metal Hg ), where all the bonding and antibonding orbitals are filled and may be approximated as nonbonding. These features of the band structure of metals are in accord with the data listed in Table 4.3 .4 and with the discussion given in section 2.4.

In the fourth row elements, the large exchange energies associated with the $3 d^{5} 4 s^{1}(\mathrm{Cr})$ and $3 \mathrm{~d}^{5} 4 \mathrm{~s}^{2}(\mathrm{Mn})$ configurations (both with either half-filled or completely filled orbitals) result in non-aufbau configurations for these elements when the metallic valence bands are populated. For these non-aufbau configurations, some electrons are not paired up, leading to magnetic properties and occupation of antibonding levels in the band. Consequently, there is a

weakening of the metal-metal bond and Cr and Mn metals have the anomalously low $\Delta H_{\mathrm{at}}^{\circ}$ values listed in Table 4.3.4.

### 4.4 Van der Waals interactions

The collective term "intermolecular forces" refers to the interactions between molecules. These interactions are different from the those involved in covalent, ionic, and metallic bonds. Intermolecular interactions include forces between ions or charged groups, dipoles or induced dipoles, hydrogen bonds, hydrophobic interactions, $\pi \cdots \pi$ overlap, nonbonding repulsions, etc. The energies of these interactions (usually operative within a range of $0.3-0.5 \mathrm{~nm}$ ) are generally below $10 \mathrm{~kJ} \mathrm{~mol}^{-1}$, or one to two order of magnitude smaller than that of an ordinary covalent bond. These interactions are briefly described below.

The interaction between charge groups, such as $-\mathrm{COO}^{-} \ldots{ }^{+} \mathrm{H}_{3} \mathrm{~N}-$, gives rise to an energy which is directly proportional to the charges on the groups and
inversely proportional to the distance between them. The interactions among dipoles and induced dipoles are proportional to $r^{-6}$, where $r$ is the separation between the interacting bodies. These interactions are collectively called van der Waals forces and they will be discussed in some detail later in this section. Hydrogen bonding is one of the most important intermolecular interactions and it will be described in some detail in section 11.2.

In protein molecules, hydrophobic side-chain groups such as phenylalanine, leucine, and isoleucine aggregate together, forming a hydrophobic zone in the interior of the molecule. The forces that hold these groups together are the hydrophobic interactions. These interactions include both energetic and entropy effects. It is of interest to note that these hydrophobic groups unite together not because they prefer each other's company, but because all of them are "repelled" by water.

The $\pi \cdots \pi$ overlap interaction is the force that holds together two or more aromatic rings that tend to be parallel to each other in molecular packing. The most well-known example is the interlayer interaction in graphite, where the distance separating layers measures 335 pm .

Finally, nonbonding repulsion exists in all types of groups. It is a short-range interacting force and is on the order of $r^{-9}$ to $r^{-12}$.

### 4.4.1 Physical origins of van der Waals interactions

The interactions between molecules are repulsive at short range and attractive at long range. When the intermolecular separation is small, the electron clouds of two adjacent molecules overlap to a significant extent, and the Pauli exclusion principle prohibits some electrons from occupying the overlap region. As the electron density in this region is reduced, the positively charged nuclei of the molecules are incompletely shielded and hence repel each other.

The long-range attractive interaction between molecules, generally known as van der Waals interaction, becomes significant when the overlap of electron clouds is small. There are three possible contributions to this long-range interaction, depending on the nature of the interacting molecules. These physical origins are discussed below.

## (1) Electrostatic contribution

A polar molecule such as HCl possesses a permanent dipole moment $\mu$ by virtue of the non-uniform electric charge distribution within the neutral molecule. The electrostatic energy $U_{\mu \mu}$ between two interacting dipoles $\mu_{1}$ and $\mu_{2}$ is strongly dependent on their relative orientation. If all relative orientations are equally probable and each orientation carries the Boltzmann weighting factor $\mathrm{e}^{-U_{\mu \mu} / k T}$, the following expression is obtained:

$$
\begin{equation*}
<U_{\mu \mu}>_{\mathrm{el}}=-\frac{2 \mu_{1}^{2} \mu_{2}^{2}}{3\left(4 \pi \epsilon_{0}\right)^{2} k T r^{6}} \tag{4.4.1}
\end{equation*}
$$

This expression shows that the attractive electrostatic interaction, commonly known as the Keesom energy, is inversely proportional to the sixth power

## Fundamentals of Bonding Theory

of the intermolecular separation, and the temperature dependence arises from orientational averaging with Boltzmann weighting.

Some non-polar molecules such as $\mathrm{CO}_{2}$ possess an electric quadrupole moment $Q$ which can contribute to the electrostatic energy in a similar manner. The results for dipole-quadrupole and quadrupole-quadrupole interactions are

$$
\begin{align*}
& <U_{\mu Q>}>_{\mathrm{el}}=-\frac{\mu_{1}^{2} Q_{2}^{2}+\mu_{2}^{2} Q_{1}^{2}}{\left(4 \pi \epsilon_{0}\right)^{2} k T r^{8}}  \tag{4.4.2}\\
& <U_{Q Q \gg_{\mathrm{el}}}=-\frac{14 Q_{1}^{2} Q_{2}^{2}}{5\left(4 \pi \epsilon_{0}\right)^{2} k T r^{10}} \tag{4.4.3}
\end{align*}
$$

## (2) Induction contribution

When a polar molecule and a non-polar molecule approach each other, the electric field of the polar molecule distorts the electron charge distribution of the non-polar molecule and produces an induced dipole moment within it. The interaction of the permanent and induced dipoles then results in an attractive force. This induction contribution to the electrostatic energy is always present when two polar molecules interact with each other.

The average induction energy (called Debye energy) between a polar molecule with dipole moment $\mu$ and a non-polar molecule with polarizability $\alpha$ is

$$
\begin{equation*}
<U_{\mu \alpha}>_{\text {ind }}=-\frac{\mu^{2} \alpha}{\left(4 \pi \epsilon_{0}\right)^{2} r^{6}} \tag{4.4.4}
\end{equation*}
$$

Note that the induction energy, unlike the electrostatic energy, is not temperature dependent although both vary as $r^{-6}$.

For two interacting polar molecules, the induction energy averaged over all orientations is

$$
\begin{equation*}
<U_{\mu \mu}>_{\text {ind }}=-\frac{\mu_{1}^{2} \alpha_{2}+\mu_{2}^{2} \alpha_{1}}{\left(4 \pi \epsilon_{0}\right)^{2} r^{6}} \tag{4.4.5}
\end{equation*}
$$

## (3) Dispersion contribution

The electrons in a molecule are in constant motion so that at any instant even a non-polar molecule such as $\mathrm{H}_{2}$ possesses an instantaneous electric dipole which fluctuates continuously in time and orientation. The instantaneous dipole in one molecule induces an instantaneous dipole in a second molecule, and interaction of the two synchronized dipoles produces an attractive dispersion energy (known as London energy). In the case of interaction between two neutral, non-polar molecules the dispersion energy is the only contribution to the long-range energy.

When an instantaneous dipole is treated as a charge of $-q$ oscillating about a charge of $+q$ with frequency $\nu_{0}$, the dispersion energy for two identical molecules in their ground states is

$$
\begin{equation*}
U_{\mathrm{disp}}=-\frac{3 \alpha^{2} h \nu_{0}}{4\left(4 \pi \epsilon_{0}\right)^{2} r^{6}} . \tag{4.4.6}
\end{equation*}
$$

For the most general case of the interaction between two polar molecules, the total long-range intermolecular energy is

$$
\begin{equation*}
U=U_{\mathrm{el}}+U_{\mathrm{ind}}+U_{\mathrm{disp}} . \tag{4.4.7}
\end{equation*}
$$

For two neutral polar molecules of the same kind that are free to rotate, the intermolecular energy is

$$
\begin{align*}
U & =-\frac{1}{\left(4 \pi \epsilon_{0}\right)^{2} r^{6}}\left[\frac{2 \mu^{4}}{3 k T}+2 \mu^{2} \alpha+\frac{3 \alpha^{2} h v_{0}}{4}\right] \\
& =-\left(c_{\mathrm{el}}+c_{\mathrm{ind}}+c_{\mathrm{disp}}\right) r^{-6} \tag{4.4.8}
\end{align*}
$$

Table 4.4.1 lists typical values of dipole moments and polarizabilities of some simple molecules and the three coefficients of the $r^{-6}$ term at 300 K . Except for $\mathrm{H}_{2} \mathrm{O}$ which is small and highly polar, the dispersion term dominates the long-range energy. The induction term is always the least significant.

Table 4.4.1. Comparison of contributions to long-range intermolecular energy for like pairs of molecules at 300 K

Molecule $\left.10^{30} \mu(\mathrm{C} \mathrm{m})^{*}\right) \quad 10^{30} \alpha\left(4 \pi \varepsilon_{0}\right)^{-1}\left(\mathrm{~m}^{3}\right) \quad 10^{79} c_{\text {el }}\left(\mathrm{J} \mathrm{m}^{2}\right) \quad 10^{79} c_{\text {ind }}\left(\mathrm{J} \mathrm{m}^{2}\right) \quad 10^{79} c_{\text {disp }}\left(\mathrm{J} \mathrm{m}^{2}\right)$

* Dipole moments are usually given in Debye units. In the rationalized SI system, the unit used is Coulomb meter $(\mathrm{C} \mathrm{m}) ; 1$ Debye $=3.33 \times 10^{-30} \mathrm{C} \mathrm{m}$.

The magnitudes of the three attractive components of the intermolecular energy per mole of gas of some simple molecules are compared in Table 4.4.2, along with the bond energy of the polyatomic species and the enthalpy of sublimation ( $\Delta H_{\mathrm{s}}^{\circ}$ ). The calculation is based on the assumption that the molecules interact in pairs at a separation $\delta$ where the total potential energy $U(\delta)=0$.

Table 4.4.2. Intermolecular energies, bond energies and enthalpies of sublimation for some simple molecules

## Fig. 4.4.1.

Lennard-Jones 12-6 potentials: $V(r)=0$ at $r=\delta ; V(r)=-\varepsilon$ at $r=r_{\mathrm{e}}=2^{1 / 6} \delta$.

It must be emphasized that the above discussion of long-range attractive interactions is very much simplified. A rigorous treatment of the subject is obviously very complicated, or even impossible if the molecules of interest are large and have complex structures.

### 4.4.2 Intermolecular potentials and van der Waals radii

A widely used energy function $V$ that describes intermolecular interaction as a function of intermolecular separation $r$ is the Lennard-Jones 12-6 potential:

$$
\begin{equation*}
V(r)=4 \varepsilon\left[(\delta / r)^{12}-(\delta / r)^{6}\right] \tag{4.4.9}
\end{equation*}
$$

The resulting potential energy curve is shown in Fig. 4.4.1 in which $r_{\mathrm{e}}$ is the equilibrium distance.

Some values for the parameters $\varepsilon$ (usually given as $\varepsilon / k$, where $k$ is Boltzmann's constant) and $\delta$ are given in Table 4.4.3. For simple and slightly polar substances, $\varepsilon$ and $\delta^{3}$ are approximately proportional to the critical temperature $T_{\mathrm{C}}$ and the critical volume $V_{\mathrm{C}}$, respectively.

Crystal structure data show that intermolecular nonbonded distances between pairs of atoms vary over a very narrow range. In the absence of hydrogen

${ }^{\dagger}$ Taken from A. Bondi, J. Phys. Chem. 68, 441-451 (1964); 70, 3006-3007 (1966).
bonding and donor-acceptor bonding, the contact between $\mathrm{C}, \mathrm{N}$, and O atoms is around 370 pm for a wide variety of compounds. This observation leads to the concept of van der Waals radii ( $r_{\mathrm{vdw}}$ ) for atoms, which can be used to calculate average minimum contacts between atoms belonging to neighboring molecules in a condensed phase. The $r_{\mathrm{vdw}}$ values of some common elements are show in Table 4.4.4. The van der Waal radius of an atom is close to the $\delta$ parameter of the Lennard-Jones 12-6 potential function, and it can also be correlated with the size of the outermost occupied atomic orbital. For instance, a carbon 2 p orbital enclosing $99 \%$ of its electron density extends from the nucleus to about 190 pm , as compared to $r_{\mathrm{vdw}}=170 \mathrm{pm}$ for carbon.

## Computational Chemistry

### 5.1 Introduction

Traditionally chemistry is an experimental science and, for a long time, mathematics played only a very minor role. For many decades, in order to justify doing computational chemistry, it was almost obligatory to start a talk or preface a book on theoretical chemistry by quoting P. A. M. Dirac (1902-84), one of the greatest physicists of the last century:

The underlying physical laws necessary for the mathematical theory of a large part of physics and the whole of chemistry are thus completely known, and the difficulty is only that the exact application of these laws leads to equations much too complicated to be soluble.

Dirac made this statement in 1929, when he was only 27 years old. He was at the University of Cambridge where he was appointed to the chair once occupied by Sir Isaac Newton. In a way, this statement by Dirac reflects a good news bad news situation: The good news is that we know how to do it in theory, and the bad news is that we cannot do it in practice!

The physical laws and the mathematical theory Dirac referred to in the aforementioned quote were, of course, the essence of quantum theory, which is briefly described in Chapter 1. As we recall, when we treat a chemical problem computationally, we are usually confronted by the task of solving the Schrödinger equation

$$
\hat{H} \psi=E \psi
$$

where $\hat{H}$, the Hamiltonian operator, is a mathematical entity characteristic of the system under study. In other words, in this equation, $\hat{H}$ is a known quantity, while $\psi$ and $E$ are the unknowns to be determined. Once we get $E$, we know the electronic energy of the system; once we get $\psi$, we have an idea of how the electrons are distributed in a molecule. From these solutions, useful information regarding the system under study, such as structure, energetics, and reactivity, may be obtained, or at least inferred.

It is important that the energy $E$ of the system is one of the solutions of the Schrödinger equation. As we mentioned in Chapter 3, atoms and molecules are rather "simple-minded" species. Their behavior is entirely dictated by the energy factor. For instance, two atoms will combine to form a molecule if the formation leads to a lowering in energy. Also, a reaction will proceed spontaneously
if again there is a lowering in energy. If a reaction does not take place spontaneously, we can still "kick-start" it by supplying energy to it. Hence, energy is the all important property if we wish to understand or predict the behavior of a molecular species.

As early as the 1930s, physicists and chemists knew that solving the Schrödinger equation held the key to understanding the nature of bonding and the reactivity of molecules. However, the task remained to be mathematically daunting for more than half of a century. Indeed, at the beginning, drastic approximations (such as those used in the Hückel molecular orbital theory introduced in Chapter 3) were made in order to make the problem solvable. Consequently, the results obtained in such a manner were at best qualitative. After decades of work on the development of theoretical models as well as the related mathematics, along with the concomitant increase in computing power made possible by faster processors and enormous data storage capacity, chemists were able to employ calculations to solve meaningful chemical problems in the latter part of the last century. At the present stage, in many cases we can obtain computational results almost as accurate as those from experiments, and such findings are clearly useful to experimentalists. As mentioned in Chapter 1, an indication that theoretical calculations in chemistry have been receiving increasing attention in the scientific community was the award of the Nobel Prize to W. Kohn and J. A. Pople for their contributions to quantum chemistry. It is of interest to note that, in his Nobel lecture, Pople made reference to the Dirac statement mentioned earlier.

The title of this chapter is clearly too ambitious: it can easily be the title of a series of monographs. In fact, the aim of this chapter is confined to introducing the kind of results that may be obtained from calculations and in what way calculations can complement experimental research. Hence, the discussion is essentially qualitative, with practically all the theoretical and mathematical details omitted.

### 5.2 Semi-empirical and ab initio methods

For a molecule composed of $n$ atoms, there should be $3 n-6$ independent structural parameters (bond lengths, bond angles, and dihedral angles). This number may be reduced somewhat if symmetry constraint is imposed on the system. For instance, for $\mathrm{H}_{2} \mathrm{O}$, there are three structural parameters (two bond lengths and one bond angle). But if $\mathrm{C}_{2 \mathrm{v}}$ symmetry (point groups will be introduced in Chapter 6) is assumed for the molecule, which is entirely reasonable, there will only be two unique parameters (one bond length and one bond angle). The electronic energy of the molecule is then a function of these two parameters; when these parameters take on the values of the equilibrium bond length and bond angle, the electronic energy is at its minimum. There are many cases where symmetry reduces the number of structural parameters drastically. Take benzene as an example. For a 12 -atom molecule with no symmetry, there will be 30 parameters. On the other hand, if we assume the six $\mathrm{C}-\mathrm{H}$ units form a regular hexagon, then there will be only two independent parameters, the $\mathrm{C}-\mathrm{C}$ and $\mathrm{C}-\mathrm{H}$ bond lengths. The concepts of symmetry will be discussed in the next chapter.

## Fundamentals of Bonding Theory

There are two general approaches to solving the Schrödinger equation of a molecular system: semi-empirical and ab initio methods. The semi-empirical methods assume an approximate Hamiltonian operator and the calculations are further simplified by approximating integrals with various experimental data such as ionization energies, electronic spectral transition energies, and bond energies. An example of these methods is the Hückel molecular orbital theory described in Chapter 3. When applied to conjugated polyenes, this method uses a one-electron Hamiltonian and treats the Coulomb integral $\alpha$ and resonance integral $\beta$ as adjustable parameters.

On the other hand, ab initio (meaning "from the beginning" in Latin) methods use a "correct" Hamiltonian operator, which includes kinetic energy of the electrons, attractions between electrons and nuclei, and repulsions between electrons and those between nuclei, to calculate all integrals without making use of any experimental data other than the values of the fundamental constants. An example of these methods is the self-consistent field (SCF) method first introduced by D. R. Hartree and V. Fock in the 1920s. This method was briefly described in Chapter 2, in connection with the atomic structure calculations. Before proceeding further, it should be mentioned that ab initio does not mean "exact" or "totally correct." This is because, as we have seen in the SCF treatment, approximations are still made in ab initio methods.

Another approach closely related to the ab initio methods that has gained increasing prominence in recent years is the density functional theory (DFT). This method bypasses the determination of the wavefunction $\psi$. Instead, it determines the molecular electronic probability density $\rho$ directly and then calculates the energy of the system from $\rho$.
$A b$ initio and DFT calculations are now routinely applied to study molecules of increasing complexity. Sometimes the results of these calculations are valuable in their own right. But more often than not these results serve as a guide or as a complement to experimental work. Clearly computational chemistry is revolutionizing how chemistry is done. In the remaining part of this chapter, the discussion will be devoted to $a b$ initio and DFT methods.

An $a b$ initio calculation is defined by two "parameters": the (atomic) basis functions (or basis sets) employed and the level of electron correlation adopted. These two topics will be described in some detail (and qualitatively) in the next two sections.

### 5.3 Basis sets

The basis sets used in ab initio calculations are composed of atomic functions. Pople and co-workers have devised a notation for various basis sets, which will be used in the following discussion.

### 5.3.1 Minimal basis set

A minimal basis set consists of just enough functions required to accommodate all the filled orbitals in an atom. Thus, for hydrogen and helium, there is only one s-type function; for elements lithium to neon, this basis set has 1 s , 2 s , and

2 p functions (making a total of five); and so on. The most popular minimal basis set is called STO-3G, where three Gaussian functions (of the form $r^{n-1} \mathrm{e}^{-\alpha r^{2}}$ ) are used to represent one Slater-type orbital (STO, which has the general form of $r^{n-1} \mathrm{e}^{-\alpha r}$ ).

The STO-3G basis set does surprisingly well in predicting molecular geometries, even though it has been found that the success is partly due to a fortuitous cancellation of errors. On the other hand, not surprisingly, the energetics results obtained using minimal basis sets are not very good.

### 5.3.2 Double zeta and split valence basis sets

In order to have a better basis set, we can replace each STO of a minimal basis set by two STOs with different orbital exponent $\zeta$ (zeta). This is known as a double zeta basis set. In this basis, there is a linear combination of a "contracted" function (with a larger zeta) and a "diffuse" function (with a smaller zeta) and the coefficients of these combinations are optimized by the SCF procedure. Using $\mathrm{H}_{2} \mathrm{O}$ as an example, a double zeta set has two 1s STOs on each H , two 1s STOs, two 2 s STOs, two $2 \mathrm{p}_{x}$, two $2 \mathrm{p}_{y}$ and two $2 \mathrm{p}_{z}$ STOs on oxygen, making a total of 14 basis functions.

If only valence orbitals are described by double zeta basis, while the inner shell (or core) orbitals retain their minimal basis character, a split valence basis set is obtained. In the early days of computational chemistry, the $3-21 \mathrm{G}$ basis was fairly popular. In this basis set, the core orbitals are described by three Gaussian functions. The valence electrons are also described by three Gaussians: the inner part by two Gaussians and the outer part by one Gaussian. More recently, the popularity of this basis set is overtaken by the $6-31 \mathrm{G}$ set, where the core orbitals are a contraction of six Gaussians, the inner part of the valence orbitals is a contraction of three Gaussians, and the outer part is represented by one Gaussian.

Similarly, the basis set can be further improved if three STOs (with three different zetas, of course) are used to describe each orbital in an atom. Such a basis is called a triple zeta set. Correspondingly, the 6-311G set is a triplesplit valence basis, with the core orbitals still described by six Gaussians and the valence orbitals split into three functions described by three, one, and one Gaussians, respectively.

### 5.3.3 Polarization functions and diffuse functions

The aforementioned split valence (or double zeta) basis sets can be further improved if polarization functions are added to the mix. The polarization functions have a higher angular momentum number $\ell$; so they correspond to p orbitals for hydrogen and helium and d orbitals for elements lithium to neon, etc. So if we add d orbitals to the split valence $6-31 \mathrm{G}$ set of a non-hydrogen element, the basis now becomes $6-31 \mathrm{G}(\mathrm{d})$. If we also include p orbitals to the hydrogens of the $6-31 \mathrm{G}(\mathrm{d})$ set, it is then called $6-31 \mathrm{G}(\mathrm{d}, \mathrm{p})$.

Why may the inclusion of polarization functions improve the quality of the basis set? Let us take the hydrogen atom, which has a symmetrical electronic distribution, as an example. When a hydrogen atom is bonded to another atom,

Fig. 5.3.1.
The addition of a polarization functions yields a distorted, but more flexible, orbital.
(a)

(b)

its electronic distribution will be attracted toward the other nucleus. Such a distortion is similar to mixing a certain amount of p orbital to the hydrogen's 1s orbital, yielding a kind of sp hybrid, as illustrated in Fig. 5.3.1(a). For a p orbital of a carbon atom, mixing in some amount of $d$ orbital will also cause a distortion (or polarization) of its electronic distribution, as shown in Fig. 5.3.1(b). It is not difficult to see that the addition of polarization functions to a basis set improves its flexibility to describe certain bonding situations. For example, the $6-31 \mathrm{G}(\mathrm{d}, \mathrm{p})$ set is found to describe the bonding in systems with bridging hydrogen atoms particularly well.

The basis sets discussed so far are suitable for systems where electrons are tightly bound. Hence they are not adequate to describe anions where the extra electron is usually quite loosely held. Indeed, even the very large basis sets such as $6-311 \mathrm{G}(\mathrm{d}, \mathrm{p})$ do not have functions that have significant amplitude far away from the nucleus. To remedy this situation, diffuse functions are added to the basis sets. The additional functions are described as diffuse because they have fairly small (on the order of $10^{-2}$ ) zeta values. If we add diffuse functions to the non-hydrogen atoms of the $6-31 \mathrm{G}(\mathrm{d}, \mathrm{p})$ set, the basis now becomes 6 $31+\mathrm{G}(\mathrm{d}, \mathrm{p})$. If we add diffuse functions to the hydrogens of the $6-31+\mathrm{G}(\mathrm{d}, \mathrm{p})$ set, it is now called $6-31++G(d, p)$.

With the addition of polarization functions and/or diffuse functions to the basis sets, the Pople notation can become rather cumbersome. For example, the $6-311++\mathrm{G}(3 \mathrm{df}, 2 \mathrm{pd})$ set has a single zeta core and triple zeta valence shell, diffuse functions for all the atoms. Regarding polarized functions, there are three sets of $d$ functions and one set of $f$ functions on the non-hydrogens and two sets of $p$ functions and one set of $d$ orbitals on the hydrogens.

Before leaving this topic, it should be mentioned that, in addition to the (Pople) basis sets discussed so far, there are others as well. The more popular ones include the Dunning-Huzinaga basis sets, correlation consistent basis sets, etc. These functions will not be described here.

### 5.4 Electron correlation

The SCF method, or the Hartree-Fock (HF) theory, assumes that each electron in a molecule moves in an average potential generated by the nuclei and the remaining electrons. This assumption is flawed in that it ignores electron correlation. What is electron correlation? Simply put, and as introduced in our
discussion in the Introduction, it is the tendency for electrons to avoid each other in an atom or in a molecule. Electrons do not like each other and wish to stay as far apart as possible in order to lower the energy of the system. Since the HF theory neglects electron correlation, correlation energy is defined as the difference between the Hartree-Fock energy and the exact energy.

There are various ways to account for the electron correlation effects. In the following we will classify these methods into three groups: configuration interaction, perturbation, and coupled cluster methods.

### 5.4.1 Configuration interaction

In our treatment on the hydrogen molecule, we mentioned that the ground state wavefunction can be improved if the ground configuration $\sigma_{1 \mathrm{~s}}^{2}$ function is admixed with a certain amount of the excited configuration $\sigma_{1 \mathrm{~s}}^{* 2}$ wavefunction. Such a method is called configuration interaction (CI), as these two configurations interact with each other (to lower the energy of the system). Note that another excited configuration, $\sigma_{1 \mathrm{~s}}^{1} \sigma_{1 \mathrm{~s}}^{* 1}$, cannot take part in the interaction with the two aforementioned configurations. This is because $\sigma_{1 \mathrm{~s}}^{1} \sigma_{1 \mathrm{~s}}^{* 1}$ does not have the proper symmetry properties, even though its energy is lower than that of $\sigma_{1 \mathrm{~s}}^{* 2}$.

Clearly more than one excited configuration can take part in CI. A full CI is the most complete treatment possible within the limitation of the basis set chosen. In most cases, a full CI is prohibitively expensive to carry out and we need to limit the excited states considered. If we consider only those wavefunctions that differ from the HF ground state wavefunction by one single spin orbital, we are said to be doing a configuration interaction singles (CIS) calculation. Similarly, there are those calculations that involve double substitutions (configuration interaction doubles, CID). Sometimes even a full CIS or CID calculation can be very difficult. In that case, we can restrict the unoccupied molecular orbitals taking part in the interaction. If we combine CIS and CID, we will then have configuration interaction singles and doubles (CISD). Still higher levels of CI treatments include CISDT and CISDTQ methods, where T and Q denote triple and quadruple excitations, respectively. At this point, it is convenient to introduce the following notation: a CISD calculation with the $6-31 \mathrm{G}(\mathrm{d})$ basis set is simply written as CISD/6-31G(d). Other types of calculations using different kinds of basis functions may be written in a similar manner. Furthermore, the longer notation CISD/6-311++G(d,p)//HF/6-31G(d) signifies an energy calculation at the CISD level with the $6-311++G(d, p)$ basis set using a molecular geometry optimized at the HF level with the $6-31 \mathrm{G}(\mathrm{d})$ basis. In this example, the computationally expensive geometry optimization is done at the lower level of theory of $\mathrm{HF} / 6-31 \mathrm{G}(\mathrm{d})$, while a "single-point" calculation at the higher level of theory of CISD/6-311++G(d,p) is carried out in order to obtain a more reliable energetic value.

In the CI methods mentioned so far, only the mixing coefficients of the excited configurations are optimized in the variational calculations. If we optimize both the coefficients of the configurations and those of the basis functions, the method is called MCSCF, which stands for multiconfiguration self-consistent field calculation. One popular MCSCF technique is the complete active-space

## Fundamentals of Bonding Theory

SCF (CASSCF) method, which divides all the molecular orbitals into three sets: those doubly occupied orbitals which do not take part in the CI calculations, those vacant orbitals which also do not participate in the CI exercise, and those occupied orbitals and vacant orbitals that form the "active space." The list of configurations that take part in the CI calculation can be generated by considering all possible substitutions of the active electrons among the active orbitals.

Finally, it should be stressed again that CI calculations are variational; i.e., the energy obtained cannot be lower than the exact energy, as stipulated by the variational principle.

### 5.4.2 Perturbation methods

Perturbation theory is a standard approximation method used in quantum mechanics. Early in 1930s, C. Møller and M. S. Plesset (MP) applied this method to treat the electron correlation problem. They found that, using the HF wavefunction as the zeroth-order wavefunction, the sum of the zeroth-order and first-order energies correspond to the HF energy. So the electron correlation energy is the sum of the second-order, third-order, fourth-order, etc., corrections. Even though these methods have long been available in the literature, the second-order (MP2) energy correction was not routinely calculated until the 1980s. Currently, even third-order (MP3) and fourth-order (MP4) corrections have become very common.

Because of its computational efficiency and good results for molecular properties, notably structural parameters, the MP2 level of theory is one of the most popular methods to include correlation effects on computed molecular properties. The other widely applied method is the density functional method, which will be introduced later.

Unlike the CI methods, which are variational, the MP corrections are perturbational. That is, they can in practice lead to an energy that is lower than the exact energy. In addition, an analysis of the trends in the MP2, MP3, and MP4 energies for many systems indicates that the convergence of perturbation theory is slow or even oscillatory.

### 5.4.3 Coupled-cluster and quadratic configuration interaction methods

Another way to improve the HF description is the coupled-cluster (CC) approach, where the CC wavefunction $\psi_{\mathrm{cc}}$ is written as an exponential of a cluster operator $\hat{T}$ working on the HF wavefunction $\psi_{0}$

$$
\begin{equation*}
\psi_{\mathrm{cc}}=\mathrm{e}^{\hat{T}_{T}} \psi_{0}=\left(\hat{T}_{1}+\hat{T}_{2}+\hat{T}_{3}+\ldots\right) \psi_{0} \tag{5.4.1}
\end{equation*}
$$

where $\hat{T}_{1}$ creates single excitations, $\hat{T}_{2}$ creates double excitations, and so on. Experience shows that the contribution of $\hat{T}_{i}$ decreases rapidly after $i=2$. Hence when a CC calculation ends after $i=2$, we have the coupled-cluster singles and doubles (CCSD) method. If we go further to include the $\hat{T}_{3}$ terms, we then have the CCSDT method, where all the triples are also involved in the calculation. Note that the CC methods introduced here are not variational.

Currently the full CCSDT model is far too expensive for routine calculations. To save time, we first carry out a CCSD calculation, which is then followed by a computation of a perturbative estimate of the triple excitations. Such an approximate method is called $\operatorname{CCSD}(\mathrm{T})$.

In the 1980s, Pople and co-workers developed the non-variational quadratic configuration interaction (QCI) method, which is intermediate between CC and CI methods. Similar to the CC methods, QCI also has the corresponding QCISD and $\operatorname{QCISD}(\mathrm{T})$ options. Both the $\operatorname{CCSD}(\mathrm{T})$ and $\operatorname{QCISD}(\mathrm{T})$ have been rated as the most reliable among the currently computationally affordable methods.

### 5.5 Density functional theory

As mentioned earlier, density functional theory (DFT) does not yield the wavefunction directly. Instead it first determines the probability density $\rho$ and calculates the energy of the system in terms of $\rho$. Why is it called density functional theory and what is a functional anyway? We can define functional by means of an example. The variational integral $E(\varphi)=\int \varphi \hat{H} \varphi \mathrm{~d} \tau / \int \varphi \varphi \mathrm{d} \tau$ is a functional of the trial wavefunction $\varphi$ and it yields a number (with energy unit) for a given $\varphi$. In other words, a functional is a function of a function. So, in the DFT theory, the energy of the system is a functional of electron density $\rho$, which itself is a function of electronic coordinates.

In the 1960s, Kohn and co-workers showed that for molecules with a nondegenerate ground state, the energy and other electronic properties can be determined in terms of the electronic probability density $\rho$ of the ground state. It was later proved this is also true for systems with degenerate ground states. Soon afterwards, physicists applied the first version of DFT (something called local spin density approximation, LSDA) to investigate the electronic structure of solids and it quickly became a popular method for studying solids. However, chemists were slow to pick up this method, probably because of numerical difficulties. In the early 1980s, after the numerical difficulties were essentially resolved, DFT LSDA calculations were applied to molecules and good results were obtained for molecular species, especially for structural parameters. After about ten years of advancement on this theory, DFT methods were added to the popular software packages such as Gaussian, and since then DFT calculations have experienced an explosive growth.

As in the case of $a b$ initio calculations, which range from the rather crude HF method to the very sophisticated $\operatorname{CCSD}(\mathrm{T})$ or $\operatorname{QCISD}(\mathrm{T})$ method, DFT also offers a variety of functionals for users to opt for. More commonly used DFT levels of theory include local exchange and correlation functional SVWN (a synonym for LSDA in the Gaussian package) and its variant SVWN5, as well as gradient-corrected functional BLYP and hybrid functionals B3LYP and B3PW91. Among these functionals, B3LYP appears to be the most popular one. In addition, it is noted that DFT methods also make use of the kind of basis sets that have been employed in ab initio calculations. So a typical DFT calculation has a notation such as B3LYP/6-31G(d).

One important reason for DFT's ever-increasing popularity is that even the most elementary calculation includes correlation effects to a certain extent but

## Fundamentals of Bonding Theory

takes roughly the same amount of time as a HF calculation, which does not take correlation into account. Indeed, there are some DFT advocates who believe DFT will replace HF as well as those correlation methods based on the HF wavefunctions (such as MP, CC, and CI), but whether this will come to fruition remains to be seen.

### 5.6 Performance of theoretical methods

How good are the ab initio and DFT methods in providing an adequate treatment of a molecule of interest? Clearly, a proper answer to this and related questions requires at least a major review article, if not a monograph (or maybe even a series of monographs). Still, it is useful to have a clear idea of the applicability and limitation of each chosen method. In this section, we concentrate on the performance of various theoretical methods in yielding the geometric parameters (bond lengths, bond angles, and dihedral angles) as well as the vibrational frequencies of a given molecule. In the next section, we shall discuss various composite methods, i.e., those that approximate the energy of a very high level of theory with a combination of lower level energetic calculations. In addition, the (energetic) performance of these methods will be assessed.

The structural parameters and vibrational frequencies of three selected examples, namely, $\mathrm{H}_{2} \mathrm{O}, \mathrm{O}_{2} \mathrm{~F}_{2}$, and $\mathrm{B}_{2} \mathrm{H}_{6}$, are summarized in Tables 5.6.1 to 5.6.3, respectively. Experimental results are also included for easy comparison. In each table, the structural parameters are optimized at ten theoretical levels, ranging from the fairly routine $\mathrm{HF} / 6-31 \mathrm{G}(\mathrm{d})$ to the relatively sophisticated $\operatorname{QCISD}(\mathrm{T}) / 6-31 \mathrm{G}(\mathrm{d})$. In passing, it is noted that, in the last six correlation methods employed, $\operatorname{CISD}(\mathrm{FC}), \operatorname{CCSD}(\mathrm{FC}), \ldots, \mathrm{QCISD}(\mathrm{T})(\mathrm{FC})$, "FC" denotes the "frozen core" approximation. In this approximation, only the correlation energy associated with the valence electrons is calculated. In other words, excitations out of the inner shell (core) orbitals of the molecule are not considered. The basis of this approximation is that the most significant chemical changes occur in the valence orbitals and the core orbitals remain essentially intact. On

Table 5.6.1. Structural parameters (in pm and degrees) and vibrational frequencies (in $\mathrm{cm}^{-1}$ ) of $\mathrm{H}_{2} \mathrm{O}$ calculated at various $a b$ initio and DFT levels

| Level of theory | O-H | H-O-H | $v_{1}\left(\mathrm{~A}_{1}\right)$ | $\nu_{2}\left(\mathrm{~A}_{1}\right)$ | $\nu_{3}\left(\mathrm{~B}_{2}\right)$ |

the other hand, in one of the methods listed in these tables, MP2(Full), "Full" indicates that all orbitals, both valence and core, are included in the correlation calculation.

When these tables are examined, it is found that, for structural parameters, most theoretical methods yield fair to excellent results when compared to the experimental data. Also, in general (though not always true), the agreement between calculated and experimental values improves gradually as we go to more and more sophisticated methods. On the other hand, it is seen that, for $\mathrm{O}_{2} \mathrm{~F}_{2}$, one level of theory, MP2(Full)/6-311+G(d,p), gives highly unsatisfactory results. In particular, the calculated O-F bond ( 185.0 pm ) is about 28 pm too long, while the $\mathrm{O}-\mathrm{O}$ bond ( 112.9 pm ) is about 10 pm too short, giving rise to an erroneous bonding description of $\mathrm{F}^{\delta+} \ldots{ }^{\delta-} \mathrm{O}-\mathrm{O}^{\delta-} \ldots{ }^{\delta+} \mathrm{F}$. Since there is no way to tell beforehand which method will lead to unacceptable results for a particular chemical species, it is often advantageous to carry out a series of calculations to make certain that convergence is attained. In Tables 5.6.1 to 5.6.3, the last five levels of theory give essentially the same results for each molecule, which lends credence to validity of the calculations. In summary, the calculated bond lengths can be within $\pm 2 \mathrm{pm}$ of the experimental value, while the corresponding accuracy for bond angles and dihedral angles is about $\pm 2^{\circ}$. For some molecules, their energies may not be very sensitive to the change of some dihedral angles. In such cases, the calculated dihedral angles may be less reliable.

Let us now turn our attention to the calculated vibrational frequencies of $\mathrm{H}_{2} \mathrm{O}, \mathrm{O}_{2} \mathrm{~F}_{2}$, and $\mathrm{B}_{2} \mathrm{H}_{6}$. First of all, it should be mentioned that the calculation of these frequencies is a computationally "expensive" task. As a result, high-level calculations of vibrational frequencies are performed only for relatively small systems. When the calculated frequencies are examined and compared with experimental data, it is found that the former are often larger than the latter. Indeed, after an extensive comparison between calculation and experiment, researchers have arrived at a scaling factor of 0.8929 for the HF/6-31G(d) frequencies. In other words, vibrational frequencies calculated at this level are

[^0]on the average about $10 \%$ too large. On the other hand, the scaling factor for the MP2(Full)/6-31G(d) frequencies is 0.9661 . While this scaling factor is very close to 1 , the absolute discrepancy can still be in the range of $100-200 \mathrm{~cm}^{-1}$, as some vibrational frequencies, especially those involving the stretching motions of X-H bonds, have energies of a few thousand wavenumbers.

### 5.7 Composite methods

It has long been a computational chemist's goal to have a method at his disposal that would yield energetic values that have "chemical accuracy," which translates to an uncertainty of $\pm 1 \mathrm{kcal} \mathrm{mol}^{-1}$, or about $\pm 4 \mathrm{~kJ} \mathrm{~mol}^{-1}$. Currently, high-level methods such as QCISD(T), CCSD(T), or MP6 with very large basis sets may be able to achieve this. However, such calculations are only possible for very small systems. To get around this difficulty, composite methods that would allow calculations on systems with a few non-hydrogen atoms have been proposed.

Since 1990, Pople and co-workers have been developing a series of Gaussian$n$ (Gn) methods: G1 in 1989, G2 in 1990, G3 in 1998, and G4 in 2007. In addition, a number of variants of the G 2 and G 3 methods have also been proposed. Since G1 did not last very long, and G4 has not yet been widely used, only G2 and G3 will be discussed here. The G2 method is an approximation for the level of theory of $\operatorname{QCISD}(\mathrm{T}) / 6-311+\mathrm{G}(3 \mathrm{df}, 2 \mathrm{p})$. In this method, instead of directly doing such an expensive calculation, a series of less timeconsuming single-points are carried out and the G2 energy is obtained by applying additivity rules to the single-points and including various corrections such as zero-point vibrational energy (ZPVE) correction and empirical "higher level" correction (HLC). On the other hand, the G3 method is an approximation for QCISD(T)/G3Large, where G3Large is an improved version of the aforementioned $6-311+G(3 d f, 2 p)$ basis set. Once again, for the G3 method, a series of single-points are performed (which are less expensive than the G2 singlepoints) and various corrections such as ZPVE, HLC, and spin-orbit interaction (newly included for G3) are taken into account.

To test the accuracy of the G2 method, Pople and co-workers used a set of very accurate experimental data consisting of 55 atomization energies, 38 ionization energies, 25 electron affinities, and 7 proton affinities of small molecules. Later, these workers also proposed an extended G2 test set of 148 gas-phase heats of formation. For this extended set of data, the average absolute errors for G2 and G3 are 6.7 and $3.8 \mathrm{~kJ} \mathrm{~mol}^{-1}$, respectively. Furthermore, it is noted that G3 is actually less expensive than G2, which shows the importance of designing a basis set judiciously. Experience indicates that, for systems of up to 10 nonhydrogen atoms, the expected absolute uncertainty for G2/G3 is about 10 to 15 $\mathrm{kJ} \mathrm{mol}{ }^{-1}$.

In addition to the Gaussian- $n$ methods, there is a variety of CBS (complete basis set) methods, including CBS-Q, CBS-q, and CBS-4, which have also enjoyed some popularity among computational chemists. In these methods, special procedures are designed to estimate the complete-basis-set limit energy by extrapolation. Similar to the G $n$ methods, single-point calculations are also
required in the CBS methods. For the aforementioned extended G2 test set of 148 heats of formation, the absolute errors for the CBS-Q, CBS-q, and CBS-4 models are $6.7,8.8$, and $13.0 \mathrm{~kJ} \mathrm{~mol}^{-1}$, respectively.

Another series of composite computational methods, Weizmann- $n(\mathrm{~W} n)$, with $n=1-4$, have been recently proposed by Martin and co-workers: W1 and W2 in 1999 and W3 and W4 in 2004. These models are particularly accurate for thermochemical calculations and they aim at approximating the CBS limit at the $\operatorname{CCSD}(\mathrm{T})$ level of theory. In all $\mathrm{W} n$ methods, the core-valence correlations, spin-orbit couplings, and relativistic effects are explicitly included. Note that in G2, for instance, the single-points are performed with the frozen core (FC) approximation, which was discussed in the previous section. In other words, there is no core-valence effect in the G2 theory. Meanwhile, in G3, the corevalence correlation is calculated at the MP2 level with a valence basis set. In the $\mathrm{W} n$ methods, the core-valence correlation is done at the more advanced $\operatorname{CCSD}(\mathrm{T})$ level with a "specially designed" core-valence basis set.

In the W3 and W4 methodologies, connected triple and quadruple correlations are incorporated in order to correct the imperfection of the $\operatorname{CCSD}(\mathrm{T})$ wavefunction. As a result, the very sophisticated W3 and W4 methods are only applicable to molecular systems with no more than three non-hydrogen atoms. For the extended G2 test set, the uncertainty for W 1 is $\pm 1.98 \mathrm{~kJ} \mathrm{~mol}^{-1}$. On the other hand, for the original G2 test set, the absolute errors for the W2 and W3 methods are 1.50 and $0.89 \mathrm{~kJ} \mathrm{~mol}^{-1}$, respectively. Tested with a very small test data set consisting of 19 atomization energies, the respective absolute errors for the W2, W3, W4a, and W4b methods are $0.96,0.64,0.60$, and $0.71 \mathrm{~kJ} \mathrm{~mol}^{-1}$, where W4a and W4b are two variants of the W4 method.

Before presenting some case examples, we note that $a b$ initio calculations are usually carried out for individual molecules (or ions or radicals). Hence, strictly speaking, theoretical results should only be compared with gas-phase experimental data. Cautions should be taken when computational results are compared with data obtained from experiments in the solid state, liquid or solution phase.

### 5.8 Illustrative examples

In the foregoing discussion, the computational methods currently being used are very briefly introduced. Indeed, in most cases, only the language and terminology of these methods are described. Despite this, we can now use a few actual examples found in the literature to see how computations can complement experiments to arrive at meaningful conclusions.

### 5.8.1 A stable argon compound: HArF

Up to the year of 2000, no compound of helium, neon, or argon was known. However, that did not discourage theoretical chemists from nominating candidate compounds to the synthetic community. In a conference in London in August 2000, there were two poster papers with the following intriguing titles: "Prediction of a stable helium compound: HHeF" by M. W. Wong and "Will

HArF be the first observed argon compound?" by N. Runeberg and co-workers. The formal paper by Wong was published in July 2000, which includes the calculated bond lengths of the linear triatomics $\mathrm{HHeF}, \mathrm{HNeF}$, and HArF , as well as the vibrational frequencies of these molecules. Interestingly, one month later, Runeberg and co-workers published an experimental article reporting the detection of HArF. This compound was made by the photolysis of HF in a solid argon matrix and then characterized by infrared spectroscopy. It was found that the measured vibrational frequencies were in good agreement with the calculated ones. One year later, calculations of still higher quality on HArF were reported by the Runeberg group.

Before discussing the computational results in more details, let us first consider the bonding of HArF in elementary and qualitative terms. In hindsight, it is perhaps not very surprising that HArF should be a stable molecule, especially since analogous Kr - and Xe-containing compounds are known to exist. In any event, the bonding of HArF may be understood in terms of a three-center four-electron ( $3 c-4 e$ ) bond, as shown in Fig. 5.8.1. In this figure, it is seen that the 1 s orbital of H and the 2 p orbitals of Ar and F combine to form three molecular orbitals: $\sigma, \sigma^{n}$, and $\sigma^{*}$, with bonding, nonbonding, and antibonding characteristics, respectively. Also, the two lower molecular orbitals are filled with electrons, leading to a $3 c-4 e$ bond for this stable molecule.

Let us now consider the calculated results. The calculated bond lengths of HArF are summarized in Table 5.8.1, while the calculated vibrational frequencies, along with the experimental data, are listed in Table 5.8.2.

Examining the results given in these two tables, it is seen that, for this small molecule, very advanced calculations can be carried out. In the tables, all the methods employed have been introduced in the previous sections. For the basis sets, aug-cc-pVnZ stands for augmented correlation consistent polarized valence $n$ zeta, with $n=2-5$ referring to double, triple, quadruple, and quintuple, respectively. Clearly, these basis functions are specially designed for

* Corrected for anharmonicity and matrix effects.
correlated calculations. The bond lengths listed in Table 5.8.1 are very consistent with one another and they should be reliable estimates. Meanwhile, as can be seen from the results in Table 5.8.2, the only physical data of the molecule, the vibrational frequencies, are in good accord with the calculated results, thus leading us to believe that this is indeed a linear molecule. Furthermore, according to these calculations, HArF should be stable in the gas phase as well. This awaits experimental confirmation.

As far as charge distribution is concerned, the charges on $\mathrm{H}, \mathrm{Ar}$, and F have been estimated to be $0.18,0.66$, and -0.74 a.u., respectively. This indicates a significant charge transfer from the F atom to the ArH moiety. In other words, the bonding of this molecule may be portrayed by the ionic description of $\mathrm{HAr}^{\delta+} \mathrm{F}^{\delta-}$. The calculations of both groups also report the reaction profile of the dissociation reaction $\mathrm{HArF} \rightarrow \mathrm{Ar}+\mathrm{HF}$. Both calculations agree that the transition state of this reaction has a bent structure, with $\mathrm{H}-\mathrm{Ar}-\mathrm{F}$ angle of about $105^{\circ}$. The barriers of dissociation calculated by Wong and Runeberg and co-workers are 96 and $117 \mathrm{~kJ} \mathrm{~mol}^{-1}$, respectively. These results indicate that HArF is trapped in a fairly deep potential well. Similarly, Wong reported that, for HHeF , the barrier of dissociation is about $36 \mathrm{~kJ} \mathrm{~mol}^{-1}$. While this potential is not as deep as that of HArF, it is still not insignificant. This may provide an incentive for experimentalists to prepare this compound.

To conclude, HArF represents one of those rare examples for which calculations preceded experiment. In addition, it nicely demonstrates that computational results can play an indispensable role in the characterization and understanding of small molecules.

### 5.8.2 An all-metal aromatic species: $\mathrm{Al}_{4}^{2-}$

Benzene $(\mathrm{CH})_{6}$, of course, is the most prototypal aromatic system. When one or more of the CH groups are replaced by other atom(s), a heterocyclic aromatic system is obtained. Well-known examples include pyridine $\mathrm{N}(\mathrm{CH})_{5}$ and pyrimidine $\mathrm{N}_{2}(\mathrm{CH})_{4}$, while lesser known cases are phosphabenzene $\mathrm{P}(\mathrm{CH})_{5}$ and arsabenzene $\mathrm{As}(\mathrm{CH})_{5}$. There are also systems where the heteroatom is a heavy transition metal; examples include $\mathrm{L}_{n} \mathrm{Os}(\mathrm{CH})_{5}$ and $\mathrm{L}_{n} \operatorname{Ir}(\mathrm{CH})_{5}$.

However, it is rare when all the atoms in an aromatic species are metals. One such system was synthesized in 2001 by A. I. Boldyrev and L.-S. Wang and their colleagues. Using a laser vaporization supersonic cluster source and a $\mathrm{Cu} / \mathrm{Al}$
alloy as the target, these scientists were able to produce the anion $\mathrm{CuAl}_{4}^{-}$. Similarly, when $\mathrm{Al} / \mathrm{Li}_{2} \mathrm{CO}_{3}$ and $\mathrm{Al} / \mathrm{Na}_{2} \mathrm{CO}_{3}$ were used as targets, anions $\mathrm{LiAl}_{4}^{-}$and $\mathrm{NaAl}_{4}^{-}$were prepared, respectively. After these anions were synthesized, their vertical detachment energies (VDEs) were measured by photoelectron spectroscopy. As its name implies, VDE is simply the energy required to detach an electron from a bonding orbital of a species and, during the ionization process, the structure of the species remains unchanged. Subsequently, the VDE data were analyzed with the aid of ab initio calculations.

Before discussing the computational results, we will attempt to understand the bonding involved in the synthesized anions, using the elementary theories introduced in Chapter 3. First of all, it should be noted that the aromatic system referred to above is not the $\mathrm{MAl}_{4}^{-}$anion as a whole. Instead, structurally, the $\mathrm{MAl}_{4}^{-}$anion should be considered as consisting of an $\mathrm{M}^{+}$cation coordinated to a square-planar $\mathrm{Al}_{4}^{2-}$ unit and it is the dianion that has aromatic character. For $\mathrm{Al}_{4}^{2-}$, there are 14 valence electrons and the resonance structures can be easily written:

In other words, for this square-planar dianion, there are four $\sigma$ bonds and one $\pi$ bond, as well as two lone pairs. Hence each Al-Al linkage has a bond order of about $1 \frac{1}{1 / 4}$. Additionally, there are two $\pi$ electrons in this planar ring system, satisfying the $(4 n+2)$-rule for aromatic species.

Now let us turn to the computational results. The structures of the square planar $\mathrm{Al}_{4}^{2-}$, and square pyramidal $\mathrm{LiAl}_{4}^{-}, \mathrm{NaAl}_{4}^{-}$and $\mathrm{CuAl}_{4}^{-}$are shown in Fig. 5.8.2. It is noted that the structure of $\mathrm{CuAl}_{4}^{-}$has been optimized at the MP2/6-311+G(d) level, while the theoretical level for the remaining three species is $\operatorname{CCSD}(\mathrm{T}) / 6-311+G(d)$. When these structures are examined, it is seen that the four-membered ring does not undergo significant structural change upon coordination to a $\mathrm{M}^{+}$cation. This is especially true when the metal is lithium

Fig. 5.8.2.
Optimized structures (with bond lengths in pm) of $\mathrm{LiAl}_{4}^{-}, \mathrm{NaAl}_{4}^{-}, \mathrm{CuAl}_{4}^{-}$, and $\mathrm{Al}_{4}^{2-}$, and the HOMO of $\mathrm{Al}_{4}^{2-}$.

Table 5.8.3. Experimental and calculated vertical electron detachment energies (VDEs, in kJ $\mathrm{mol}^{-1}$ ) for $\mathrm{LiAl}_{4}^{-}, \mathrm{NaAl}_{4}^{-}$, and $\mathrm{CuAl}_{4}^{-}$

| Species | VDE (experimental) | VDE $^{*}$ (calculated) | Molecular orbital involved |
| :--- | :---: | :---: | :---: |
| $\mathrm{LiAl}_{4}^{-}$ | $207.4 \pm 5.8$ | 201.7 | $3 a_{1}$ |
|  | $212.3 \pm 5.8$ | 209.4 | $1 b_{1}$ |
|  | $272.1 \pm 7.7$ | 259.5 | $2 a_{1}$ |
|  | $298.1 \pm 3.9$ | 286.6 | $1 b_{2}$ |
| $\mathrm{NaAl}_{4}^{-}$ | $196.8 \pm 4.8$ | 185.3 | $3 a_{1}$ |
|  | $201.7 \pm 4.8$ | 197.8 | $1 b_{1}$ |
|  | $260.5 \pm 4.8$ | 243.1 | $2 a_{1}$ |
|  | $285.6 \pm 4.8$ | 275.9 | $1 b_{2}$ |
| $\mathrm{CuAl}_{4}^{-}$ | $223.8 \pm 5.8$ | 223.8 | $2 b_{1}$ |
|  | $226.7 \pm 5.8$ | 230.6 | $4 a_{1}$ |
|  | $312.6 \pm 8.7$ | 323.2 | $2 b_{2}$ |
|  | $370.5 \pm 5.8$ | 352.2 | $3 a_{1}$ |

* VDE's are calculated at the theoretical level of OVGF/6-311+G(2df), based on the structures shown in Fig. 5.8.2.
or sodium. When $\mathrm{M}^{+}$is $\mathrm{Cu}^{+}$, there is a change of $0.11 \AA$ in the $\mathrm{Al}-\mathrm{Al}$ bond lengths. Such a relative large change may be due to the fact that $\mathrm{Cu}^{+}$is bigger than $\mathrm{Li}^{+}$or $\mathrm{Na}^{+}$; it may also be due to the fact that the structure of $\mathrm{CuAl}_{4}^{-}$is optimized at a different theoretical level. In any event, the optimized structures of these four species support the argument that $\mathrm{Al}_{4}^{2-}$ is an aromatic species. Also shown in Fig. 5.8.2 is the HOMO of $\mathrm{Al}_{4}^{2-}$, which is very similar to the most stable $\pi$ molecular orbital of benzene shown in Fig. 7.1.12. The only difference is that benzene is a six-membered ring, while $\mathrm{Al}_{4}^{2-}$ is a four-membered ring. Also, while benzene has two more filled delocalized $\pi$ molecular orbitals (making a total of three to accommodate its six $\pi$ electrons), $\mathrm{Al}_{4}^{2-}$ has only one delocalized $\pi$ molecular orbital for its two $\pi$ electrons.

The calculated and experimental VDEs of $\mathrm{LiAl}_{4}^{-}, \mathrm{NaAl}_{4}^{-}$, and $\mathrm{CuAl}_{4}^{-}$are summarized in Table 5.8.3. The calculated VDEs have been obtained using the outer valence Green function (OVGF) method with the $6-311+\mathrm{G}(2 \mathrm{df})$ basis, based on the structures shown in Fig. 5.8.2. The OVGF model is a relatively new method designed to calculate correlated electron affinities and ionization energies. As seen from the table, the agreement between the calculated results and the experimental data is, on the whole, fairly good. Such an agreement is in support of the proposed square-pyramidal structure for the $\mathrm{MAl}_{4}^{-}$anions. The notation for the molecular orbitals shown in the table will be discussed in Chapters 6 and 7.

### 5.8.3 A novel pentanitrogen cation: $\mathrm{N}_{5}^{+}$

Even though nitrogen is a very common and abundant element, there are very few stable polynitrogen species, i.e., those compounds containing only nitrogen atoms. Among the few known examples, dinitrogen, $\mathrm{N}_{2}$, isolated in 1772, is the most familiar. Another one is the azide anion, $\mathrm{N}_{3}^{-}$, which was discovered in 1890. Other species such as $\mathrm{N}_{3}$ and $\mathrm{N}_{4}$, as well as their corresponding cations,
$\mathrm{N}_{3}^{+}$and $\mathrm{N}_{4}^{+}$, have been observed only as free gaseous or matrix-isolated ions or radicals. The only polynitrogen species synthesized on a macroscopic scale thus far is the pentanitrogen cation $\mathrm{N}_{5}^{+}$by Christe and co-workers in 1999.

Before discussing $\mathrm{N}_{5}^{+}$, maybe we should ask why polynitrogen species are so interesting. It is noted that the bond energy of the $\mathrm{N} \equiv \mathrm{N}$ triple bond (in $\mathrm{N}_{2}, 942$ $\mathrm{kJ} \mathrm{mol}^{-1}$ ) is much larger than those of the $\mathrm{N}-\mathrm{N}$ single bond ( $160 \mathrm{~kJ} \mathrm{~mol}^{-1}$ ) and the $\mathrm{N}=\mathrm{N}$ double bond ( $418 \mathrm{~kJ} \mathrm{~mol}^{-1}$ ). In other words, any dissociation of a polynitrogen species to $\mathrm{N}_{2}$ molecules will be highly exothermic. Hence, polynitrogen compounds are potential high-energy density materials (HEDM), which, by definition, have high ratios between the energy released in a fragmentation reaction and the specific weight. Clearly, HEDM have applications as explosives and in rocket propulsion.

The first synthesis of a $\mathrm{N}_{5}^{+}$compound was accomplished in the following straightforward manner:

$$
\mathrm{N}_{2} \mathrm{~F}^{+} \mathrm{AsF}_{6}^{-}+\mathrm{HN}_{3} \xrightarrow[-78^{\circ} \mathrm{C}]{\mathrm{HF}} \mathrm{~N}_{5}^{+} \mathrm{AsF}_{6}^{-}+\mathrm{HF} .
$$

In the authors' words, the product " $\mathrm{N}_{5}^{+} \mathrm{AsF}_{6}^{-}$is a highly energetic, strongly oxidizing material that can detonate violently." Upon synthesizing the compound, low-temperature $\operatorname{Raman}\left(-130^{\circ} \mathrm{C}\right)$ and infrared $\left(-196^{\circ} \mathrm{C}\right)$ spectra were recorded, and high-level ab initio calculations were performed in order to determine the structure of the cation and to make assignments of the spectra.

The structure of the $\mathrm{N}_{5}^{+}$cation, optimized at the $\operatorname{CCSD}(\mathrm{T}) / 6-311+\mathrm{G}(2 \mathrm{~d})$ level, is shown in Fig. 5.8.3. This structure is V-shaped, having two short terminal bonds and two longer inner bonds. With such a structure, it is not difficult to visualize a simple bonding description for the cation. In this bonding picture, which is also shown in the same figure, the hybridization scheme for the central N atom is $\mathrm{sp}^{2}$, while that for its neighboring nitrogen atoms is sp . For the central atom, the exo $\mathrm{sp}^{2}$ hybrid and the $\mathrm{p}_{z}$ orbital are filled by four valence electrons, while the remaining two $\mathrm{sp}^{2}$ hybrids interact with two terminal $\mathrm{N}_{2}$ units to complete the bonding scheme. Based on such a description, we can quickly write down the following resonance structures for the $\mathrm{N}_{5}^{+}$cation:

$\Delta H_{\mathrm{f} 298}=1463 \mathrm{~kJ} \mathrm{~mol}^{-1}$

Fig. 5.8.3.
Optimized V-shape structure (bond lengths in pm and bond angles in degrees) of $\mathrm{N}_{5}^{+}$, and its bonding scheme. The heat of formation is calculated at the G3 level.

Table 5.8.4. Raman and infrared bands (in $\mathrm{cm}^{-1}$ ) of $\mathrm{N}_{5}^{+}$ (in solid $\mathrm{N}_{5}^{+} \mathrm{AsF}_{6}^{-}$) and their assignments based on calculated harmonic frequencies (in $\mathrm{cm}^{-1}$ ) of gaseous $\mathrm{N}_{5}^{+}$

* At the theoretical level of $\operatorname{CCSD}(\mathrm{T}) / 6-311+\mathrm{G}(2 \mathrm{~d})$. The grouptheoretic notation of the vibrational spectra will be made clear in Chapters 6 and 7.

While the three resonance structures may not be of equal importance, it is safe to say that the two terminal $\mathrm{N}-\mathrm{N}$ bonds have a bond order between 2 and 3 , and the remaining two bonds are somewhere between a single bond and a double bond. The optimized bond lengths are in good accord with this description. If, for simplicity, we consider only these three resonance structures and assume they contribute equally, the bond orders of the outer and inner $\mathrm{N}-\mathrm{N}$ bonds are $2^{2 / 3}$ and $1^{1 / 3}$, respectively.

Based on the optimized structure, the harmonic vibrational frequencies of $\mathrm{N}_{5}^{+}$ have been calculated at the $\operatorname{CCSD}(\mathrm{T}) / 6-311+\mathrm{G}(2 \mathrm{~d})$ level, and these results are listed in Table 5.8.4, along with the experimental data. Comparing the experimental and calculated results, we can see that there is fairly good agreement between them, bearing in mind that the calculations are done on individual cations and experimental data are measured in the solid state. Such an agreement lends credence to the structure optimized by theoretical methods.

Before leaving this novel cation, it is of interest to point out that in the literature, four more structures (optimized at the MP2/6-31G(d) level) have been considered for the $\mathrm{N}_{5}^{+}$cation, and these are shown in Fig. 5.8.4. However, as can be seen from the G3 heats of formation listed in Figs. 5.8.3 and 5.8.4 for these five isomers, the V-shaped isomer is by far the most stable. The other four isomers are much less stable by about 500 to $1,000 \mathrm{~kJ} \mathrm{~mol}^{-1}$.

### 5.8.4 Linear triatomics with noble gas-metal bonds

Since the turn of the present century, a series of linear complexes with the general formula $\mathrm{NgMX}(\mathrm{Ng}=\mathrm{Ar}, \mathrm{Kr}, \mathrm{Xe} ; \mathrm{M}=\mathrm{Cu}, \mathrm{Ag}, \mathrm{Au} ; \mathrm{X}=\mathrm{F}, \mathrm{Cl}, \mathrm{Br})$ have been prepared and characterized by physical methods. These complexes were prepared by laser ablation of the metal from its solid and letting the resulting plasma react with the appropriate precursor. The complexes formed were then stabilized in a supersonic jet of argon gas. Characterization of these complexes was carried out mainly by microwave spectroscopy.

$$

Fig. 5.8.4.
Optimized structures (bond lengths in pm and bond angles in degrees) and G3 heats of formation of four other $\mathrm{N}_{5}^{+}$isomers.

The linear structure of NgMX is found to be rigid with small centrifugal distortion constants. (A molecule's centrifugal distortion constant is a measure of its flexibility, and this quantity may be determined from its microwave spectrum.) The $\mathrm{Ng}-\mathrm{M}$ bond lengths are fairly short, and they range from $\sim 225 \mathrm{pm}$ for $\mathrm{Ar}-\mathrm{Cu}, \sim 245 \mathrm{pm}$ for $\mathrm{Ar}-\mathrm{Au}, \sim 260 \mathrm{pm}$ for $\mathrm{Ar}-\mathrm{Ag}, \sim 265 \mathrm{pm}$ for $\mathrm{Kr}-\mathrm{Ag}$, etc. In addition, based on the centrifugal distortion constants, the $\mathrm{Ng}-\mathrm{M}$ stretching frequencies can be estimated and they are found to be above $100 \mathrm{~cm}^{-1}$. Summarized in Table 5.8.5 are the experimental and calculated $\mathrm{Ng}-\mathrm{M}$ bond lengths and stretching frequencies as well as force constants and computed electronic dissociation energies for the $\mathrm{Ng}-\mathrm{M}$ bonds in NgMX complexes. The calculated results were obtained at the MP2 correlated level. The basis set used for F was $6-311 \mathrm{G}(\mathrm{d}, \mathrm{p})$ and those for the remaining elements were of comparable quality (such as triple zeta sets). In the following paragraphs we shall discuss these results in some detail from four different, yet interconnected, perspectives.

## (1) $\mathrm{Ng}-\mathrm{M}$ bond lengths

Comparing the experimental and calculated $\mathrm{Ng}-\mathrm{M}$ bond lengths tabulated in Table 5.8.5, it is seen that the ab initio methods adopted do reproduce this quantity very well. In order to obtain a better understanding of the nature of the $\mathrm{Ng}-\mathrm{M}$ bonds, let us compare these bond lengths with values estimated from

Table 5.8.5. Experimental and calculated (in brackets) $\mathrm{Ng}-\mathrm{M}$ bond lengths and stretching frequencies $v$ as well as computed electronic dissociation energies $D_{\mathrm{e}}$ for the $\mathrm{Ng}-\mathrm{M}$ bonds in NgMX complexes

| NgMX | $\mathrm{Ng}-\mathrm{M}(\mathrm{pm})$ | $\nu(\mathrm{Ng}-\mathrm{M})\left(\mathrm{cm}^{-1}\right)$ | $\nu(\mathrm{M}-\mathrm{X})\left(\mathrm{cm}^{-1}\right)$ | $D_{\mathrm{e}}(\mathrm{kJ} \mathrm{mol}$ |
| :---: | :---: | :---: | :---: | :---: |
|  |  |  |  |  |
| ArCuF | $222(219)$ | $224(228)$ | $621(674)$ | 44 |
| ArCuCl | $227(224)$ | $197(190)$ | $418(456)$ | 33 |
| ArCuBr | $230(226)$ | $170(164)$ | $313(350)$ | - |
| KrCuF | $232(232)$ | $(185)$ | - | 48 |
| ArAgF | $256(256)$ | $141(127)$ | $513(541)$ | 14 |
| ArAgCl | $261(259)$ | $135(120)$ | $344(357)$ | 16 |
| KrAgF | $259(260)$ | $125(113)$ | $513(544)$ | 17 |
| KrAgCl | $264(263)$ | $117(105)$ | $344(352)$ | 15 |
| KrAgBr | $266(269)$ | $106(89)$ | $247(255)$ | 17 |
| XeAgF | $265(268)$ | 130 | - | 43 |
| ArAuF | $239(239)$ | $221(214)$ | $544(583)$ | 55 |
| ArAuCl | $247(246)$ | $198(184)$ | $383(413)$ | 42 |
| ArAuBr | $250(249)$ | $178(165)$ | $264(286)$ | - |
| KrAuF | $246(245)$ | $176(184)$ | 544 | 58 |
| KrAuCl | $252(251)$ | $161(163)$ | $383(409)$ | 44 |
| XeAuF | $254(255)$ | $169(165)$ | - | 97 |

standard parameters such as van der Waals radius ( $r_{\mathrm{vdW}}$ ), ionic radius ( $r_{\text {ion }}$ ), and covalent radius ( $r_{\text {cov }}$ ). For instance, we may take the sums $r_{\text {cov }}(\mathrm{Ng})+r_{\mathrm{cov}}\left(\mathrm{M}^{\mathrm{I}}\right)$ as a covalent limit and $r_{\mathrm{vdW}}(\mathrm{Ng})+r_{\text {ion }}\left(\mathrm{M}^{+}\right)$as a van der Waals limit.

Among the NgMX complexes, the $\mathrm{Ar}-\mathrm{Ag}$ bond length is closer to the van der Waals limit than the covalent limit: the $\mathrm{Ar}-\mathrm{Ag}$ bond lengths in ArAgX range from 256 to 264 pm , while the $\mathrm{r}_{\mathrm{vdW}}(\mathrm{Ar})+\mathrm{r}_{\text {ion }}\left(\mathrm{Ag}^{+}\right)$sum is 269 pm and the $r_{\text {cov }}(A r)+r_{\text {cov }}\left(\mathrm{Ag}^{\mathrm{I}}\right)$ sum is 226 pm . At the other end of the spectrum, the $\mathrm{Xe}-\mathrm{Au}$ bond length ( 254 pm ) in XeAuF is very close to the covalent limit: the $r_{\text {cov }}(\mathrm{Xe})+\mathrm{r}_{\mathrm{cov}}\left(\mathrm{Au}^{\mathrm{I}}\right)$ sum is 257 pm , while the van der Waals limit of $\mathrm{r}_{\mathrm{vdW}}(\mathrm{Xe})+$ $\mathrm{r}_{\text {ion }}\left(\mathrm{Au}^{+}\right)$is much longer at 295 pm . Summarizing all the results for all the NgMX complexes, it may be concluded that covalent character increases in the orders of $\mathrm{Ar}<\mathrm{Kr}<\mathrm{Xe}$ and $\mathrm{Ag}<\mathrm{Cu}<\mathrm{Au}$.

## (2) Stretching frequencies

The small centrifugal distortion constants ( 4 to 95 kHz ) of the NgMX complexes are consistent with the high rigidity of their linear skeleton. These constants correlate well with the short $\mathrm{Ng}-\mathrm{M}$ bond lengths, implying strong $\mathrm{Ng}-\mathrm{M}$ bonding. They also lead to high $\mathrm{Ng}-\mathrm{M}$ stretching vibrational frequencies, all of which exceed $100 \mathrm{~cm}^{-1}$. The $\mathrm{Ng}-\mathrm{M}$ and $\mathrm{M}-\mathrm{X}$ frequencies calculated with the MP2 method agree fairly well with the experimental data, as shown in Table 5.8.5.

When the $\mathrm{Ng}-\mathrm{M}$ stretching force constants of the NgMX complexes listed in Table 5.8.5 are examined, it is seen that these values are approximately half of that for the bond stretching vibration of $\mathrm{KrF}_{2}$, ranging from $30 \mathrm{~N} \mathrm{~m}^{-1}$ for ArAgBr (recall that the $\mathrm{Ar}-\mathrm{Ag}$ bond length in ArAgX is near the "van der Waals limit") to $137 \mathrm{~N} \mathrm{~m}^{-1}$ for XeAuF (whose Xe-Au bond length is essentially at the "covalent limit"). In comparison, the corresponding value for $\mathrm{Ar}-\mathrm{NaCl}$, which may be considered as a benchmark van der Waals complex, is $0.6 \mathrm{~N} \mathrm{~m}^{-1}$. Thus
in this respect the $\mathrm{Ng}-\mathrm{M}$ bonding in NgMX is considerably stronger than typical van der Waals interaction.

## (3) Electronic dissociation energies

As shown in Table 5.8.5, the calculated $\mathrm{Ng}-\mathrm{M}$ dissociation energies cover a rather wide range, from $14 \mathrm{~kJ} \mathrm{~mol}^{-1}$ in $\mathrm{Ar}-\mathrm{AgF}$ to $97 \mathrm{~kJ} \mathrm{~mol}^{-1}$ in $\mathrm{Xe}-\mathrm{AuF}$. In comparison, for the aforementioned van der Waals complex $\mathrm{Ar}-\mathrm{NaCl}$, the corresponding value for the $\mathrm{Ar}-\mathrm{Na}$ bond is estimated to be $8 \mathrm{~kJ} \mathrm{~mol}^{-1}$. Also, the mean $\mathrm{Kr}-\mathrm{F}$ and $\mathrm{Xe}-\mathrm{F}$ bond energies in $\mathrm{KrF}_{2}$ and $\mathrm{XeF}_{2}$ are 49 and 134 kJ $\mathrm{mol}^{-1}$, respectively.

It is instructive to compare the $\mathrm{Ng}-\mathrm{M}$ bond energies with purely electrostatic induction energies such as dipole-induced dipole and charge-induced dipole interactions. Without going into the computational details, we simply note that the dipole-induced dipole energy is $\sim 35 \%$ of the charge-induced dipole interaction. Furthermore, for NgAuF complexes, the charge-induced dipole interaction is $\sim 10 \%$ of the dissociation energy, while the corresponding value for NgCuF and NgAgF complexes is $\sim 60 \%$. In comparison, for the "typical" van der Waals complex $\mathrm{Ar}-\mathrm{NaCl}$, the charge-induced dipole interaction exceeds its dissociation energy. Based on these results, it may be concluded that, in NgCuF and NgAgF complexes, the $\mathrm{Ng}-\mathrm{M}$ bonds are unlikely to be electrostatic in nature. For NgAuF complexes, particularly for XeAuF , the $\mathrm{Xe}-\mathrm{Au}$ bond is almost certainly not electrostatic.

## (4) Electronic distribution of the $\mathrm{Ng}-\mathrm{M}$ bond

We can also obtain some idea about the nature of the $\mathrm{Ng}-\mathrm{M}$ bond by studying the electronic distribution in the complexes. For KrAuF , there is a $\sigma$-donation of 0.21 electron from Kr to AuF accompanied by a smaller $\pi$-donation. A comparable result is also found for KrAuCl , while the corresponding values for ArAuF and ArAuCl are $0.12-0.14$ electron. For NgAgX complexes, the calculated donation from Ng to AgX is significantly less, about 0.06-0.07 electron. For XeAuF , the complex with the largest dissociation energy so far, the corresponding donation is about 0.26 electron. For XeAgF , the donation is $\sim 0.1$ electron less than that in XeAuF. So the "interaction strength" in these complexes once again follows the trends mentioned previously: $\mathrm{Ar}<\mathrm{Kr}<\mathrm{Xe}$ and $\mathrm{Ag}<\mathrm{Cu}<\mathrm{Au}$.

In summary, the physical properties of the NgMX complexes may vary quantitatively, but these properties remain remarkably similar qualitatively as we go from one complex to the next. For instance, all complexes feature a short, rigid $\mathrm{Ng}-\mathrm{M}$ bond with stretching frequency above $100 \mathrm{~cm}^{-1}$. Also, the $\mathrm{Ng}-$ M dissociation energies is relatively large, and there is noticeable electronic rearrangement upon the formation of the $\mathrm{Ng}-\mathrm{M}$ bond. Neither the dissociation energies nor the electronic re-distribution upon bond formation can be fully accounted for by electrostatic interaction alone. For XeAuF, the complex with the largest interaction strength, it is fairly certain that the $\mathrm{Xe}-\mathrm{Au}$ bond is covalent in nature. At the same time, we may also conclude that there is $\mathrm{Ng}-\mathrm{M}$ chemical bonding, to a greater or lesser degree, in all the remaining NgMX complexes.

## Fundamentals of Bonding Theory

Before leaving the NgMX complexes and the compound HArF introduced in Section 5.8.1, it is noted that a fuller discussion on the chemistry of noble gases may be found in Section 17.5, including a subsection on gold-xenon complexes in Section 17.5.6.

With reference to the four examples given in this section, each literature article describing the preparation of the relevant compound(s) also includes a computational section reporting the calculated results, which are used to interpret the experimental data obtained by various physical methods. Clearly, computation has become a very common tool to the experimentalists, not much different from an infrared spectrophotometer or a mass spectrometer. Another point worth noting is that, while high-level calculations can give us a more detailed bonding description, in the examples shown here, we can make use of the simple concepts introduced in Chapters 2 and 3, such as Lewis electron-pair, $\sigma$ and $\pi$ bonds, hybridization schemes, resonance theory, ionic radii, covalent radii, and van der Waals radii, to obtain a qualitative, but useful, bonding description of the novel molecular species.

### 5.9 Software packages

Currently there are numerous software packages that perform the $a b$ initio or DFT calculations introduced in this section. Most of these programs are available commercially, but there are a few distributed to the scientific community free of charge. Some popular programs are briefly described below, and the list is by no means exhaustive.
(1) Gaussian (http://www.gaussian.com): This is probably the most popular package around. It was first released in 1970 as Gaussian 70 and the latest version is Gaussian 03, issued in 2003. It does essentially every type of $a b$ initio, DFT, and semi-empirical methods and it is easy to use. Its popularity is well earned.
(2) Gamess (http://www.msg.ameslab.gov/GAMESS): This is another popular package and it is available free of charge. It is able to calculate molecular properties at various correlated levels, but it requires a good understanding of the theories.
(3) MOLPRO (http://www.molpro.net): This program is highly optimized for CCSD calculations and it has a special input format which allows the user to define sophisticated computational steps.
(4) SPARTAN (http://www.wavefun.com): This is a very user-friendly program and it is popular among experimental organic and organometallic chemists. Most of the calculations beyond HF level are carried out by a modified Q-Chem (see below) package that comes with SPARTAN.
(5) Q-Chem (http://www.q-chem.com): This commercial package is able to perform energy calculations and geometry optimizations at ground state and excited states at various $a b$ initio and DFT levels. It also performs calculations of NMR chemical shifts, solvation effects, etc.
(6) NWChem (http://www.emsl.pnl.gov/docs/nwchem/newchem.html): This program is free of charge for faculty members or staff members of academic institutions.
(7) MQPC (http://www.mqpc.org): This program is also available free of charge and its source code is accessible for modification by users.
(8) MOPAC 2000 (http://www.schrodinger.com/Products/mopac.html): This commercial package is mainly for semi-empirical calculations.
(9) AMPAC (http://www.semichem.com/ampac/index.html): This is another commercial package for semi-empirical calculations.
(10) HyperChem (www.hyper.com): This is an inexpensive PC-based package for molecular modeling and visualization.

## Symmetry in Chemistry

In the study of the structure and properties of molecules and crystals, the concept of symmetry is of fundamental importance. Symmetry is an abstract concept associated with harmony and balance in nature or in social relationship. Yet in chemistry this ever-evolving concept does have a very practical role to play.

The main advantage of studying the symmetry characteristics of a chemical system is that we can apply symmetry arguments to solve physical problems of chemical interest. Specifically, we utilize a mathematical tool called group theory to simplify the physical problem and to yield solutions of chemical significance. The advantage of this method becomes more obvious when the symmetry of the chemical system increases. Quite often, for highly symmetric molecules or crystals, very complex problems can have simple and elegant solutions. Even for less symmetric systems, symmetry arguments can lead to meaningful results that cannot be easily obtained otherwise.

Before applying group theory, we need to recognize the symmetry properties of a chemical system. For individual molecules, we only need to consider the symmetry of the species itself, but not the symmetry that may exist between the species and its neighbors. In trying to determine the symmetry of a molecule, we need to see whether it has any symmetry elements, which are defined as geometrical entities such as an axis, a plane, or a point about which symmetry operations can be carried out. A symmetry operation on a molecule may be defined as an exchange of atoms in the molecule about a symmetry element such that the molecule's outward appearance, including orientation and location, remains the same after the exchange. Chapters 6 and 7 discuss molecular symmetry and elementary group theory, as well as chemical applications of group theory. In Chapter 8, the coordination bond is described, again with symmetry and group theory playing an important role. Also, the presentation of group theory in these chapters is informal and includes many illustrations and examples, while essentially all the mathematical derivations are omitted.

In contrast to discrete molecules, crystals have a lattice structure exhibiting three-dimensional periodicity. As a result, we need to consider additional symmetry elements that apply to an infinitely extended object, namely the translations, screw axes, and glide planes. Chapters 9 and 10 introduce the concept and nomenclature of space groups and their application in describing the structures of crystals, as well as a survey of the basic inorganic crystalline materials.

## Symmetry and Elements of Group Theory

In this chapter, we first discuss the concept of symmetry and the identification of the point group of any given molecule. Then we present the rudiments of group theory, focusing mainly on the character tables of point groups and their use.

### 6.1 Symmetry elements and symmetry operations

Symmetry is a fundamental concept of paramount importance in art, mathematics, and all areas of natural science. In the context of chemistry, once we know the symmetry characteristics (i.e., point group) of a molecule, it is often possible for us to draw qualitative inferences about its electronic structure, its vibrational spectra, as well as other properties such as dipole moment and optical activity.
To determine the symmetry of a molecule, we first need to identify the symmetry elements it may possess and the symmetry operations generated by these elements. The twin concepts of symmetry operation and symmetry element are intricately connected and it is easy to confuse one with the other. In the following discussion, we first give definitions and then use examples to illustrate their distinction.

A symmetry operation is an atom-exchange operation (or more precisely, a coordinate transformation) performed on a molecule such that, after the interchange, the equivalent molecular configuration is attained; in other words, the shape and orientation of the molecule are not altered, although the position of some or all of the atoms may be moved to their equivalent sites. On the other hand, a symmetry element is a geometrical entity such as a point, an axis, or a plane, with respect to which the symmetry operations can be carried out. We shall now discuss symmetry elements and symmetry operations of each type in more detail.

### 6.1.1 Proper rotation axis $C_{n}$

This denotes an axis through the molecule about which a rotation of $360^{\circ} / n$ can be carried out. For example, in $\mathrm{H}_{2} \mathrm{O}$ the $C_{2}$ axis is a symmetry element (Fig. 6.1.1), which gives rise to the symmetry operation $\boldsymbol{C}_{2}$. (In this book all symmetry operations will be indicated in bold font.) Meanwhile, $\mathrm{NH}_{3}$ has a symmetry element $C_{3}$ (Fig. 6.1.2), but now there are two symmetry operations

Fig. 6.1.1.
The $C_{2}$ axis in $\mathrm{H}_{2} \mathrm{O}$.

Fig. 6.1.2.
The $C_{3}$ axis in $\mathrm{NH}_{3}$.

## Fig. 6.1.3.

## Fig. 6.1.4.

Two views of $\mathrm{SF}_{6}$ showing the $C_{4}$ and $C_{3}$ axes. In the figure on the right, the $C_{3}$ axis is perpendicular to the paper and passes through the S atom. In both figures, a secondary $C_{2}$ axis (the same one!) is also shown.

Fig. 6.1.5.
Two views of cyclohexane showing the principal $C_{3}$ axis (perpendicular to the paper in the figure on the right) and three secondary $C_{2}$ axes. In the figure on the right, the + and - signs label the C atoms lying above and below the mean plane of the molecule, respectively.

$\left(T_{\mathrm{d}}\right)$

generated by this element: a rotation of $120^{\circ}$ and another of $240^{\circ}$. Sometimes it is easy to identify the $C_{n}$ axis in a molecule (as in the cases of $\mathrm{H}_{2} \mathrm{O}$ and $\mathrm{NH}_{3}$ ), and sometimes it is not. To clearly see one particular rotational axis, often it is advantageous to draw the molecule in a certain orientation. Figure 6.1 .3 shows $\mathrm{CH}_{4}$ in two orientations; for one it is easy to see the $C_{3}$ axis, and for the other the $C_{2}$ axis. Similarly, Fig. 6.1.4 shows $\mathrm{SF}_{6}$ in two orientations, one for the $C_{4}$ axis and the other for the $C_{3}$ axis. Cyclohexane has one $C_{3}$ axis and three $C_{2}$ axes perpendicular to it; these are clearly shown in Fig. 6.1.5. In this molecule, the $C_{3}$ axis is called the principal symmetry axis.

### 6.1.2 Symmetry plane $\sigma$

This denotes a plane through the molecule, about which a reflection operation may be carried out. The symbol $\sigma$ originates from the German word Spiegel, which means a mirror. In $\mathrm{H}_{2} \mathrm{O}$ (Fig. 6.1.1), when one of the hydrogen atoms is substituted by its isotope D , the $C_{2}$ axis no longer exists. However, the molecular plane is still a symmetry plane.

Symmetry (or mirror) planes may be further classified into three types. First, there are the vertical planes $\sigma_{\mathrm{v}}$ whose common intersection constitutes the rotation axis $C_{n}$. For example, it is obvious that there are two $\sigma_{\mathrm{v}}$ 's in $\mathrm{H}_{2} \mathrm{O}$ (Fig. 6.1.1)
and three $\sigma_{\mathrm{v}}$ 's in $\mathrm{NH}_{3}$ (Fig. 6.1.2). Generally speaking, for a molecule with a rotational axis $C_{n}$, the identification of one $\sigma_{\mathrm{v}}$ necessarily implies the presence of $n \sigma_{\mathrm{v}}$ 's.

Secondly, there is the horizontal plane $\sigma_{\mathrm{h}}$ which lies perpendicular to the principal axis $C_{n}$. Examples are given in Figs. 6.1.6 and 6.1.7. Note that some highly symmetric molecules have more than one $\sigma_{\mathrm{h}}$; for instance, octahedral $\mathrm{SF}_{6}$ has three $\sigma_{\mathrm{h}}$ 's that are mutually orthogonal to one another.

Lastly, in molecules with a principal rotational axis $C_{n}$ and $n$ secondary $C_{2}$ axes perpendicular to it, sometimes there are additionally $n$ vertical planes which bisect the angles formed between the $C_{2}$ axes. These vertical planes are called $\sigma_{\mathrm{d}}$, or dihedral planes. In cyclohexane, there are three $\sigma_{\mathrm{d}}$ 's, each lying between a pair of $C_{2}$ axes (Fig. 6.1.5). It should be noted that sometimes $\sigma_{\mathrm{v}}$ 's and $\sigma_{\mathrm{d}}$ 's cannot be differentiated unambiguously. For example, in $\mathrm{BrF}_{4}^{-}$(Fig. 6.1.8), in addition to the principal $C_{4}$ axis, there are four $C_{2}$ axes perpendicular to $C_{4}$, and four vertical planes containing the $C_{4}$ axis. By convention, the two $C_{2}$ axes passing through the F atoms are called $C_{2}^{\prime}$, while those which do not pass through the F atoms are the $C_{2}^{\prime \prime}$ axes. Furthermore, the vertical planes containing the $C_{2}^{\prime}$ axes are called $\sigma_{\mathrm{v}}$ 's, while those containing the $C_{2}^{\prime \prime}$ axes are $\sigma_{\mathrm{d}}$ 's. In group theory, it can be shown that the $C_{2}^{\prime}$ axes form a class of symmetry operations. Other distinct classes are composed of the $C_{2}^{\prime \prime}$ axes, the $\sigma_{\mathrm{v}}$ 's, and the $\sigma_{\mathrm{d}}$ 's.

### 6.1.3 Inversion center $i$

The inversion operation is carried out by joining a point to the inversion center (or center of symmetry) and extending it an equal distance to arrive at an equivalent point. Molecules which possess an inversion center are termed centrosymmetric. Among the eight examples given so far, $\mathrm{SF}_{6}$ (Fig. 6.1.4), cyclohexane (Fig. 6.1.5), trans- $\mathrm{N}_{2} \mathrm{~F}_{2}$ (Fig. 6.1.6), and $\mathrm{BrF}_{4}^{-}$(Fig. 6.1.8) are centrosymmetric systems. Molecules lacking an inversion center are called non-centrosymmetric.

### 6.1.4 Improper rotation axis $S_{n}$

This denotes an axis about which a rotation-reflection (or improper rotation) operation may be carried out. The rotation-reflection operation $S_{n}$ involves a

Fig. 6.1.6.
The molecular plane in trans $-\mathrm{N}_{2} \mathrm{~F}_{2}$ is a $\sigma_{\mathrm{h}}$.

$\left(C_{3 \mathrm{~h}}\right)$

Fig. 6.1.7.

Fig. 6.1.9.
The $\boldsymbol{S}_{6}$ operation in ethane.

rotation of the molecule by $360^{\circ} / n$ about the improper rotation axis $S_{n}$, which is followed by a reflection of all atoms through a plane perpendicular to the $S_{n}$ axis. Note that the rotation-reflection operation $\boldsymbol{S}_{n}$ can be carried out in either order, i.e., $\boldsymbol{S}_{n}=\boldsymbol{C}_{n} \boldsymbol{\sigma}=\boldsymbol{\sigma} \boldsymbol{C}_{n}$. An example of the $\boldsymbol{S}_{6}$ operation in ethane is shown in Fig. 6.1.9. Now it is obvious that the three $C_{2}$ axes in $\mathrm{CH}_{4}$ (Fig. 6.1.3) coincide with the corresponding $S_{4}$ axes, the $C_{4}$ and $C_{3}$ axes in $\mathrm{SF}_{6}$ (Fig. 6.1.4) are $S_{4}$ and $S_{6}$ axes, respectively, and the $C_{3}$ axis in cyclohexane (Fig. 6.1.5) is also an $S_{6}$ axis. Finally, it is pointed out that operation $\boldsymbol{S}_{1}$ is the same as $\boldsymbol{\sigma}$ (e.g., HOD), and the operation $\boldsymbol{S}_{2}$ is equivalent to the inversion $\boldsymbol{i}$ (e.g., trans $-\mathrm{N}_{2} \mathrm{~F}_{2}$ in Fig. 6.1.6).

### 6.1.5 Identity element $E$

The symbol $E$ comes from the German word Einheit meaning unity. This element generates an operation $\boldsymbol{E}$ which leaves the molecule unchanged. All molecules possess such an element or operation. The need for this seemingly trivial "do nothing" or "leave it alone" operation arises from the mathematical requirements of group theory, as we shall see in Chapter 7. Note that in some books the symbol $I$ (for identity) is used in place of $E$.

### 6.2 Molecular point groups

### 6.2.1 Classification of point groups

When we say a molecule belongs to a certain point group, it is meant that the molecule possesses a specific, self-consistent set of symmetry elements. The most common point groups are described below with illustrative examples.

## (1) Point group $\boldsymbol{C}_{1}$

This group has only one symmetry element: identity element $E$; i.e., the molecule concerned is asymmetric. Examples include methane derivatives with the central carbon atom bonded to four different groups, e.g., CHFClBr .

## (2) Point group $C_{s}$

This group has only two symmetry elements: $E$ and $\sigma$. The aforementioned HOD belongs to this group. Other examples include thionyl halide $\mathrm{SOX}_{2}$ and secondary amines $\mathrm{R}_{2} \mathrm{NH}$ (Fig. 6.2.1).

## (3) Point group $C_{i}$

This group has only two symmetry elements: $E$ and $i$. There are not many molecules with this kind of symmetry. Two examples are given in Fig. 6.2.2.

## (4) Point group $\boldsymbol{C}_{\boldsymbol{n}}$

This group has only symmetry elements $E$ and $C_{n}$. Examples for the $C_{n}$ group are shown in Fig. 6.2.3.

Note that the term "dissymmetric" is reserved for describing a molecule not superimposable on its own mirror image. Accordingly, an object with no improper rotation (rotation-reflection) axis must be dissymmetric. All asymmetric objects are dissymmetric, but the converse is not necessarily true. In fact, those molecules that possess one or more rotational axes of any order as the only symmetry elements are dissymmetric; for instance, the 1,3,5-triphenylbenzene molecule in the three-leaved propeller configuration (point group $C_{3}$ ) and the $\left[\operatorname{Co}(\mathrm{en})_{3}\right]^{3+}$ cation (point group $D_{3}$ ) are dissymmetric species. Note that the term "asymmetric unit" has a special meaning in crystallography, as explained in Section 9.3.6.

$\left(C_{i}\right)$

## (5) Point group $\boldsymbol{C}_{\boldsymbol{n}}$ v

This group has symmetry elements $E$, a rotational axis $C_{n}$, and $n \sigma_{\mathrm{v}}$ planes. The $\mathrm{H}_{2} \mathrm{O}$ (Fig. 6.1.1) and $\mathrm{NH}_{3}$ (Fig. 6.1.2) molecules have $C_{2 \mathrm{v}}$ and $C_{3 \mathrm{v}}$ symmetry, respectively. Other examples are given in Fig. 6.2.4.

The fragment $\mathrm{N} \frown \mathrm{N}$ represents the bidentate chelating ligand ethylenediamine $\mathrm{H}_{2} \mathrm{NCH}_{2} \mathrm{CH}_{2} \mathrm{NH}_{2}$, while $\mathrm{A} \frown \mathrm{B}$ represents a bidentate chelating ligand with different coordinating sites such as $\mathrm{Me}_{2} \mathrm{NCH}_{2} \mathrm{CH}_{2} \mathrm{NH}_{2}$.
(a)

$\left(C_{4 \mathrm{v}}\right)$
(b)

(c)

## (6) Point group $\boldsymbol{C}_{\boldsymbol{n}}$

This group has symmetry element $E$, a rotational axis $C_{n}$, and a horizontal plane $\sigma_{\mathrm{h}}$ perpendicular to $C_{n}$. Note that $S_{n}$ also exists as a consequence of the elements already present ( $C_{n}$ and $\sigma_{\mathrm{h}}$ ). Also, when $n$ is even, the presence of $i$ is again a necessary consequence. Examples include trans $-\mathrm{N}_{2} \mathrm{~F}_{2}\left(C_{2 \mathrm{~h}}\right.$; Fig. 6.1.6), all-trans-1,5,9-cyclododecatriene ( $C_{3 \mathrm{~h}}$; Fig. 6.1.7), and boric acid $\mathrm{B}(\mathrm{OH})_{3}\left(C_{3 \mathrm{~h}}\right.$; Fig. 13.5.1).

## (7) Point group $\boldsymbol{D}_{\boldsymbol{n}}$

This group has a principal $C_{n}$ axis with $n$ secondary $C_{2}$ axes perpendicular to it. The symbol $D$ arises from the German Diedergruppe, which means dihedral group. Examples of this group are uncommon, as the presence of $D_{n}$ is usually accompanied by other symmetry elements. An organic molecule of this type is cycloocta-1,5-diene $\left(D_{2}\right)$. The most important as well as interesting inorganic examples are the chiral tris-chelated transition metal complexes such as $\mathrm{Mn}(\mathrm{acac})_{3}$ (acac = acetylacetonate) and tris(ethylenediamine)chromium(III), which is illustrated in Fig. 6.2.5.

## (8) Point group $\boldsymbol{D}_{\boldsymbol{n}}$

This group has symmetry element $E$, a principal $C_{n}$ axis, $n$ secondary $C_{2}$ axes perpendicular to $C_{n}$, and a $\sigma_{\mathrm{h}}$ also perpendicular to $C_{n}$. The necessary consequences of such combination of elements are a $S_{n}$ axis coincident with the $C_{n}$ axis and a set of $n \sigma_{\mathrm{v}}$ 's containing the $C_{2}$ axes. Also, when $n$ is even, symmetry center $i$ is necessarily present. The $\mathrm{BrF}_{4}^{-}$molecule has point group symmetry $D_{4 \mathrm{~h}}$, as shown in Fig. 6.1.8. Examples of other molecules belonging to point groups $D_{2 \mathrm{~h}}, D_{3 \mathrm{~h}}, D_{5 \mathrm{~h}}$ and $D_{6 \mathrm{~h}}$ are given in Fig. 6.2.6.

## (9) Point group $\boldsymbol{D}_{\boldsymbol{n d}}$

This group consists of $E$, a principal $C_{n}$ axis, $n C_{2}$ 's perpendicular to $C_{n}$, and $n \sigma_{\mathrm{d}}$ 's between the $C_{2}$ axes. A necessary consequence of such a combination
(a)

( $D_{2 \mathrm{~h}}$ )

( $D_{4 \mathrm{~d}}$ )

Fig. 6.2.7.
Examples of molecules with $D_{n \mathrm{~d}}$ symmetry: (a) allene and (b) $\mathrm{Mn}_{2}(\mathrm{CO})_{10}$.
A general geometrical relationship holds for any molecule that can be represented as two regular polygons of $n$ vertices ( $n$-gons) separated by a distance along the principal $C_{n}$ rotation axis. In the fully eclipsed conformation, i.e., when the two polygons exactly overlap when viewed along $C_{n}$, the point group is $D_{n \mathrm{~h}}$. In the perfectly staggered conformation, the point group is $D_{n \mathrm{~d}}$. In the skew (or gauche) conformation, the point group is $D_{n}$. Common examples illustrating such patterns are ethane and sandwich-type metallocenes $\left(\eta-\mathrm{C}_{n} \mathrm{H}_{n}\right)_{2} \mathrm{M}$.

## (10) Point group $\boldsymbol{S}_{\boldsymbol{n}}$

This point group has only two symmetry elements: $E$ and $S_{n}$. Since carrying out the $S_{n}$ operation $n$ times should generate the identity operation $E$, integer $n$ must be even. Also, $n \geq 4$. Examples of this point group are rare; two are given in Fig. 6.2.8. Molecules belonging to $S_{n}$ with $n \geq 6$ are quite uncommon. In hexakis(pyridine $N$-oxide)coblalt(II) perchlorate [Fig. 6.2.8(d)], the pyridine N -oxide ligand is coordinated to the metal center at a $\mathrm{Co}-\mathrm{O}-\mathrm{N}$ bond angle of $119.5(2)^{\circ}$; the dihedral angle between the plane containing these three atoms and the pyridine ring is $72.2^{\circ}$.

## (11) Point groups $D_{\infty h}$ and $C_{\infty v}$

Symmetric linear molecules such as $\mathrm{H}_{2}, \mathrm{CO}_{2}$, and $\mathrm{HC} \equiv \mathrm{CH}$ have $D_{\infty h}$ symmetry, while unsymmetric linear molecules such as $\mathrm{CO}, \mathrm{HCN}$, and FCCH belong to the $C_{\infty \mathrm{v}}$ point group.

## (12) High-symmetry point groups $\boldsymbol{T}_{\mathrm{d}}, \boldsymbol{O}_{\mathrm{h}}$, and $\boldsymbol{I}_{\mathrm{h}}$

Tetrahedral molecules such as $\mathrm{CH}_{4}$ (Fig. 6.1.3) have 24 symmetry operations ( $\boldsymbol{E}, 8 \boldsymbol{C}_{3}, 3 \boldsymbol{C}_{2}, 6 \boldsymbol{S}_{4}$ and $6 \boldsymbol{\sigma}_{\mathrm{d}}$ ) and belong to the $T_{\mathrm{d}}$ point group. In comparison, octahedral molecules such as $\mathrm{SF}_{6}$ (Fig. 6.1.4) have 48 symmetry operations $\left(\boldsymbol{E}, 8 \boldsymbol{C}_{3}, 6 \boldsymbol{C}_{2}, 6 \boldsymbol{C}_{4}, 3 \boldsymbol{C}_{2}=3 \boldsymbol{C}_{4}^{2}, \boldsymbol{i}, 6 \boldsymbol{S}_{4}, 8 \boldsymbol{S}_{6}, 3 \sigma_{\mathrm{h}}\right.$, and $\left.6 \sigma_{\mathrm{d}}\right)$ and belong to the $O_{\mathrm{h}}$ point group. It would be instructive for students to examine all the operations for these two important high-symmetry point groups with the aid of molecular models.

Among organic molecules, cubane $\mathrm{C}_{8} \mathrm{H}_{8}\left(\mathrm{O}_{\mathrm{h}}\right)$ and adamantane $(\mathrm{CH})_{4}\left(\mathrm{CH}_{2}\right)_{6}$ ( $T_{\mathrm{d}}$ ) stand out distinctly by virtue of their highly symmetric cage structures. In contrast to the scarcity of organic analogs such as hexamethylenetetramine $\mathrm{N}_{4}\left(\mathrm{CH}_{2}\right)_{6}$ and hexathiaadamantane $(\mathrm{CH})_{4} \mathrm{~S}_{6}$, there exists an impressive diversity of inorganic and organometallic compounds containing cubane-like and adamantane-like molecular skeletons. In current usage, the term cubane-like (cubanoid) generally refers to a $\mathrm{M}_{4} \mathrm{Y}_{4}$ core composed of two interpenetrating tetrahedra of separate atom types, resulting in a distorted cubic framework of idealized symmetry $T_{\mathrm{d}}$ (Fig. 6.2.9(a)). Similarly, the adamantane-like (adamantoid) $\mathrm{M}_{4} \mathrm{Y}_{6}$ skeleton consists of a $\mathrm{M}_{4}$ tetrahedron and a $\mathrm{Y}_{6}$ octahedron which interpenetrate, giving rise to a fused system of four chair-shaped rings with overall symmetry $T_{\mathrm{d}}$ (Fig. 6.2.9 (b)). If M stands for a metal atom, the compound is often described as tetranuclear or tetrameric. In either structural type additional ligand atoms or groups L and $\mathrm{L}^{\prime}$ may be symmetrically appended

Fig. 6.2.9.
(a) Cubane-like $\mathrm{M}_{4} \mathrm{Y}_{4}$ core referred to a Cartesian frame. (b) Adamantane-like $\mathrm{M}_{4} \mathrm{Y}_{6}$ core referred to a Cartesian frame. The reference cube is outlined by broken lines. Atoms of type M and Y are represented by open and solid circles, respectively.
to core atoms M and Y , respectively. The two families of cubane-like and adamantane-like cage compounds may be formulated as $\left(\mathrm{L}_{m} \mathrm{M}\right)_{4}\left(\mathrm{YL}_{n}^{\prime}\right)_{4}$ (with $m=0,1,3 ; n=0,1)$ and $\left(\mathrm{L}_{m} \mathrm{M}\right)_{4}\left(\mathrm{YL}_{n}^{\prime}\right)_{6}$ (with $m=0,1 ; n=0,1,2$ ), respectively. Not included in these two categories are structurally related compounds such as the oligomeric silasesquioxane $\mathrm{Me}_{8} \mathrm{Si}_{8} \mathrm{O}_{12}$ and basic beryllium acetate $\mathrm{Be}_{4} \mathrm{O}\left(\mathrm{CH}_{3} \mathrm{COO}\right)_{6}$, in which the core atoms are bridged by oxygen atoms.

\end{align*}
$$

In describing the idealized $T_{\mathrm{d}}$ cage structure of either the cubane or adamantane type, it is customary to give the bond length $d$, the Y-M-Y angle $\alpha$, and the $\mathrm{M}-\mathrm{Y}-\mathrm{M}$ angle $\beta$. While the parameter $d$ readily conveys an appreciation of molecular size, it is not generally appreciated that only one bond angle suffices to define the molecular geometry uniquely. Derivation of the bond-angle relationship between $\alpha$ and $\beta$ for both structural types are outlined in Table 6.2.1. If an external ligand atom L is bound to core atom M , the bond angle $\mathrm{L}-\mathrm{M}-\mathrm{Y}(\gamma)$ may be calculated from $\alpha$ using the equation $\sin (\pi-\gamma)=2 \sin (\alpha / 2) /(3)^{1 / 2}$ for local $C_{3 \mathrm{v}}$ symmetry. For the $\mathrm{M}_{4} \mathrm{Y}_{6}$ core, if a pair of ligand atoms $\mathrm{L}^{\prime}$ are symmetrically attached to atom Y to attain local $C_{2 \mathrm{v}}$ symmetry, the bond angle $\mathrm{L}^{\prime}-\mathrm{Y}-\mathrm{L}^{\prime}(\delta)$ may be calculated from $\beta$ using the equation $\cot ^{2}(\delta / 2)+\cot ^{2}(\beta / 2)=1$.

If either $\alpha$ or $\beta$ is known for a given structure, eqs. (1)-(4) in Table 6.2.1 can be used to evaluate the remaining angle. Another possible use of these equations is in assessing the extent to which the cores of related compounds deviate from idealized $T_{\mathrm{d}}$ symmetry. For this purpose we assume that there is no systematic variation in the observed $\mathrm{M}-\mathrm{Y}$ bond distances and define a goodness-of-fit index $S$ by the equation:

$$
\begin{equation*}
S=\sum_{i, j} \frac{\left[\left(\alpha_{i}-\alpha_{\mathrm{c}}\right)^{2} / n_{\alpha}+\left(\beta_{j}-\bar{\beta}\right)^{2} / n_{\beta}\right]^{\frac{1}{2}}}{\sigma_{\max }} \tag{5}
\end{equation*}
$$

where $n_{\alpha}$ and $n_{\beta}$ are, respectively, the numbers of independently measured angles $\alpha_{i}$ and $\beta_{j}, \bar{\beta}$ is the average of $\beta_{j}, \alpha_{\mathrm{c}}$ is calculated from $\bar{\beta}$ with equation (1) or ( $\mathbf{1}^{\prime}$ ) for cubane-like and (3) or ( $\mathbf{3}^{\prime}$ ) for adamantane-like systems, and $\sigma_{\max }$ is the maximum value of the estimated standard deviations of individual bond angles. In Table 6.2.2, the computed $S$ values of 2.2,5.7, and 37 for the cubanelike $\mathrm{Fe}_{4} \mathrm{C}_{4}, \mathrm{Fe}_{4} \mathrm{~S}_{4}$, and $\mathrm{Co}_{4} \mathrm{~S}_{4}$ cores, respectively, indicate increasing deviations from idealized $T_{\mathrm{d}}$ symmetry. This is in accord with the assignment of the core symmetries in the literature as $T_{\mathrm{d}}, D_{2 \mathrm{~d}}$, and lower than $D_{2 \mathrm{~d}}$, respectively. In the case of the adamantane-like $\left[\mathrm{Cu}_{4} \mathrm{OCl}_{10}\right]^{4-}$ anion ( Cu coordinated by three bridging Cl , an external Cl , and the O atom at the center), which occupies sites of different symmetry in four reported crystal structures, consideration of the relative $S$ values in Table 6.2.2 leads to the conclusion that it conforms to $T_{\mathrm{d}}$ symmetry in its tetramethylammonium salt, and becomes increasingly more distorted in the $N, N, N^{\prime}, N^{\prime}$,-tetraethylenediammonium, potassium, and diethylammonium salts. The present procedure, when applied to a series of related molecules, yields a set of numbers which allow one to spot a trend and distinguish between clear-cut cases.

The most characteristic feature of point group $I_{\mathrm{h}}$ is the presence of six fivefold rotation axes, ten threefold rotation axes, and 15 twofold rotation axes. A $\sigma$ plane lies perpendicular to each $C_{2}$ axis. Group $I_{\mathrm{h}}$ has 120 symmetry operations $\left(\boldsymbol{E}, 12 \boldsymbol{C}_{5}, 12 \boldsymbol{C}_{5}^{2}, 20 \boldsymbol{C}_{3}, 15 \boldsymbol{C}_{2}, \boldsymbol{i}, 12 \boldsymbol{S}_{10}, 12 \boldsymbol{S}_{10}^{3}, 20 \boldsymbol{S}_{6}\right.$, and $15 \sigma$ ). Well-known cage-like molecules that belong to this point group are icosahedral $\mathrm{B}_{12} \mathrm{H}_{12}^{2-}$ and

dodecahedrane $\mathrm{C}_{20} \mathrm{H}_{20}$. Fullerene $\mathrm{C}_{60}$ is a truncated icosahedron that exhibits $I_{\mathrm{h}}$ symmetry, and the $C_{2}, C_{3}$, and $C_{5}$ axes of this cage system are shown in Fig. 6.2.10.

The point groups $T_{\mathrm{d}}$ and $O_{\mathrm{h}}$, together with their subgroups $T, T_{\mathrm{h}}$, and $O$, are known as cubic groups because they are geometrically related to the cube. The point groups $I_{\mathrm{h}}$ and $I$ are known as icosahedral groups. These seven point groups reflect part or all of the symmetry properties of the five Platonic solids: the tetrahedron, the cube, the octahedron, the pentagonal dodecahedron, and the icosahedron. Note that the eight-coordinate dodecahedral complexes such as $\left[\mathrm{Mo}(\mathrm{CN})_{8}\right]^{4-},\left[\mathrm{ZrF}_{8}\right]^{4-}$, and $\left[\mathrm{Zr}_{4}(\mathrm{OH})_{8}\left(\mathrm{H}_{2} \mathrm{O}\right)_{16}\right]^{8+}$ are based on the triangulated dodecahedron, which has $D_{2 \mathrm{~d}}$ symmetry.

(b)

(c)

## (13) Rarely occurring point groups $O, T, T_{\mathrm{h}}, I$, and $K_{\mathrm{h}}$

Point groups $O$ is derived from $O_{\mathrm{h}}$ by removing all symmetry elements except the rotational axes. A rare example is octamethylcubane, $\mathrm{C}_{8}\left(\mathrm{CH}_{3}\right)_{8}$, in which the $\mathrm{CH}_{3}$ group is rotated about an exo-polyhedral $\mathrm{C}-\mathrm{C}$ bond to destroy the $\sigma_{\mathrm{d}}$ plane; note that this simultaneously eliminates symmetry elements $i, \sigma_{\mathrm{h}}$, $S_{4}$, and $S_{6}$. Similarly, point group $T$ is derived from $T_{\mathrm{d}}$ by leaving out the $\sigma_{\mathrm{d}}$ planes. Examples of molecules that possess point symmetry $T$ are tetrahedral $\mathrm{Pt}\left(\mathrm{PF}_{3}\right)_{4}$ and $\mathrm{Si}\left(\mathrm{SiMe}_{3}\right)_{4}$, in which the two sets of substituents attached to atoms forming the corresponding $\mathrm{Pt}-\mathrm{P}$ or $\mathrm{Si}-\mathrm{Si}$ single bond take the gauche conformation.

Point group $T_{\mathrm{h}}$ has 24 symmetry operations $\left(\boldsymbol{E}, 4 \boldsymbol{C}_{3}, 4 \boldsymbol{C}_{3}^{2}, 3 \boldsymbol{C}_{2}, \boldsymbol{i}\right.$, $4 \boldsymbol{S}_{4}, 4 \boldsymbol{S}_{4}$, and $3 \sigma_{\mathrm{h}}$ ). Inorganic complexes that belong to this point group are $\left[\mathrm{Fe}\left(\mathrm{C}_{5} \mathrm{H}_{5} \mathrm{~N}\right)_{6}\right]^{2+}$ and $\left[\mathrm{M}_{\left.\left(\mathrm{NO}_{2}\right)_{6}\right]^{n-}(\mathrm{M}=\mathrm{Co}, n=3 ; \mathrm{M}=\mathrm{Ni}, n=}\right.$ 4), as shown in Figs. 6.2.11(a) and (b), respectively. In each complex, three pairs of monodentate ligands lie on mutually orthogonal mirror planes (Fig. 6.2.11(c)).

Fig. 6.2.10.
Perspective views of $\mathrm{C}_{60}$ along its $C_{2}$, $C_{3}$ and $C_{5}$ axes ( $I_{\mathrm{h}}$ symmetry).

Fig. 6.2.11.
Examples of molecules with $T_{\mathrm{h}}$ symmetry: (a) $\left[\mathrm{Fe}\left(\mathrm{C}_{5} \mathrm{H}_{5} \mathrm{~N}\right)_{6}\right]^{2+}$ and (b) $\left[\mathrm{M}\left(\mathrm{NO}_{2}\right)_{6}\right]^{n-}$ viewed along a $C_{3}$ axis. In (c), the three pairs of bars (each bar representing a planar ligand) lying on the faces of a reference cube exhibit the same symmetry.

## Symmetry in Chemistry

Point group $I$ is derived from $I_{\mathrm{h}}$ by deleting the $\sigma$ planes normal to the 15 $C_{2}$ axes. It is inconceivable that any molecule having symmetry $I$ can ever be constructed.

A finite object that exhibits the highest possible symmetry is the sphere, whose point group symbol $K_{\mathrm{h}}$ is derived form the German word Kugel. It has an infinite number of rotation axes of any order in every direction, all passing through the center, as well as an infinite number of $\sigma_{\mathrm{h}}$ planes each perpendicular to a $C_{\infty}$ axis. Obviously, $K_{\mathrm{h}}$ is merely of theoretical interest as no chemical molecule can possess such symmetry.

### 6.2.2 Identifying point groups

To help students to determine the symmetry point group of a molecule, various flow charts have been devised. One such flow chart is shown in Table 6.2.3. However, experience indicates that, once we are familiar with the various operations and with visualizing objects from different orientations, we will dispense with this kind of device.

Often it is difficult to recognize the symmetry elements present in a molecule from a perspective drawing. A useful technique is to sketch a projection of the molecule along its principal axis. Plus and negative signs may be used to indicate the relative locations of atoms lying above and below the mean plane, respectively. Cyclohexane has been used as an example in Fig. 6.1.5. The identification of the point groups of some other non-planar cyclic molecules with the aid of projection diagrams is illustrated in Table 6.2.4.

Table 6.2.4. Point group identification of some cyclic molecules
Compound Perspective diagram Point group

### 6.2.3 Dipole moment and optical activity

The existence of a dipole moment tells us something about the molecular geometry or symmetry, and vice versa. For example, the existence of a dipole moment for $\mathrm{H}_{2} \mathrm{O}$ and $\mathrm{NH}_{3}$ implies that the former cannot be linear and the latter cannot be trigonal planar. Indeed, it is not difficult to show that molecules that possess dipole moments belong only to point groups $C_{n}, C_{s}$, or $C_{n \mathrm{v}}$.

For a molecule to be optically active, it and its mirror image cannot be superimposed on each other; i.e., they are dissymmetric (see Section 6.1.3). In the language of symmetry operations, this means that an optically active molecule cannot have any $S_{n}$ element. In particular, since $S_{1}$ is $\sigma$ and $S_{2}$ is $i$, any molecule that possesses a symmetry plane or a center of inversion cannot be optically active.

## Symmetry in Chemistry

### 6.3 Character tables

In the next chapter, we will present various chemical applications of group theory, including molecular orbital and hybridization theories, spectroscopic selection rules, and molecular vibrations. Before proceeding to these topics, we first need to introduce the character tables of symmetry groups. It should be emphasized that the following treatment is in no way mathematically rigorous. Rather, the presentation is example- and application-oriented.

According to group theory, for a molecule belonging to a certain symmetry point group, each electronic or vibrational wavefunction of this molecule must have the symmetry of one of the irreducible representations of the point group. For simplicity, we sometimes replace the mathematical term "irreducible representation" with the simple name "symmetry species." For a given point group, there are only a limited number of symmetry species, and the properties of each symmetry species are contained in the characters of the species. The characters of all the irreducible representations of a point group are summarized in the character table of this group. A typical character table, that of the $C_{2 v}$ group, will now be examined in detail.
As shown in Table 6.3.1, we can see that the $C_{2 v}$ character table is divided into four parts: Areas I to IV. We now discuss these four areas one by one.

Area I. In this area, we see that the four symmetry operations of the $C_{2 \mathrm{v}}$ group, $\boldsymbol{E}, \boldsymbol{C}_{2}, \boldsymbol{\sigma}_{\mathrm{v}}(x z), \boldsymbol{\sigma}_{\mathrm{v}}^{\prime}(y z)$, constitute four classes of operations; i.e., each class has one operation. According to group theory, for any point group, the number of irreducible representations is equal to the number of (symmetry operation) classes. Here, for $C_{2 \mathrm{v}}$, there are four irreducible representations and the characters of the representations are given in this area. For the first representation, called $A_{1}$, all the characters are 1 , which signifies that any wavefunction with $A_{1}$ symmetry is symmetric (with character 1) with respect to all four symmetry operations. (Examples will be given later.) On the other hand, representation $A_{2}$ is symmetric with respect to operation $E$ and $C_{2}$, but antisymmetric (with character -1 ) with respect to the two mirror reflections. For the remaining two representations, $B_{1}$ and $B_{2}$, they are antisymmetric with respect to $C_{2}$ and to one of the mirror reflections.

Additionally, it is noted that, mathematically, each irreducible representation is a square matrix and the character of the representation is the sum of the diagonal matrix elements. In the simple example of the $C_{2 v}$ character table, all the irreducible representations are one-dimensional; i.e., the characters are simply the lone elements of the matrices. For one-dimensional representations, the character for operation $\boldsymbol{R}, \chi(\boldsymbol{R})$, is either 1 or -1 .

Table 6.3.1. Character table of point group $C_{2 v}$

| $C_{2 \mathrm{v}}$ | $\boldsymbol{E}$ | $\boldsymbol{C}_{2}$ | $\boldsymbol{\sigma}_{\mathrm{v}}(x z)$ | $\boldsymbol{\sigma}_{\mathrm{v}}^{\prime}(x z)$ |  |  |
| :--- | ---: | ---: | ---: | ---: | :--- | :--- |
| $A_{1}$ | 1 | 1 | 1 | 1 | $z$ | $x^{2}, y^{2}, z^{2}$ |
| $A_{2}$ | 1 | 1 | -1 | -1 | $R_{z}$ | $x y$ |
| $B_{1}$ | 1 | -1 | 1 | -1 | $x, R_{y}$ | $x z$ |
| $B_{2}$ | 1 | -1 | -1 | 1 | $y, R_{x}$ | $y z$ |
| Area II |  |  | Area I |  | Area III | Area IV |

$v_{2}=1559 \mathrm{~cm}^{-1}$

$v_{3}=3756 \mathrm{~cm}^{-1}$

Fig. 6.3.1.
Normal vibrational modes of the water molecule; $v_{1}$ (symmetric stretch) and $\nu_{2}$ (bending) have $A_{1}$ symmetry, while $\nu_{3}$ (asymmetric stretch) has $B_{2}$ symmetry.

Before leaving the discussion of this area, let us consider a specific chemical example. The water molecule has $C_{2 \mathrm{v}}$ symmetry, hence its normal vibrational modes have $A_{1}, A_{2}, B_{1}$, or $B_{2}$ symmetry. The three normal modes of $\mathrm{H}_{2} \mathrm{O}$ are pictorially depicted in Fig. 6.3.1. From these illustrations, it can be readily seen that the atomic motions of the symmetric stretching mode, $\nu_{1}$, are symmetric with respect to $\boldsymbol{C}_{2}, \boldsymbol{\sigma}_{\mathrm{v}}(x z)$ and $\boldsymbol{\sigma}_{\mathrm{v}}^{\prime}(y z)$; thus $\nu_{1}$ has $A_{1}$ symmetry. Similarly, it is obvious that the bending mode, $\nu_{2}$, also has $A_{1}$ symmetry. Finally, the atomic motions of the asymmetric stretching mode, $\nu_{3}$, is antisymmetric with respect to $\boldsymbol{C}_{2}$ and $\boldsymbol{\sigma}_{\mathrm{v}}(x z)$, but symmetric with respect to $\boldsymbol{\sigma}_{\mathrm{v}}^{\prime}(y z)$. Hence $\nu_{3}$ has $\boldsymbol{B}_{2}$ symmetry. This example demonstrates all vibrational modes of a molecule must have the symmetry of one of the irreducible representations of the point group to which this molecule belongs. As will be shown later, molecular electronic wavefunctions may be also classified in this manner.

Area II. In this area, we have the Mulliken symbols for the representations. The meaning of these symbols carry is summarized in Table 6.3.2.

Referring to the $C_{2 \mathrm{v}}$ character table and the nomenclature rules in Table 6.3.2, we can see that all symmetry species of the $C_{2 v}$ group are one-dimensional; i.e., they are either $A$ or $B$ representations. The first two symmetry species, with $\chi\left(\boldsymbol{C}_{2}\right)=1$, are clearly $A$ representations, while the remaining two are $B$ representations. To these representations, subscripts 1 or 2 can be easily added, according to the rules laid down in Table 6.3.2. (It is noted that the classification of $B_{1}$ and $B_{2}$ cannot be unambiguously assigned.) Also, the first representation, with all characters equal to 1 , is called the totally symmetric representation (sometimes denoted as $\Gamma_{\mathrm{TS}}$ ). Such a representation exists for all groups, even though $\Gamma_{\mathrm{TS}}$ is not called $A_{1}$ in all instances.

Before concluding the discussion on the notation of the irreducible representations, we use $C_{2 \mathrm{v}}$ point group as an example to repeat what we mentioned previously: since this point group has only four symmetry species, $A_{1}, A_{2}, B_{1}$, and $B_{2}$, the electronic or vibrational wavefunctions of all $C_{2 \mathrm{v}}$ molecules (such as $\mathrm{H}_{2} \mathrm{O}, \mathrm{H}_{2} \mathrm{~S}$ ) must have the symmetry of one of these four representations. In addition, since this group has only one-dimensional representations, we will discuss degenerate representations such as $E$ and $T$ in subsequent examples.

Area III. In this part of the table, there will always be six symbols: $x, y, z, R_{x}$, $R_{y}, R_{z}$, which may be taken as the three components of the translational vector $(x, y, z)$ and the three rotations around the $x, y, z$ axes $\left(R_{x}, R_{y}, R_{z}\right)$. For the $C_{2 v}$ character table, $z$ appears in the row of $A_{1}$. This means that the $z$ component of the translational vector has $A_{1}$ symmetry. Similarly, the $x$ and $y$ components have $B_{1}$ and $B_{2}$ symmetry, respectively. The symmetries of rotations $R_{x}, R_{y}$, and $R_{z}$ can be seen from this table accordingly.

Table 6.3.2. Mulliken symbols for irreducible representations

## Dimensionality

A: One-dimensional, i.e., $\chi(\boldsymbol{E})=1$; symmetric with respect to $\boldsymbol{C}_{n}$, i.e., $\chi\left(\boldsymbol{C}_{n}\right)=1$
$B$ : One-dimensional, i.e., $\chi(\boldsymbol{E})=1$; antisymmetric with respect to $\boldsymbol{C}_{n}$, i.e., $\chi\left(\boldsymbol{C}_{n}\right)=-1$
$E$ : Two-dimensional, i.e., $\chi(\boldsymbol{E})=2$
$T$ : Three-dimensional, i.e., $\chi(\boldsymbol{E})=3$
$G$ : Four-dimensional, i.e., $\chi(\boldsymbol{E})=4$
$H$ : Five-dimensional, i.e., $\chi(\boldsymbol{E})=5$
Superscript
/: Symmetric with respect to $\sigma_{\mathrm{h}}$, i.e., $\chi\left(\sigma_{\mathrm{h}}\right)=1$
": Antisymmetric with respect to $\sigma_{\mathrm{h}}$, i.e., $\chi\left(\sigma_{\mathrm{h}}\right)=-1$

## Subscript

(i) $\mathrm{g}:$ Symmetric with respect to $\boldsymbol{i}$, i.e., $\chi(\boldsymbol{i})=1$
$\mathrm{u}:$ Antisymmetric with respect to $i$, i.e., $\chi(\boldsymbol{i})=-1$
(ii) For $A$ and $B$ representations, 1 : Symmetric with respect to $\boldsymbol{C}_{2}$ or $\boldsymbol{\sigma}_{\mathrm{v}}$, i.e., $\chi\left(\boldsymbol{C}_{2}\right)$ or $\chi\left(\boldsymbol{\sigma}_{\mathrm{v}}\right)=1$
2 : Antisymmetric with respect to $\boldsymbol{C}_{2}$ or $\boldsymbol{\sigma}_{\mathrm{v}}$, i.e., $\chi\left(\boldsymbol{C}_{2}\right)$ or $\chi\left(\boldsymbol{\sigma}_{\mathrm{v}}\right)=-1$
(iii) For $E$ and $T$ representations, numerical subscripts $1,2, \ldots$, are also employed in a general way which does not always indicate symmetry relative to $\boldsymbol{C}_{2}$ or $\boldsymbol{\sigma}_{\mathrm{v}}$.

For linear molecules with $C_{\infty v}$ and $D_{\infty \mathrm{h}}$ symmetry
$\Sigma^{+} \quad$ One-dimensional, symmetric with respect to $\sigma_{\mathrm{v}}$ or $\boldsymbol{C}_{2}$, i.e., $\chi(\boldsymbol{E})=1, \chi\left(\boldsymbol{\sigma}_{\mathrm{v}}\right)$ or $\chi\left(\boldsymbol{C}_{2}\right)=1$
$\Sigma^{-} \quad$ One-dimensional, antisymmetric with respect to $\sigma_{\mathrm{v}}$ or $\boldsymbol{C}_{2}$, i.e., $\chi(\boldsymbol{E})=1, \chi\left(\boldsymbol{\sigma}_{\mathrm{v}}\right)$
or $\chi\left(\boldsymbol{C}_{2}\right)=-1$
$\Pi$ Two-dimensional, i.e., $\chi(\boldsymbol{E})=2$
$\Delta$ Two-dimensional, i.e., $\chi(\boldsymbol{E})=2$
$\Phi$ Two-dimensional, i.e., $\chi(\boldsymbol{E})=2$
Lower case letters ( $a, b, e, t, \sigma, \pi, \ldots$ ) are used for the symmetries of individual orbitals; capital letters ( $A, B, E, T, \Sigma, \Pi, \ldots$ ) for the symmetries of the overall states.

Another way of rationalizing these results is to treat $x, y, z$ as $\mathrm{p}_{x}, \mathrm{p}_{y}, \mathrm{p}_{z}$ orbitals of central atom A in an $\mathrm{AH}_{n}$ molecule. A molecule with $C_{2 \mathrm{v}}$ symmetry is $\mathrm{H}_{2} \mathrm{~S}$. A convention to set up the Cartesian coordinates for this molecule is as follows. Take the principle axis ( $C_{2}$ in this case) as the $z$ axis. Since $\mathrm{H}_{2} \mathrm{~S}$ is planar, we take the $x$ axis to be perpendicular to the molecular plane. Finally, the $y$ axis is taken so as to form a right-handed system. Following this convention, the $\mathrm{p}_{x}$, $\mathrm{p}_{y}, \mathrm{p}_{z}$ orbitals on sulfur in a $\mathrm{H}_{2} \mathrm{~S}$ molecule are shown in Fig. 6.3.2. When the orientations of these orbitals are examined, it is obvious that the $\mathrm{p}_{z}$ orbital is symmetric with respect to all four operations of the $C_{2 \mathrm{v}}$ point group: $\boldsymbol{E}, \boldsymbol{C}_{2}$, $\boldsymbol{\sigma}_{\mathrm{v}}(x z), \boldsymbol{\sigma}_{\mathrm{v}}^{\prime}(y z)$. Thus the $\mathrm{p}_{z}$ orbital has $A_{1}$ symmetry. On the other hand, the $\mathrm{p}_{x}$ orbital is symmetric with respect to $\boldsymbol{E}$ and $\boldsymbol{\sigma}_{\mathrm{v}}(x z)$, but antisymmetric with respect to $\boldsymbol{C}_{2}$ and $\boldsymbol{\sigma}_{\mathrm{v}}^{\prime}(y z)$; hence $\mathrm{p}_{x}$ has $B_{1}$ symmetry.

Now it can be easily deduced that the $\mathrm{p}_{y}$ orbital has $B_{2}$ symmetry.
Area IV. This area contains the quadratic terms $x^{2}, y^{2}, z^{2}, x y, y z, x z$ or their linear combinations. Sometimes, instead of $x^{2}$ and $y^{2}$, we use their combinations $x^{2}+y^{2}$ and $x^{2}-y^{2}$. Following the discussion on Area III for the $\mathrm{H}_{2} \mathrm{~S}$ molecule, one might be inclined to consider these six entities as possible d functions of central atom A in an $\mathrm{AH}_{2}$ molecule, as shown in Fig. 6.3.3. Noting that there exist only five independent d orbitals each possessing two nodes, the $x^{2}+y^{2}$ function can be ruled out as it is devoid of nodal property. Furthermore, the

Fig. 6.3.2.
The three p orbitals of sulfur in a $\mathrm{H}_{2} \mathrm{~S}$ molecule, which lies in the $y z$ plane.

Fig. 6.3.3.
The quadratic functions $x^{2}+y^{2}$, $x^{2}-y^{2}, z^{2}$ (more correctly $3 z^{2}-1$ ), $x y$, $x z$, and $y z$. The $x^{2}+y^{2}$ function cannot represent a d orbital because it does not have a node. The remaining five are taken as pictorial representations of the five d orbitals of central atom A in the $\mathrm{AH}_{2}$ molecule. Note that $x y, x z, y z$, and $x^{2}-y^{2}$ each has two nodal planes, whereas the nodes of $z^{2}$ are the curved surfaces of two co-axial cones sharing a common vertex.
presence of $x^{2}-y^{2}$ implies that we can write down the equivalent terms $y^{2}-z^{2}$ and $z^{2}-x^{2}$; however, these three functions are not linearly independent. If $x^{2}-y^{2}$ is chosen, the sum of $y^{2}-z^{2}$ and $z^{2}-x^{2}$ gives $y^{2}-x^{2}$, which is the same as $x^{2}-y^{2}$ except for a reversal in sign, but the difference of $y^{2}-z^{2}$ and $z^{2}-x^{2}$ gives the new function $2 z^{2}-x^{2}-y^{2}$, which can be simplified to $3 z^{2}-1$ since $x^{2}+y^{2}+z^{2}=1$ (polar coordinate $r$ with unit length). In practice, it is conventional to denote the $3 z^{2}-1$ function simply as $z^{2}$. The five d orbitals are therefore labelled $z^{2}, x^{2}-y^{2}, x y, y z$, and $x z$.

Examining the six quadratic functions displayed in Fig. 6.3.3, it is clear that $x^{2}+y^{2}, x^{2}-y^{2}$, and $z^{2}$ are symmetric with respect to all four operations of the $C_{2 \mathrm{v}}$ point group. Hence they belong to the totally symmetric species $A_{1}$, as do $x^{2}$ and $y^{2}$ since they are merely linear combinations of $x^{2}+y^{2}$ and $x^{2}-y^{2}$. Similarly, the $x y$ function is symmetric with respect to $\boldsymbol{E}$ and $\boldsymbol{C}_{2}$ and antisymmetric with respect to the reflection operations, and hence it has $A_{2}$ symmetry. The symmetries of the $x z$ and $y z$ functions can be determined easily in an analogous manner.

The character tables of most familiar point groups are listed in Appendix 6.1 at the end of this chapter. It is noted that some collections of character tables, such as those given in Appendix 6.1, also include an "Area V," where the symmetry species of the seven $f$ orbitals (on the central atom) is indicated. Since the $f$

## Symmetry in Chemistry

orbitals are treated in Section 8.11 of this book, we will ignore this area in this initial discussion on the character tables.

Before we leave the $C_{2 \mathrm{v}}$ character table, it is noted that the characters of all groups satisfy the "orthonormal" relation:

$$
\frac{1}{h} \sum_{\boldsymbol{R}} \chi_{i}(\boldsymbol{R}) \chi_{j}(\boldsymbol{R})=\delta_{i j}=\left\{\begin{array}{ll}
1 & \text { when } i=j  \tag{6.3.1}\\
0 & \text { when } i \neq j
\end{array},\right.
$$

where $h$ is the order of the group (the number of operations in the group; for $C_{2 \mathrm{v}}, h=4$ ) and $\chi_{i}(\boldsymbol{R})$ is the character of operation $\boldsymbol{R}$ for the irreducible representation $\Gamma_{i}$, etc. The relation can be illustrated by the following two examples:

When $\Gamma_{i}=\Gamma_{j}=A_{2}$, eq. (6.3.1) becomes

$$
\begin{equation*}
\frac{1}{4}[(1)(1)+(1)(1)+(-1)(-1)+(-1)(-1)]=1 . \tag{6.3.2}
\end{equation*}
$$

When $\Gamma_{i}=A_{2}$ and $\Gamma_{j}=B_{1}$, eq. (6.3.1) now has the form

$$
\begin{equation*}
\frac{1}{4}[(1)(1)+(1)(-1)+(-1)(1)+(-1)(-1)]=0 . \tag{6.3.3}
\end{equation*}
$$

After a fairly lengthy discussion on the character table of the $C_{2 \mathrm{v}}$ group, we will proceed to those for the $C_{3 \mathrm{v}}$ and $C_{4 \mathrm{v}}$ point groups. The character tables of these two groups are shown in Tables 6.3.3 and 6.3.4, respectively. When Table 6.3.3 is examined, it is seen that the six operations of the $C_{3 \mathrm{v}}$ group are divided into three classes: $\boldsymbol{E} ; \boldsymbol{C}_{3}$, and $\boldsymbol{C}_{3}^{-1}$; the three $\boldsymbol{\sigma}_{\mathrm{v}}$ 's. Hence there are three symmetry species for this group. According to group theory, if the dimensions of the irreducible representations of a group are called $\ell_{1}, \ell_{2}, \ldots$, then we have

$$
\begin{equation*}
\sum_{i} \ell_{i}^{2}=h \tag{6.3.4}
\end{equation*}
$$

Table 6.3.3. Character table of point group $C_{3 \mathrm{v}}$

| $E$ | 2 | 0 | -2 | 0 | 0 | $(x, y)\left(R_{x}, R_{y}\right)$ | $(x z, y z)$ |

where, once again, $h$ is the order of the group. So, for the $C_{3 \mathrm{v}}$ group, with $h=6$, $\ell_{1}=1, \ell_{2}=1$, and $\ell_{3}=2$.

When examining Table 6.3.3, the first one-dimensional (totally symmetric) representation is again called $A_{1}$. The second one-dimensional representation, which is symmetric with respect to the $\boldsymbol{C}_{3}$ and $\boldsymbol{C}_{3}^{-1}$ operations and antisymmetric with respect to the three $\sigma_{\mathrm{v}}$ operations, is called $A_{2}$. From these results, it is now obvious that, for a given representation, operations belonging to the same class have the same character. Also, the $A_{1}$ and $A_{2}$ representations are "orthogonal" to each other, as stipulated by eq. (6.3.1):

$$
\begin{equation*}
\frac{1}{h} \sum_{R} \chi_{A_{1}}(\boldsymbol{R}) \chi_{A_{2}}(\boldsymbol{R})=\left(\frac{1}{6}\right)[(1)(1)+2(1)(1)+3(1)(-1)]=0 \tag{6.3.5}
\end{equation*}
$$

The last symmetry species of the $C_{3 \mathrm{v}}$ group is a two-dimensional $E$ representation. If we consider the p orbitals of phosphorus in $\mathrm{PF}_{3}$, a $C_{3 \mathrm{v}}$ molecule, we can see that the $\mathrm{p}_{z}$ orbital has $A_{1}$ symmetry. On the other hand, the $\mathrm{p}_{x}$ and $\mathrm{p}_{y}$ orbitals form an inseparable set with $E$ symmetry. In other words, no single function can have $E$ symmetry and it takes two functions to form an $E$ set. It is straightforward to show that the $E$ representation is orthogonal to both $A_{1}$ and $A_{2}$. Similarly, the $x^{2}-y^{2}$ and $x y$ functions for an $E$ set and the $x z$ and $y z$ functions constitute yet another $E$ set. In passing, it is pointed that the notation of representation $E$ originates from the German word entartet, meaning degenerate or abnormal. It should not be confused with the identity operation $E$, which, as already mentioned, is from Einheit meaning unity.

A similar situation exists for the $C_{4 \mathrm{v}}$ group, as shown in Table 6.3.4. Now there are five classes of operations and hence five irreducible representations. With $h=8$, there are four one-dimensional and one two-dimensional representations [cf. eq. (6.3.4)]. For a hypothetical $\mathrm{AX}_{4}$ (or $\mathrm{AX}_{5}$ ) molecule with $C_{4 \mathrm{v}}$ symmetry, the $\mathrm{p}_{z}$ orbital on A has $A_{1}$ symmetry (note that the $C_{4}$ axis is taken as the $z$ axis), while the $\mathrm{p}_{x}$ and $\mathrm{p}_{y}$ functions form an $E$ pair. Regarding the d orbitals on A , the $\mathrm{d}_{z^{2}}$ orbital has $A_{1}$ symmetry, the $\mathrm{d}_{x^{2}-y^{2}}$ orbital has $B_{1}$ symmetry, the $\mathrm{d}_{x y}$ orbital has $B_{2}$ symmetry, while the $\mathrm{d}_{x z}$ and $\mathrm{d}_{y z}$ orbitals form an $E$ set.

### 6.4 The direct product and its use

### 6.4.1 The direct product

In this section we discuss the direct product of two irreducible representations. The concept of direct product may seem abstract initially. But it should become easily acceptable once its applications are discussed in subsequent sections.

When we obtain the direct product $\Gamma_{i j}$ of two irreducible representations $\Gamma_{i}$ and $\Gamma_{j}$, i.e.,

$$
\begin{equation*}
\Gamma_{i} \times \Gamma_{j}=\Gamma_{i j}\left(\text { sometimes written as } \Gamma_{i} \otimes \Gamma_{j}\right) \tag{6.4.1}
\end{equation*}
$$

$\Gamma_{i j}$ has the following properties:
(1) The dimension of $\Gamma_{i j}$ is the product of the dimensions of $\Gamma_{i}$ and $\Gamma_{j}$;

Table 6.4.1. Direct products of the representations of the $C_{3 \mathrm{v}}$ group

| $C_{3 \mathrm{v}}$ | $\boldsymbol{E}$ | $2 \boldsymbol{C}_{3}$ | $3 \boldsymbol{\sigma}_{\mathrm{v}}$ |  |
| :--- | :--- | ---: | ---: | :--- |
| $A_{1}$ | 1 | 1 | 1 |  |
| $A_{2}$ | 1 | 1 | -1 |  |
| $E$ | 2 | -1 | 0 |  |
| $A_{1} \times A_{1}$ | 1 | 1 | 1 | $\equiv A_{1}$ |
| $A_{1} \times A_{2}$ | 1 | 1 | -1 | $\equiv A_{2}$ |
| $A_{1} \times E$ | 2 | -1 | 0 | $\equiv E$ |
| $A_{2} \times A_{2}$ | 1 | 1 | 1 | $\equiv A_{1}$ |
| $A_{2} \times E$ | 2 | -1 | 0 | $\equiv E$ |
| $E \times E$ | 4 | 1 | 0 | $\equiv A_{1}+A_{2}+E^{*}$ |

$$
\begin{aligned}
& \text { * } n\left(A_{1}\right)=(1 / 6)[(4)(1)+2(1)(1)+3(0)(1)]=1 \text {; } \\
& n\left(A_{2}\right)=(1 / 6)[(4)(1)+2(1)(1)+3(0)(-1)]=1 \text {; } \\
& n(E)=(1 / 6)[(4)(2)+2(1)(-1)+3(0)(0)]=1 \text {. }
\end{aligned}
$$

(2) The character of $\Gamma_{i j}$ for operation $\boldsymbol{R}$ is equal to the product of the characters of $\Gamma_{i}$ and $\Gamma_{j}$ for the same operation:

$$
\begin{equation*}
\chi_{i j}(\boldsymbol{R})=\chi_{i}(\boldsymbol{R}) \chi_{j}(\boldsymbol{R}) \tag{6.4.2}
\end{equation*}
$$

(3) In general, $\Gamma_{i j}$ is a reducible representation, i.e., a combination of irreducible representations. The number of times the irreducible representation $\Gamma_{k}$ occurs in the direct product $\Gamma_{i j}$ can be determined by:

$$
\begin{equation*}
n_{k}=\frac{1}{h} \sum_{\boldsymbol{R}} \chi_{i j}(\boldsymbol{R}) \chi_{k}(\boldsymbol{R}) . \tag{6.4.3}
\end{equation*}
$$

Now let us apply these formulas to some examples. All the direct products formed by the three irreducible representations of the $C_{3 \mathrm{v}}$ group are summarized in Table 6.4.1. These results show that the direct product of two irreducible representations is sometimes also an irreducible representation. When it is not, its constitution can be readily determined using eq. (6.4.3).

When eq. (6.4.3) is examined more closely, it is seen that, the division by $h$, the group order, makes the equation untenable for groups with an infinite order, namely, $C_{\infty v}$ and $D_{\infty h}$. Fortunately, in most cases the decomposition of a reducible representation for such groups can be achieved by inspection. Also, a work-around method is available in the literature (see references 19 and 20 listed at the end of the chapter). In any event, examples will be given later.

Based on the rather limited examples of direct products involving the representations of the $C_{3 \mathrm{v}}$ group, we can draw the following conclusions (or guidelines) regarding the totally symmetric representation $\Gamma_{\mathrm{TS}}$ :
(1) The direct product of any representation $\Gamma_{i}$ with $\Gamma_{\mathrm{TS}}$ is simply $\Gamma_{i}$.
(2) The direct product of any representation $\Gamma_{i}$ with itself, i.e., $\Gamma_{i} \times \Gamma_{i}$, is or contains $\Gamma_{\mathrm{TS}}$. In fact, only the direct product of a representation with itself is or contains $\Gamma_{\mathrm{TS}}$.

These results are useful in identifying non-zero integrals involving in various applications of quantum mechanics to molecular systems. This is the subject to be taken up in the next section.

### 6.4.2 Identifying non-zero integrals and selection rules in spectroscopy

The importance of direct products becomes more obvious when we consider some of the integrals we encounter in quantum chemistry. Take the simple case of

$$
\begin{equation*}
I_{1}=\int \psi_{i} \psi_{j} \mathrm{~d} \tau \tag{6.4.4}
\end{equation*}
$$

An example of $I_{1}$ is the overlap integral with $\psi_{i}$ being an orbital on one atom and $\psi_{j}$ an orbital on a different atom. Integral $I_{1}$ will vanish unless the integrand is invariant under all symmetry operations of the point group to which the molecule belongs. This condition is a generalization of the simple case of

$$
\begin{equation*}
I_{2}=\int_{-\infty}^{\infty} y \mathrm{~d} x=\int_{-\infty}^{\infty} f(x) \mathrm{d} x \tag{6.4.5}
\end{equation*}
$$

When $f(x)$ is an odd function, i.e., $f(-x)=-f(x), I_{2}=0$. Integral $I_{2}$ vanishes because the integrand is not invariant to the inversion operation.

Returning to integral $I_{1}$, when we say that integrand $\psi_{i} \psi_{j}$ is invariant to all symmetry operations, it means, in group theory language, the representation for $\psi_{i} \psi_{j}$ (denoted $\Gamma_{i j}$ ) is or contains $\Gamma_{\mathrm{TS}}$. In order for $\Gamma_{i j}$ to be or contain $\Gamma_{\mathrm{TS}}$, $\Gamma_{i}$ (representation for $\psi_{i}$ ) and $\Gamma_{j}$ (representation for $\psi_{j}$ ) must be one and the same. In chemical bonding language, for two atomic orbitals to have non-zero overlap, they must have the same symmetry.

Another integral that appears often in quantum chemistry is the energy interaction integral between orbitals $\psi_{i}$ and $\psi_{j}$

$$
\begin{equation*}
I_{3}=\int \psi_{i} \hat{H} \psi_{j} \mathrm{~d} \tau \tag{6.4.6}
\end{equation*}
$$

where $\hat{H}$ is the Hamiltonian operator. Since $\hat{H}$ is the operator for the energy of the molecule, it must be invariant to all symmetry operations; i.e., it has the symmetry of $\Gamma_{\mathrm{TS}}$. It follows that the symmetry of the integrand of $I_{3}$ is simply $\Gamma_{i} \times \Gamma_{\mathrm{TS}} \times \Gamma_{j}=\Gamma_{i} \times \Gamma_{j}$.
For $\Gamma_{i} \times \Gamma_{j}$ to be or to contain $\Gamma_{\mathrm{TS}}, \Gamma_{i}=\Gamma_{j}$. In non-mathematical language, only orbitals of the same symmetry will interact with each other.

Integrals of the form

$$
\begin{equation*}
I_{4}=\int \psi_{i} \hat{A} \psi_{j} \mathrm{~d} \tau \tag{6.4.7}
\end{equation*}
$$

where $\hat{A}$ is a certain quantum mechanical operator, are also common in quantum chemistry. For these integrals to be non-vanishing, $\Gamma_{i} \times \Gamma_{A} \times \Gamma_{j}$ is or contains $\Gamma_{\mathrm{TS}}$. For such condition to hold, $\Gamma_{i} \times \Gamma_{j}$ must be or contain $\Gamma_{A}$. (So $I_{3}$ is a special case of $I_{4}$.) In the following, we consider a special case of $I_{4}$.

In spectroscopy, for an electronic transition between the $i$ th state with wavefunction $\psi_{i}$ and the $j$ th state with wavefunction $\psi_{j}$, its intensity in the $x, y$, or
$z$ direction (denoted as $I_{x}, I_{y}$, and $I_{z}$, respectively) is proportional to the square of an integral similar to $I_{4}$ :

$$
\begin{align*}
I_{x} & \propto\left|\int \psi_{i} x \psi_{j} \mathrm{~d} \tau\right|^{2}  \tag{6.4.8}\\
I_{y} & \propto\left|\int \psi_{i} y \psi_{j} \mathrm{~d} \tau\right|^{2}  \tag{6.4.9}\\
I_{z} & \propto\left|\int \psi_{i} z \psi_{j} \mathrm{~d} \tau\right|^{2} \tag{6.4.10}
\end{align*}
$$

Stating the conditions for $I_{x}, I_{y}$, and $I_{z}$ to be non-zero amounts to laying down the selection rule for the electric dipole transitions. Based on the foregoing discussion, it is now obvious that, for a transition between states with wavefunctions $\psi_{i}$ and $\psi_{j}$ to be allowed, direct product $\Gamma_{i} \times \Gamma_{j}$ must be or contain $\Gamma_{x}, \Gamma_{y}$, or $\Gamma_{z}$.

Let us now apply this method to see whether the electron transition between states $A_{2}$ and $B_{2}$ is allowed for a molecule with $C_{2 \mathrm{v}}$ symmetry (such as $\mathrm{H}_{2} \mathrm{~S}$ ):

$$
\begin{aligned}
& \Gamma_{i}=A_{2}, \Gamma_{x}=B_{1}, \Gamma_{j}=B_{2}: A_{2} \times B_{1} \times B_{2}=A_{1}, \text { allowed in the } x \text { direction; } \\
& \Gamma_{i}=A_{2}, \Gamma_{y}=B_{2}, \Gamma_{j}=B_{2}: A_{2} \times B_{2} \times B_{2}=A_{2}, \text { forbidden in the } y \text { direction; } \\
& \Gamma_{i}=A_{2}, \Gamma_{z}=A_{1}, \Gamma_{j}=B_{2}: A_{2} \times A_{1} \times B_{2}=B_{1}, \text { forbidden in the } z \text { direction. }
\end{aligned}
$$

So the transition $A_{2} \leftrightarrow B_{2}$ is allowed in the $x$ direction, or $x$-polarized. The polarization of other transitions can be determined in a similar manner. The polarization of the allowed transitions for a $C_{2 \mathrm{v}}$ molecule is summarized in Fig. 6.4.1.

A well-known selection rule concerning centrosymmetric systems (those with a center of inversion) is the Laporte's rule. For such systems, states are either g (even) or u (odd). Laporte's rule states that only transitions between g and u states are allowed; i.e., transitions between two g states and those between two $u$ states are forbidden. With the foregoing discussion, this rule can now be easily proved. For centrosymmetric molecules, the three components of the dipole moment vector are all $u$. For $g \leftrightarrow g$ transitions, the overall symmetry

Fig. 6.4.1.
Polarization of all electric dipole transitions for a $C_{2 \mathrm{v}}$ molecule.

of the transition dipole moment is $\mathrm{g} \times \mathrm{u} \times \mathrm{g}=\mathrm{u}$ (antisymmetric) and hence the transition is not allowed. For $u \leftrightarrow u$ transitions, we have $u \times u \times u=u$ and the transitions are again forbidden. For $u \leftrightarrow g$ ones, we get $u \times u \times g=g$ (symmetric) and they are allowed.

In this section, we have shown that, by determining the symmetry of the integrand, we can identify the non-zero integrals and, in turn, derive the various selection rules in electronic spectroscopy.

### 6.4.3 Molecular term symbols

In our treatment on the bonding in linear molecules, we called the molecular orbitals of these systems either $\sigma$ or $\pi$ orbitals. We now know that $\sigma$ and $\pi$ are actually irreducible representations of the $C_{\infty v}$ or $D_{\infty h}$ groups. For nonlinear molecules, names such as $\sigma$ and $\pi$ no longer apply. Instead, we should use the symbols of the irreducible representations of the symmetry group to which the molecule belongs. So for the $C_{2 \mathrm{v}}$ molecules such as $\mathrm{H}_{2} \mathrm{~S}$ and $\mathrm{H}_{2} \mathrm{O}$, the molecular orbitals are $a_{1}, a_{2}, b_{1}$, or $b_{2}$ orbitals. (Again we note that we use lower case letters for individual orbitals and capital letters for the overall states. This is a convention we also use for atoms: we have s, $\mathrm{p}, \mathrm{d}, \ldots$ atomic orbitals and $S, P, D, \ldots$ atomic states.) If the molecular orbitals have the symmetries of the irreducible representations, so do the states, or the molecular term symbols, arising from the electronic configurations. This is the subject to be taken up in this section.

When the electronic configuration has only filled orbitals, there is only one state: ${ }^{1} \Gamma_{\mathrm{TS}}$, where $\Gamma_{\mathrm{TS}}$ is the totally symmetric representation. If the configuration has only one open shell (having symmetry $\Gamma_{i}$ ) with one electron, we again have only one state: ${ }^{2} \Gamma_{i}$. When there are two open shells (having symmetries $\Gamma_{i}$ and $\Gamma_{j}$ ) each with one electron, the symmetry of the state is $\Gamma_{i} \times \Gamma_{j}=\Gamma_{i j}$ and the overall states (including spin) are ${ }^{3} \Gamma_{i j}$ and ${ }^{1} \Gamma_{i j}$.

Let us now apply this method to a specific example. Consider the ethylene molecule with $D_{2 \mathrm{~h}}$ symmetry. As can be seen from the character table of the $D_{2 \mathrm{~h}}$ point group (Table 6.4.2), this group has eight symmetry species. Hence the molecular orbitals of ethylene must have the symmetry of one of these eight representations. In fact, the ground electronic configuration for ethylene is

$$
\left(1 a_{\mathrm{g}}\right)^{2}\left(1 b_{1 \mathrm{u}}\right)^{2}\left(2 a_{\mathrm{g}}\right)^{2}\left(2 b_{1 \mathrm{u}}\right)^{2}\left(1 b_{2 \mathrm{u}}\right)^{2}\left(3 a_{\mathrm{g}}\right)^{2}\left(1 b_{3 \mathrm{~g}}\right)^{2}\left(1 b_{3 \mathrm{u}}\right)^{2}\left(1 b_{2 \mathrm{~g}}\right)^{0}
$$

Table 6.4.2. Character table of point group $D_{2 \mathrm{~h}}$

| $D_{2 \mathrm{~h}}$ | $\boldsymbol{E}$ | $\boldsymbol{C}_{2}(z)$ | $\boldsymbol{C}_{2}(y)$ | $\boldsymbol{C}_{2}(x)$ | $\boldsymbol{i}$ | $\boldsymbol{\sigma}(x y)$ | $\boldsymbol{\sigma}(x z)$ | $\boldsymbol{\sigma}(y z)$ |  |
| :--- | ---: | ---: | ---: | ---: | :--- | ---: | ---: | ---: | :--- |
| $A_{\mathrm{g}}$ | 1 | 1 | 1 | 1 | 1 | 1 | 1 | 1 |  |
| $B_{1 \mathrm{~g}}$ | 1 | 1 | -1 | -1 | 1 | 1 | -1 | -1 | $R_{z}$ |
| $x^{2}, y^{2}, z^{2}$ |  |  |  |  |  |  |  |  |  |
| $B_{2 \mathrm{~g}}$ | 1 | -1 | 1 | -1 | 1 | -1 | 1 | -1 | $R_{y}$ |
| $B_{3 \mathrm{~g}}$ | 1 | -1 | -1 | 1 | 1 | -1 | -1 | 1 | $R_{x}$ |
| $A_{\mathrm{u}}$ | 1 | 1 | 1 | 1 | -1 | -1 | -1 | -1 |  |
| $B_{1 \mathrm{u}}$ | 1 | 1 | -1 | -1 | -1 | -1 | 1 | 1 | $z$ |
| $B_{2 \mathrm{u}}$ | 1 | -1 | 1 | -1 | -1 | 1 | -1 | 1 | $y$ |
| $B_{3 \mathrm{u}}$ | 1 | -1 | -1 | 1 | -1 | 1 | -1 | -1 | $x$ |

So the eight pairs of electrons of this molecule occupy delocalized molecular orbitals $1 a_{\mathrm{g}}$ to $1 b_{3 \mathrm{u}}$, while the first vacant orbital is $1 b_{2 \mathrm{~g}}$. Note that the names of these orbitals are simply the symmetry species of the $D_{2 \mathrm{~h}}$ point group. In other words, molecular orbitals are labeled by the irreducible representations of the point group to which the molecule belongs. So for ethylene there are three filled orbitals with $A_{\mathrm{g}}$ symmetry; the one with the lowest energy is called $1 a_{\mathrm{g}}$, the next one is $2 a_{\mathrm{g}}$, etc. Similarly, there are two orbitals with $B_{1 \mathrm{u}}$ symmetry and they are called $1 b_{1 \mathrm{u}}$ and $2 b_{1 \mathrm{u}}$. All the molecular orbitals listed above, except the first two, are illustrated pictorially in Fig. 6.4.2. By checking the $D_{2 \mathrm{~h}}$ character table with reference to the chosen coordinate system shown in Fig. 6.4.2, it can be readily confirmed that these orbitals do have the labeled symmetry. In passing, it is noted that the two filled molecular orbitals of ethylene not displayed in Fig. $6.4 .2,1 a_{\mathrm{g}}$ and $1 b_{1 \mathrm{u}}$, are simply the sum and difference, respectively, of the two carbon 1 s orbitals.

So for the ethylene molecule, with an electronic configuration having only filled orbitals, the ground state is simply ${ }^{1} A_{\mathrm{g}}$, where $A_{\mathrm{g}}$ is the totally symmetric species of the $D_{2 \mathrm{~h}}$ point group. For the ethylene cation, with configuration $\ldots\left(1 b_{3 \mathrm{u}}\right)^{1}$, the electronic state is ${ }^{2} B_{3 \mathrm{u}}$. For ethylene with the excited configuration $\ldots\left(1 b_{3 \mathrm{u}}\right)^{1}\left(1 b_{2 \mathrm{~g}}\right)^{1}$, the electronic states are ${ }^{1} B_{1 \mathrm{u}}$ and ${ }^{3} B_{1 \mathrm{u}}$, as $B_{3 \mathrm{u}} \times B_{2 \mathrm{~g}}=B_{1 \mathrm{u}}$.

If, in the configuration, there are a number of completely filled orbitals and one open (degenerate) shell with two (equivalent) electrons, there will be singlet as well as triplet states. To determine the spatial symmetry of these states, we make use of the formulas:

$$
\begin{align*}
n=2: \quad \chi(\boldsymbol{R}, \text { singlet }) & =1 / 2\left[\chi^{2}(\boldsymbol{R})+\chi\left(\boldsymbol{R}^{2}\right)\right],  \tag{6.4.11}\\
\quad \chi(\boldsymbol{R}, \text { triplet }) & =1 / 2\left[\chi^{2}(\boldsymbol{R})-\chi\left(\boldsymbol{R}^{2}\right)\right] . \tag{6.4.12}
\end{align*}
$$

In eqs. (6.4.11) and (6.4.12), $\chi^{2}(\boldsymbol{R})$ is the square of $\chi(\boldsymbol{R})$, while $\chi\left(\boldsymbol{R}^{2}\right)$ is the character of operation $\boldsymbol{R}^{2}$, which, according to group theory, must also be an operation of the group.

Table 6.4.3. Derivation of the electronic states arising from configuration $(e)^{2}$ of a molecule with $C_{3 \mathrm{v}}$ symmetry

| $C_{3 \mathrm{v}}$ | $\boldsymbol{E}$ | $2 \boldsymbol{C}_{3}$ | $3 \sigma_{\mathrm{v}}$ |  |
| :--- | ---: | ---: | ---: | :--- |
| $A_{1}$ | 1 | 1 | 1 |  |
| $A_{2}$ | 1 | 1 | -1 |  |
| $E$ | 2 | -1 | 0 |  |
| $\boldsymbol{R}$ | $\boldsymbol{E}$ | $\boldsymbol{C}_{3}$ | $\boldsymbol{\sigma}_{\mathrm{v}}$ |  |
| $\boldsymbol{R}^{2}$ | $\boldsymbol{E}$ | $\boldsymbol{C}_{3}$ | $\boldsymbol{E}$ |  |
| $\chi(\boldsymbol{R})$ in $E$ representation | 2 | -1 | 0 |  |
| $\chi^{2}(\boldsymbol{R})$ in $E$ representation | 4 | 1 | 0 |  |
| $\chi\left(\boldsymbol{R}^{2}\right)$ in $E$ representation | 2 | -1 | 2 |  |
| $\chi(\boldsymbol{R}$, singlet $)=1 / 2\left[\chi^{2}(\boldsymbol{R})+\chi\left(\boldsymbol{R}^{2}\right)\right]$ | 3 | 0 | 1 | $\equiv{ }^{1} E+{ }^{1} A_{1}$ |
| $\chi(\boldsymbol{R}$, triplet $)={ }^{1} / 2\left[\chi^{2}(\boldsymbol{R})-\chi\left(\boldsymbol{R}^{2}\right)\right]$ | 1 | 1 | -1 | $\equiv{ }^{3} A_{2}$ |

For a molecule with $C_{3 \mathrm{v}}$ symmetry, when there are two electrons in an $e$ orbital; i.e., when we have a configuration of $(e)^{2}$ (note that it takes four electrons to completely fill the doubly degenerate $e$ orbital), we can use eqs. (6.4.11) and (6.4.12) to derive the electronic states of this configuration, as shown in Table 6.4.3.
According to Hund's rule, among the three electronic states derived, ${ }^{3} A_{2}$ should have the lowest energy. So for a molecule with $C_{3 \mathrm{v}}$ symmetry, configurations involving $e$ orbitals will lead to the following electronic states: $(e)^{1}$, ${ }^{2} E ;(e)^{2},{ }^{3} A_{2}$ (lowest energy), ${ }^{1} E,{ }^{1} A_{1} ;(e)^{3},{ }^{2} E ;(e)^{4},{ }^{1} A_{1}$. Note that $(e){ }^{1}$ and $(e)^{3}$, being conjugate configurations, have the same state(s), analogous to the $p^{1}$ and $p^{5}$ configurations for atomic systems.

Now let us turn to a three-dimensional irreducible representation for the first time. Take the $T_{2 \mathrm{~g}}$ representation of a molecule with $O_{\mathrm{h}}$ symmetry as an example. For configurations $\left(t_{2 \mathrm{~g}}\right)^{1}$ and $\left(t_{2 \mathrm{~g}}\right)^{5}$, the only electronic state is ${ }^{2} T_{2 \mathrm{~g}}$. (Note that a $t_{2 \mathrm{~g}}$ orbital can accommodate up to six electrons.) For configurations $\left(t_{2 \mathrm{~g}}\right)^{2}$ and $\left(t_{2 \mathrm{~g}}\right)^{4}$, the states are ${ }^{3} T_{1 \mathrm{~g}}$ (lowest energy), ${ }^{1} T_{2 \mathrm{~g}},{ }^{1} E_{\mathrm{g}}$, and ${ }^{1} A_{1 \mathrm{~g}}$. The detailed derivation of these states is summarized in Table 6.4.4. For $\left(t_{2 \mathrm{~g}}\right)^{6}$, a closed-shell configuration, the only term is ${ }^{1} A_{1 \mathrm{~g}}$, a singlet state with totally symmetric spatial wavefunction. For the only remaining configuration, $\left(t_{2 \mathrm{~g}}\right)^{3}$, there will be doublet and quartet states. To derive these states, we require the following formulas:

$$
\begin{align*}
& n=3: \quad \chi(\boldsymbol{R}, \text { doublet })=\frac{1}{3}\left[\chi^{3}(\boldsymbol{R})-\chi\left(\boldsymbol{R}^{3}\right)\right]  \tag{6.4.13}\\
& \chi(\boldsymbol{R}, \text { quartet })  \tag{6.4.14}\\
&=\left(\frac{1}{6}\right)\left[\chi^{3}(\boldsymbol{R})-3 \chi(\boldsymbol{R}) \chi\left(\boldsymbol{R}^{2}\right)+2 \chi\left(\boldsymbol{R}^{3}\right)\right] .
\end{align*}
$$

In eqs. (6.4.13) and (6.4.14), $\chi\left(\boldsymbol{R}^{3}\right)$ is the character of operation $\boldsymbol{R}^{3}$ which of course is also one of the operations in the group. Applying these equations, we can derive the following states for the $\left(t_{2 \mathrm{~g}}\right)^{3}$ configuration: ${ }^{4} A_{2 \mathrm{~g}}$ (lowest energy), ${ }^{2} T_{1 \mathrm{~g}},{ }^{2} T_{2 \mathrm{~g}}$, and ${ }^{2} E_{\mathrm{g}}$, as shown in Table 6.4.4.

## Symmetry in Chemistry

Table 6.4.4. Derivation of the electronic states arising from the configurations $\left(t_{2 \mathrm{~g}}\right)^{2}$ and $\left(t_{2 \mathrm{~g}}\right)^{3}$ of a coordination complex with $O_{\mathrm{h}}$ symmetry

For the sake of completeness, we give below the formulas for open-shell systems with four or five equivalent electrons:

$$
\begin{align*}
n=4: \chi(\boldsymbol{R}, \text { singlet })=\left(\frac{1}{12}\right) & {\left[\chi^{4}(\boldsymbol{R})-4 \chi(\boldsymbol{R}) \chi\left(\boldsymbol{R}^{3}\right)+3 \chi^{2}\left(\boldsymbol{R}^{2}\right)\right], }  \tag{6.4.15}\\
\chi(\boldsymbol{R}, \text { triplet })=\left(\frac{1}{8}\right) & {\left[\chi^{4}(\boldsymbol{R})-2 \chi^{2}(\boldsymbol{R}) \chi\left(\boldsymbol{R}^{2}\right)\right.} \\
& \left.+2 \chi\left(\boldsymbol{R}^{4}\right)-\chi^{2}\left(\boldsymbol{R}^{2}\right)\right],  \tag{6.4.16}\\
\chi(\boldsymbol{R}, \text { quintet })=\left(\frac{1}{24}\right) & {\left[\chi^{4}(\boldsymbol{R})-6 \chi^{2}(\boldsymbol{R}) \chi\left(\boldsymbol{R}^{2}\right)+8 \chi(\boldsymbol{R}) \chi\left(\boldsymbol{R}^{3}\right)\right.} \\
& \left.-6 \chi\left(\boldsymbol{R}^{4}\right)+3 \chi^{2}\left(\boldsymbol{R}^{2}\right)\right] .  \tag{6.4.17}\\
n=5: \quad \chi(\boldsymbol{R}, \text { doublet })=\left(\frac{1}{24}\right) & {\left[\chi^{5}(\boldsymbol{R})-2 \chi^{3}(\boldsymbol{R}) \chi\left(\boldsymbol{R}^{2}\right)-4 \chi^{2}(\boldsymbol{R}) \chi\left(\boldsymbol{R}^{3}\right)\right.} \\
& +6 \chi(\boldsymbol{R}) \chi\left(\boldsymbol{R}^{4}\right)+3 \chi(\boldsymbol{R}) \chi^{2}\left(\boldsymbol{R}^{2}\right) \\
& \left.-4 \chi\left(\boldsymbol{R}^{2}\right) \chi\left(\boldsymbol{R}^{3}\right)\right],  \tag{6.4.18}\\
\chi(\boldsymbol{R}, \text { quartet })=\left(\frac{1}{30}\right) & {\left[\chi^{5}(\boldsymbol{R})-5 \chi^{3}(\boldsymbol{R}) \chi\left(\boldsymbol{R}^{2}\right)+5 \chi^{2}(\boldsymbol{R}) \chi\left(\boldsymbol{R}^{3}\right)\right.} \\
& \left.+5 \chi\left(\boldsymbol{R}^{2}\right) \chi\left(\boldsymbol{R}^{3}\right)-6 \chi\left(\boldsymbol{R}^{5}\right)\right], \tag{6.4.19}
\end{align*}
$$

Table 6.4.5. The direct product of $\Pi \times \Pi$ or a molecule with $C_{\infty \mathrm{v}}$ symmetry

$$
\begin{align*}
\chi(\boldsymbol{R}, \text { sextet })=\left(\frac{1}{120}\right) & {\left[\chi^{5}(\boldsymbol{R})-10 \chi^{3}(\boldsymbol{R}) \chi\left(\boldsymbol{R}^{2}\right)+20 \chi^{2}(\boldsymbol{R}) \chi\left(\boldsymbol{R}^{3}\right)\right.} \\
& -30 \chi(\boldsymbol{R}) \chi\left(\boldsymbol{R}^{4}\right)+15 \chi(\boldsymbol{R}) \chi^{2}\left(\boldsymbol{R}^{2}\right) \\
& \left.-20 \chi\left(\boldsymbol{R}^{2}\right) \chi\left(\boldsymbol{R}^{3}\right)+24 \chi\left(\boldsymbol{R}^{5}\right)\right] . \tag{6.4.20}
\end{align*}
$$

Equations (6.4.15) to (6.4.20) may be of use for systems with $I_{\mathrm{h}}$ symmetry. For such systems, we may be dealing with orbitals with $G$ or $H$ symmetry, which have four- and five-fold degeneracy, respectively.

To conclude this section, we discuss an example involving a linear molecule, for which eq. (6.4.3) is not applicable. Consider configuration $(1 \pi)^{1}(2 \pi)^{1}$ for linear molecule XYZ with $C_{\infty v}$ symmetry. As shown in Table 6.4.5, we can decompose the direct product $\Pi \times \Pi$ into the symmetry species of the $C_{\infty v}$ group, without using eq. (6.4.3) explicitly.

To decompose $\Gamma(\Pi \times \Pi)$, by inspecting $\chi\left(C_{\infty}^{\phi}\right)$, we can see that $\Gamma(\Pi \times \Pi)$ must contain $\Delta$ once. Elimination of $\Delta$ from $\Gamma(\Pi \times \Pi)$ yields characters (2, $2, \ldots, 0$ ), which is simply the sum of $\Sigma^{+}$and $\Sigma^{-}$. Hence, after considering the spin part, it can be readily seen that the states arising from configuration $(1 \pi)^{1}(2 \pi)^{1}$ are ${ }^{3} \Delta,{ }^{1} \Delta,{ }^{3} \Sigma^{+},{ }^{1} \Sigma^{+},{ }^{3} \Sigma^{-}$, and ${ }^{1} \Sigma^{-}$.

In addition to the derivation of selection rules in electronic spectroscopy and electronic states from a given configuration, there are many other fruitful applications of group theory to chemical problems, some of which will be discussed in the next chapter.

10. The groups $C_{\infty \mathrm{v}}$ and $D_{\infty h}$ for linear molecules

11. The Icosahedral groups

Note: In these groups and others containing $C_{5}$, the following relationships may be useful:

$$
\begin{aligned}
& \eta^{+}=1 / 2\left[1+(5)^{1 / 2}\right]=1.61803 \ldots=-2 \cos 144^{\circ} \\
& \eta^{-}=1^{1 / 2}\left[1-(5)^{1 / 2}\right]=-0.61803 \ldots=-2 \cos 72^{\circ} \\
& \eta^{+} \times \eta^{+}=1+\eta^{+}, \quad \eta^{-} \times \eta^{-}=1+\eta^{-}, \eta^{+} \times \eta^{-}=-1 .
\end{aligned}
$$

## Application of Group Theory to Molecular Systems

In this chapter, we discuss the various applications of group theory to chemical problems. These include the description of structure and bonding based on hybridization and molecular orbital theories, selection rules in infrared and Raman spectroscopy, and symmetry of molecular vibrations. As will be seen, even though most of the arguments used are qualitative in nature, meaningful results and conclusions can be obtained.

### 7.1 Molecular orbital theory

As mentioned previously in Chapter 3, when we treat the bonding of a molecule by applying molecular orbital theory, we need to solve the secular determinant

$$
\left|\begin{array}{cccc}
H_{11}-E S_{11} & H_{12}-E S_{12} & \ldots & H_{1 n}-E S_{1 n}  \tag{7.1.1}\\
H_{12}-E S_{12} & H_{22}-E S_{22} & \ldots & H_{2 n}-E S_{2 n} \\
\vdots & \vdots & & \vdots \\
H_{1 n}-E S_{1 n} & H_{2 n}-E S_{2 n} & \ldots & H_{n n}-E S_{n n}
\end{array}\right|=0 .
$$

In eq. (7.1.1), energy $E$ is the only unknown, while energy interaction integrals $H_{i j}\left(\equiv \int \phi_{i} \hat{H} \phi_{j} \mathrm{~d} \tau\right)$ and overlap integrals $S_{i j}\left(\equiv \int \phi_{i} \phi_{j} d \tau\right)$ are calculated with known atomic orbitals $\phi_{1}, \phi_{2}, \ldots \phi_{n}$. After solving for $E$ ( $n$ of them in all), we can substitute each $E$ in the following secular equations to determine the values of coefficients $c_{i}$ :

In molecular orbital theory, the molecular orbitals are expressed as linear combinations of atomic orbitals:

$$
\begin{equation*}
\psi=\sum_{i=1}^{n} c_{i} \phi_{i}=c_{1} \phi_{1}+c_{2} \phi_{2}+\ldots+c_{n} \phi_{n} \tag{7.1.3}
\end{equation*}
$$

## Symmetry in Chemistry

So we have $n E$ 's from eq. (7.1.1), and each $E$ value leads to a set of coefficients, or to one molecular orbital. In other words, $n$ atomic orbitals form $n$ molecular orbitals; i.e., the number of orbitals is conserved.

The solution of eq. (7.1.1) is made easier if the secular determinant can be put in block-diagonal form, or block-factored:

We will then be solving several small determinants ( $k \times k ; l \times l ; \ldots ; m \times m$ ) instead of a very large one $(n \times n)$. By taking advantage of the symmetry property of the system, group theory can do just that. In this section, we illustrate the reduction of the secular determinant by studying several representative molecular systems.

Fig. 7.1.1.
Coordinate system for the $\mathrm{H}_{2} \mathrm{O}$ molecule. Note that the $x$ axis points toward the reader.

### 7.1.1 $\quad \mathrm{AH}_{n}(\mathrm{n}=2-6)$ molecules

As mentioned in Chapter 3, to construct the molecular orbitals for an $\mathrm{AX}_{n}$ molecule, we need to combine the atomic orbitals on X and then match the resultant combinations with the atomic orbitals on the central atom A. With group theory, we can derive the linear combinations systematically.

Let us use the simple molecule $\mathrm{H}_{2} \mathrm{O}$ as the first example. The coordinate system we adopt for this molecule is shown in Fig. 7.1.1. The orientation of the adopted set of axes is similar to that for $\mathrm{H}_{2} \mathrm{~S}$ in Fig. 6.4.2.

If we assume that the 2 s and 2 p orbitals of oxygen and the 1 s orbitals of the hydrogen atoms take part in the bonding, the secular determinant to be solved has the dimensions $6 \times 6$. Now we proceed to determine the symmetries of the participating atomic orbitals. From the $C_{2 \mathrm{v}}$ character table, it can be seen that the $2 \mathrm{p}_{x}, 2 \mathrm{p}_{y}$, and $2 \mathrm{p}_{z}$ orbitals on oxygen have $B_{1}, B_{2}$, and $A_{1}$ symmetries, respectively, while the oxygen 2 s orbital, being totally symmetric, has $A_{1}$ symmetry. To determine the characters of the representation generated by the hydrogen 1s orbitals, we make use of this simple rule: the character (of an operation) is equal to the number of objects (vectors or orbitals) unshifted by the operation. So, for the hydrogen 1s orbitals:

| $C_{2 \mathrm{v}}$ | $\boldsymbol{E}$ | $\boldsymbol{C}_{2}$ | $\boldsymbol{\sigma}_{\mathrm{v}}(x z)$ | $\boldsymbol{\sigma}_{\mathrm{v}}^{\prime}(y z)$ |  |
| :--- | :--- | :--- | :--- | :--- | :--- |
| $\Gamma_{\mathrm{H}}$ | 2 | 0 | 0 | 2 | $\equiv A_{1}+B_{2}$ |

In other words, the two 1 s orbitals will form two linear combinations, one with $A_{1}$ symmetry and the other with $B_{2}$ symmetry. To deduce these two linear combinations, we need to employ the projection operator, which is defined as

$$
\begin{equation*}
P^{i}=\sum_{j=1}^{h} \chi^{i}\left(\boldsymbol{R}_{j}\right) \boldsymbol{R}_{j}, \tag{7.1.5}
\end{equation*}
$$

where $P^{i}$ is the projection operator for representation $\Gamma_{i}, \chi^{i}\left(\boldsymbol{R}_{j}\right)$ is the character of the representation $\Gamma_{i}$ for operation $\boldsymbol{R}_{j}$, and the summation is over all the symmetry operations ( $h$ in total). To derive the linear combinations of the hydrogen 1s orbitals with $A_{1}$ symmetry, we apply $P^{A_{1}}$ on, say, the 1 s orbital on $\mathrm{H}_{a}$ (denoted as $1 \mathrm{~s}_{a}$ ). So we need to know the result of applying every symmetry operation in the $C_{2 \mathrm{v}}$ group to $1 \mathrm{~s}_{a}$ :

| $C_{2 \mathrm{v}}$ | $\boldsymbol{E}$ | $\boldsymbol{C}_{2}$ | $\boldsymbol{\sigma}_{\mathrm{v}}(x z)$ | $\boldsymbol{\sigma}_{\mathrm{v}}^{\prime}(y z)$ |
| :---: | :---: | :---: | :---: | :---: |
| $1 \mathrm{~s}_{a}$ | $1 \mathrm{~s}_{a}$ | $1 \mathrm{~s}_{b}$ | $1 \mathrm{~s}_{b}$ | $1 \mathrm{~s}_{a}$ |

Now we apply $P^{A_{1}}$ to $1 \mathrm{~s}_{a}$ :

$$
\begin{align*}
P^{A_{1}}\left(1 \mathrm{~s}_{a}\right)= & {\left[1 \cdot \boldsymbol{E}+1 \cdot \boldsymbol{C}_{2}+1 \cdot \boldsymbol{\sigma}_{\mathrm{v}}(x z)+1 \cdot \boldsymbol{\sigma}_{\mathrm{v}}^{\prime}(y z)\right] 1 \mathrm{~s}_{a} } \\
= & 1 \mathrm{~s}_{a}+1 \mathrm{~s}_{b}+1 \mathrm{~s}_{b}+1 \mathrm{~s}_{a}=2\left(1 \mathrm{~s}_{a}\right)+2\left(1 \mathrm{~s}_{b}\right) \\
& \Rightarrow(2)^{-1 / 2}\left(1 \mathrm{~s}_{a}+1 \mathrm{~s}_{b}\right) \quad \text { (after normalization) } \tag{7.1.6}
\end{align*}
$$

To obtain the combination with $B_{2}$ symmetry:

$$
\begin{align*}
P^{B_{2}}\left(1 \mathrm{~s}_{a}\right)= & {\left[1 \cdot \boldsymbol{E}+(-1) \boldsymbol{C}_{2}+(-1) \boldsymbol{\sigma}_{\mathrm{v}}(x z)+1 \cdot \boldsymbol{\sigma}_{\mathrm{v}}^{\prime}(y z)\right] 1 \mathrm{~s}_{a} } \\
= & 1 \mathrm{~s}_{a}-1 \mathrm{~s}_{b}-1 \mathrm{~s}_{b}+1 \mathrm{~s}_{a}=2\left(1 \mathrm{~s}_{a}\right)-2\left(1 \mathrm{~s}_{b}\right) \\
& \Rightarrow(2)^{-1 / 2}\left(1 \mathrm{~s}_{a}-1 \mathrm{~s}_{b}\right) \quad \text { (after normalization) } . \tag{7.1.7}
\end{align*}
$$

In Table 7.1.1 we summarize the way in which the molecular orbitals are formed in $\mathrm{H}_{2} \mathrm{O}$. From these results, we can see that the original $6 \times 6$ secular determinant is now block-factored into three smaller ones: one $3 \times 3$ for functions with $A_{1}$ symmetry, one $2 \times 2$ with $B_{2}$ symmetry, and one $1 \times 1$ with $B_{1}$ symmetry. A schematic energy diagram for this molecule is shown in Fig. 7.1.2. From this diagram, we can see that there are two bonding orbtals ( $1 a_{1}$ and $1 b_{2}$ ), two other orbitals essentially nonbonding ( $2 a_{1}$ and $1 b_{1}$ ), and two antibonding orbitals ( $2 b_{2}$ and $3 a_{1}$ ). Also, all the bonding and nonbonding orbitals are filled, giving rise to a ground electronic configuration of $\left(1 a_{1}\right)^{2}\left(1 b_{2}\right)^{2}\left(2 a_{1}\right)^{2}\left(1 b_{1}\right)^{2}$ and an electronic state of ${ }^{1} A_{1}$. This bonding picture indicates that $\mathrm{H}_{2} \mathrm{O}$ has two $\sigma$ bonds and two filled nonbonding orbitals. Such a result is in qualitative agreement with the familiar valence bond description for this molecule.

In passing, it is of interest to note that, according to Fig. 7.1.2, the first excited electronic configuration is $\left(1 a_{1}\right)^{2}\left(1 b_{2}\right)^{2}\left(2 a_{1}\right)^{2}\left(1 b_{1}\right)^{1}\left(2 b_{2}\right)^{1}$, giving rise to states ${ }^{3} A_{2}$ and ${ }^{1} A_{2}$. It is easy to show that electronic transition $A_{1} \rightarrow A_{2}$ is not allowed for a molecule with $C_{2 \mathrm{v}}$ symmetry. In other words, ${ }^{1} A_{1} \rightarrow{ }^{1} A_{2}$

Table 7.1.1. Formation of the molecular orbitals in $\mathrm{H}_{2} \mathrm{O}$

| Symmetry | Orbital on O | Orbitals on H | Molecular orbitals |
| :--- | :--- | :--- | :--- |
| $A_{1}$ | 2 s | $(2)^{1 / 2}\left(1 \mathrm{~s}_{a}+1 \mathrm{~s}_{b}\right)$ | $1 a_{1}, 2 a_{1}, 3 a_{1}$ |
| $B_{1}$ | $2 \mathrm{p}_{z}$ | - | $1 b_{1}$ |
| $B_{2}$ | $2 \mathrm{p}_{x}$ | - | $(2)^{1 / 2}\left(1 s_{a}-1 s_{b}\right)$ |

## 216

Fig. 7.1.2.
A schematic energy level diagram for $\mathrm{H}_{2} \mathrm{O}$.

Fig. 7.1.3.
Coordinate system for $\mathrm{BH}_{3}$.

Symmetry in Chemistry

is spin-allowed and symmetry-forbidden, while ${ }^{1} A_{1} \rightarrow{ }^{3} A_{2}$ is both spin- and symmetry-forbidden.

Now let us turn to a slightly more complicated system, that of $\mathrm{BH}_{3}$ with $D_{3 h}$ symmetry. Note that $\mathrm{BH}_{3}$ is not a stable species: it dimerizes spontaneously to form diborane, $\mathrm{B}_{2} \mathrm{H}_{6}$. A convenient coordinate system for $\mathrm{BH}_{3}$ is shown in Fig. 7.1.3.

From the $D_{3 \mathrm{~h}}$ character table, it is readily seen that boron 2 s and $2 \mathrm{p}_{z}$ orbitals have $A_{1}^{\prime}$ and $A_{2}^{\prime \prime}$ symmetry, respectively, while the $2 \mathrm{p}_{x}$ and $2 \mathrm{p}_{y}$ orbitals form an $E^{\prime}$ set. To determine the symmetry species of the hydrogen 1 s orbital combinations, we perform the operations

$$
\begin{array}{l|ccccccl}
D_{3 \mathrm{~h}} & \boldsymbol{E} & 2 \boldsymbol{C}_{3} & 3 \boldsymbol{C}_{2} & \boldsymbol{\sigma}_{h} & 2 \boldsymbol{S}_{3} & 3 \boldsymbol{\sigma}_{\mathrm{v}} & \\
\hline \Gamma_{\mathrm{H}} & 3 & 0 & 1 & 3 & 0 & 1 & \equiv A_{1}^{\prime}+E^{\prime}
\end{array}
$$

So, among the three linear combinations of hydrogen 1s orbitals, one has $A_{1}^{\prime}$ symmetry, while the remaining two form an $E^{\prime}$ set. To obtain the explicit functions, we require the symmetry operation results

$$
\begin{array}{c|cccccc}
D_{3 \mathrm{~h}} & \boldsymbol{E} & 2 \boldsymbol{C}_{3} & 3 \boldsymbol{C}_{2} & \boldsymbol{\sigma}_{\mathrm{h}} & 2 \boldsymbol{S}_{3} & 3 \boldsymbol{\sigma}_{\mathrm{v}} \\
\hline 1 \mathrm{~s}_{a} & 1 \mathrm{~s}_{a} & 1 \mathrm{~s}_{b}, 1 \mathrm{~s}_{c} & 1 \mathrm{~s}_{a}, 1 \mathrm{~s}_{b}, 1 \mathrm{~s}_{c} & 1 \mathrm{~s}_{a} & 1 \mathrm{~s}_{b}, 1 \mathrm{~s}_{c} & 1 \mathrm{~s}_{a}, 1 \mathrm{~s}_{b}, 1 \mathrm{~s}_{c}
\end{array}
$$

Now, it is straightforward to obtain the linear combinations

$$
\begin{align*}
P^{A_{1}^{\prime}}\left(1 \mathrm{~s}_{a}\right)= & 1\left(1 \mathrm{~s}_{a}\right)+1\left(1 \mathrm{~s}_{b}+1 \mathrm{~s}_{c}\right)+1\left(1 \mathrm{~s}_{a}+1 \mathrm{~s}_{b}+1 \mathrm{~s}_{c}\right)+1\left(1 \mathrm{~s}_{a}\right) \\
& +1\left(1 \mathrm{~s}_{b}+1 \mathrm{~s}_{c}\right)+1\left(1 \mathrm{~s}_{a}+1 \mathrm{~s}_{b}+1 \mathrm{~s}_{c}\right) \\
= & 4\left(1 \mathrm{~s}_{a}+1 \mathrm{~s}_{b}+1 \mathrm{~s}_{c}\right) \\
& \Rightarrow(3)^{-1 / 2}\left(1 \mathrm{~s}_{a}+1 \mathrm{~s}_{b}+1 \mathrm{~s}_{c}\right) \quad \text { (after normalization) }  \tag{7.1.8}\\
P^{E^{\prime}}\left(1 \mathrm{~s}_{a}\right)= & 2\left(1 \mathrm{~s}_{a}\right)-1\left(1 \mathrm{~s}_{b}+1 \mathrm{~s}_{c}\right)+2\left(1 \mathrm{~s}_{a}\right)-1\left(1 \mathrm{~s}_{b}+1 \mathrm{~s}_{c}\right) \\
= & 4\left(1 s_{a}\right)-2\left(1 s_{b}+1 s_{c}\right) \\
& \Rightarrow(6)^{-1 / 2}\left[2\left(1 \mathrm{~s}_{a}\right)-1 \mathrm{~s}_{b}-1 \mathrm{~s}_{c}\right] \quad \text { (after normalization). } \tag{7.1.9}
\end{align*}
$$

Still one more combination is required to complete the $E^{\prime}$ set. It is not difficult to see that when we operate $P^{E^{\prime}}$ on $1 \mathrm{~s}_{b}$ and $1 \mathrm{~s}_{c}$, we get

$$
\begin{align*}
& P^{E^{\prime}}\left(1 \mathrm{~s}_{b}\right)=(6)^{-1 / 2}\left[2\left(1 \mathrm{~s}_{b}\right)-1 \mathrm{~s}_{a}-1 \mathrm{~s}_{c}\right]  \tag{7.1.10}\\
& P^{E^{\prime}}\left(1 \mathrm{~s}_{c}\right)=(6)^{-1 / 2}\left[2\left(1 \mathrm{~s}_{c}\right)-1 \mathrm{~s}_{a}-1 \mathrm{~s}_{b}\right] \tag{7.1.11}
\end{align*}
$$

Since the two combinations of an $E^{\prime}$ set must be linearly independent, and summation of eqs. (7.1.10) and (7.1.11) yield eq. (7.1.9) (aside from a normalization factor), we need to take the difference of eqs. (7.1.10) and (7.1.11) to obtain the remaining combination:

$$
\begin{align*}
& {\left[2\left(1 \mathrm{~s}_{b}\right)-1 \mathrm{~s}_{a}-1 \mathrm{~s}_{c}\right]-\left[2\left(1 \mathrm{~s}_{c}\right)-1 \mathrm{~s}_{a}-1 \mathrm{~s}_{b}\right]=3\left(1 \mathrm{~s}_{b}-1 \mathrm{~s}_{c}\right)} \\
& \quad \Rightarrow(2)^{-1 / 2}\left(1 \mathrm{~s}_{b}-1 \mathrm{~s}_{c}\right) \quad[\text { after normalization }] . \tag{7.1.12}
\end{align*}
$$

Obviously, there are different ways to choose the combination of an $E^{\prime}$ set. We choose the ones given by eqs. (7.1.9) and (7.1.12) because these functions overlap with the boron $2 \mathrm{p}_{x}$ and $2 \mathrm{p}_{y}$ orbitals, respectively, as shown in Fig. 7.1.4.

Table 7.1.2 summarizes how the molecular orbitals in $\mathrm{BH}_{3}$ are formed. From these results, we can see that the original $7 \times 7$ secular determinant (four orbitals from B and three from the H's) is block-factored into three $2 \times 2$ and one $1 \times 1$ determinants. The $1 \times 1$ has $A_{2}^{\prime \prime}$ symmetry, one $2 \times 2$ has $A_{1}^{\prime}$ symmetry, while the remaining two $2 \times 2$ form an $E^{\prime}$ set. It is important to note that the two $2 \times 2$ determinants that form the $E^{\prime}$ pair have the same pair of roots; i.e., we only need to solve one of these two determinants! A schematic energy level diagram for $\mathrm{BH}_{3}$ is shown in Fig. 7.1.5. According to this diagram, the ground configuration for $\mathrm{BH}_{3}$ is $\left(1 a_{1}^{\prime}\right)^{2}\left(1 e^{\prime}\right)^{4}$ and the ground state is ${ }^{1} A_{1}^{\prime}$.

Fig. 7.1.4.
(a) Overlap between the boron $2 \mathrm{p}_{x}$ orbital with combination
(6) $)^{-1 / 2}\left[2\left(1 \mathrm{~s}_{a}\right)-1 \mathrm{~s}_{b}-1 \mathrm{~s}_{c}\right]$.
(b) Overlap between the boron $2 \mathrm{p}_{y}$ orbital with the combination (2) ${ }^{-1 / 2}\left[1 \mathrm{~s}_{b}-1 \mathrm{~s}_{c}\right]$. By symmetry, the total overlaps in (a) and (b) are the same.

Table 7.1.2. Summary of the formation of the molecular orbitals in $\mathrm{BH}_{3}$

| Symmetry | Orbital on B | Orbitals on H | Molecular orbitals |
| :--- | :--- | :--- | :--- |
| $A_{1}^{\prime}$ | 2 s | $(3)^{-1 / 2}\left(1 \mathrm{~s}_{a}+1 \mathrm{~s}_{b}+1 \mathrm{~s}_{c}\right)$ | $1 a_{1}^{\prime}, 2 a_{1}^{\prime}$ |
| $E^{\prime}$ | $\left\{\begin{array}{lll}2 \mathrm{p}_{x} \\ 2 \mathrm{p}_{y}\end{array}\right.$ | $\left\{\begin{array}{l}(6)^{-1 / 2}\left[2\left(1 \mathrm{~s}_{a}\right)-1 \mathrm{~s}_{b}-1 \mathrm{~s}_{c}\right] \\ (2)^{-1 / 2}\left(1 \mathrm{~s}_{b}-1 \mathrm{~s}_{c}\right)\end{array}\right.$ | $1 e^{\prime}, 2 e^{\prime}$ |
| $A_{2}^{\prime \prime}$ | $2 \mathrm{p}_{z}$ | - | $1 a_{2}^{\prime \prime}$ |

## 218

Fig. 7.1.6.
Coordinate system for $\mathrm{CH}_{4}$.

Symmetry in Chemistry

Next we turn to the highly symmetric molecule $\mathrm{CH}_{4}$, which belongs to point group $T_{\mathrm{d}}$. A coordinate system for this molecule is shown in Fig. 7.1.6. For this molecule, there are eight valence atomic orbitals: 2 s and 2 p orbitals of carbon and the 1 s orbitals of the hydrogens. Regarding the carbon orbitals, 2 s has $A_{1}$ symmetry, while the $2 \mathrm{p}_{x}, 2 \mathrm{p}_{y}$, and $2 \mathrm{p}_{z}$ orbitals form a $T_{2}$ set. The irreducible representations spanned by the hydrogen 1 s orbitals can be readily determined:

$$
\begin{array}{c|cccccl}
T_{d} & \boldsymbol{E} & 8 \boldsymbol{C}_{3} & 3 \boldsymbol{C}_{2} & 6 \boldsymbol{S}_{4} & 6 \boldsymbol{\sigma}_{\mathrm{d}} & \\
\hline \Gamma_{\mathrm{H}} & 4 & 1 & 0 & 0 & 2 & \equiv A_{1}+T_{2}
\end{array}
$$

So the four hydrogen 1 s orbitals form one linear combination with $A_{1}$ symmetry and three other combinations that make up a $T_{2}$ set. To obtain these combinations, we make use of the symmetry operation results

| $T_{\mathrm{d}}$ | $\boldsymbol{E}$ | $8 \boldsymbol{C}_{3}$ | $3 \boldsymbol{C}_{2}$ | $6 \boldsymbol{S}_{4}$ | $6 \boldsymbol{\sigma}_{\mathrm{d}}$ |
| :--- | :---: | :---: | :---: | :---: | :---: |
| $1 \mathrm{~s}_{a}$ | $1 \mathrm{~s}_{a}$ | $2\left(1 \mathrm{~s}_{a}\right), 2\left(1 \mathrm{~s}_{b}\right)$, | $1 \mathrm{~s}_{b}, 1 \mathrm{~s}_{c}$, | $2\left(1 \mathrm{~s}_{b}\right), 2\left(1 \mathrm{~s}_{c}\right)$, | $3\left(1 \mathrm{~s}_{a}\right), 1 \mathrm{~s}_{b}, 1 \mathrm{~s}_{c}$, |
|  |  | $2\left(1 \mathrm{~s}_{c}\right), 2\left(1 \mathrm{~s}_{d}\right)$ | $1 \mathrm{~s}_{d}$ | $2\left(1 \mathrm{~s}_{d}\right)$ | $1 \mathrm{~s}_{d}$ |

Now the linear combination can be obtained readily:

$$
\begin{align*}
P^{A_{1}}\left(1 \mathrm{~s}_{a}\right)= & 1\left(1 \mathrm{~s}_{a}\right)+1\left[2\left(1 \mathrm{~s}_{a}\right)+2\left(1 \mathrm{~s}_{b}\right)+2\left(1 \mathrm{~s}_{c}\right)+2\left(1 \mathrm{~s}_{d}\right)\right] \\
& +1\left(1 \mathrm{~s}_{b}+1 \mathrm{~s}_{c}+1 \mathrm{~s}_{d}\right)+1\left[2\left(1 \mathrm{~s}_{b}\right)+2\left(1 \mathrm{~s}_{c}\right)+2\left(1 \mathrm{~s}_{d}\right)\right] \\
& +1\left[3\left(1 \mathrm{~s}_{a}\right)+1 \mathrm{~s}_{b}+1 \mathrm{~s}_{c}+1 \mathrm{~s}_{d}\right] \\
& \left.\Rightarrow \frac{1}{2}\left(1 \mathrm{~s}_{a}+1 \mathrm{~s}_{b}+1 \mathrm{~s}_{c}+1 \mathrm{~s}_{d}\right) \quad \text { (after normalization }\right) .  \tag{7.1.13}\\
P^{T_{2}}\left(1 \mathrm{~s}_{a}\right)= & 3\left(1 \mathrm{~s}_{a}\right)-1\left(1 \mathrm{~s}_{b}+1 \mathrm{~s}_{c}+1 \mathrm{~s}_{d}\right)-1\left[2\left(1 \mathrm{~s}_{b}\right)+2\left(1 \mathrm{~s}_{c}\right)+2\left(1 \mathrm{~s}_{d}\right)\right] \\
& +1\left[3\left(1 \mathrm{~s}_{a}\right)+1 \mathrm{~s}_{b}+1 \mathrm{~s}_{c}+1 \mathrm{~s}_{d}\right] \\
& =6\left(1 \mathrm{~s}_{a}\right)-2\left(1 \mathrm{~s}_{b}\right)-2\left(1 \mathrm{~s}_{c}\right)-2\left(1 \mathrm{~s}_{d}\right) . \tag{7.1.14}
\end{align*}
$$

Similarly, when we operate $P^{T_{2}}$ on $1 \mathrm{~s}_{b}, 1 \mathrm{~s}_{c}, 1 \mathrm{~s}_{d}$, we obtain

$$
\begin{align*}
& P^{T_{2}}\left(1 \mathrm{~s}_{b}\right)=6\left(1 \mathrm{~s}_{b}\right)-2\left(1 \mathrm{~s}_{a}\right)-2\left(1 \mathrm{~s}_{c}\right)-2\left(1 \mathrm{~s}_{d}\right)  \tag{7.1.15}\\
& P^{T_{2}}\left(1 \mathrm{~s}_{c}\right)=6\left(1 \mathrm{~s}_{c}\right)-2\left(1 \mathrm{~s}_{a}\right)-2\left(1 \mathrm{~s}_{b}\right)-2\left(1 \mathrm{~s}_{d}\right)  \tag{7.1.16}\\
& P^{T_{2}}\left(1 \mathrm{~s}_{d}\right)=6\left(1 \mathrm{~s}_{d}\right)-2\left(1 \mathrm{~s}_{a}\right)-2\left(1 \mathrm{~s}_{b}\right)-2\left(1 \mathrm{~s}_{c}\right) \tag{7.1.17}
\end{align*}
$$

To obtain the three linear combinations of the $T_{2}$ set, we combine eqs. (7.1.14) to (7.1.17) in the following manner:

Sum of eqs. (7.1.14) and (7.1.15):

$$
\begin{equation*}
4\left(1 \mathrm{~s}_{a}\right)+4\left(1 \mathrm{~s}_{b}\right)-4\left(1 \mathrm{~s}_{c}\right)-4\left(1 \mathrm{~s}_{d}\right)=\frac{1}{2}\left(1 \mathrm{~s}_{a}+1 \mathrm{~s}_{b}-1 \mathrm{~s}_{c}-1 \mathrm{~s}_{d}\right) \tag{7.1.18}
\end{equation*}
$$

(after normalization).
Sum of eqs. (7.1.14) and (7.1.16): $\frac{1}{2}\left(1 \mathrm{~s}_{a}-1 \mathrm{~s}_{b}+1 \mathrm{~s}_{c}-1 \mathrm{~s}_{d}\right)$.
Sum of eqs. (7.1.14) and (7.1.17): $\frac{1}{2}\left(1 \mathrm{~s}_{a}-1 \mathrm{~s}_{b}-1 \mathrm{~s}_{c}+1 \mathrm{~s}_{d}\right)$.
There are many ways of combining eqs. (7.1.14) to (7.1.17) to arrive at the three combinations that form the $T_{2}$ set. We choose those ones given by eqs. (7.1.18) to (7.1.20) as these functions overlap effectively with the $2 \mathrm{p}_{z}, 2 \mathrm{p}_{x}$, and $2 \mathrm{p}_{y}$ orbitals, respectively, as shown in Fig. 7.1.7.

Table 7.1.3 summarizes the formation of the molecular orbitals in $\mathrm{CH}_{4}$. For this molecule, the original $8 \times 8$ secular determinants is reduced to four $2 \times 2$ ones, one with $A_{1}$ symmetry, while the other three form a $T_{2}$ set. In other words, we only need to solve the $A_{1} 2 \times 2$ determinant as well as one of the three determinants that form the $T_{2}$ set. By symmetry, the three determinants

forming the $T_{2}$ set have the same roots. A schematic energy level diagram for $\mathrm{CH}_{4}$ is shown in Fig. 7.1.8. According to this diagram, the ground configuration is simply $\left(1 a_{1}\right)^{2}\left(1 t_{2}\right)^{6}$ and the ground state is ${ }^{1} A_{1}$.

So far we have illustrated the method for constructing the linear combinations of atomic orbitals, using $\mathrm{H}_{2} \mathrm{O}, \mathrm{BH}_{3}$, and $\mathrm{CH}_{4}$ as examples. In these simple systems, all the ligand orbitals are equivalent to each other. For molecules with non-equivalent ligand sites, we first linearly combine the orbitals on the equivalent atoms. Then, if the need arises, we can further combine the combinations that have the same symmetry. Take a hypothetical molecule $\mathrm{AH}_{5}$ with trigonal bipyramidal structure ( $D_{3 \mathrm{~h}}$ symmetry) as an example. Figure 7.1.9 shows a convenient coordinate system for this molecule. It is clear that these are two sets of hydrogen atoms: equatorial hydrogens $\mathrm{H}_{c}, \mathrm{H}_{d}$, and $\mathrm{H}_{e}$ and axial hydrogens $\mathrm{H}_{a}$ and $\mathrm{H}_{b}$.

When we linearly combine the orbitals on $\mathrm{H}_{a}$ and $\mathrm{H}_{b}$, two (un-normalized) combinations are obtained: $1 \mathrm{~s}_{a}+1 \mathrm{~s}_{b}$ ( $A_{1}^{\prime}$ symmetry), $1 s_{a}-1 s_{b}\left(A_{2}^{\prime \prime}\right)$. On the other hand, the combinations for the orbitals on the equatorial hydrogens are $1 \mathrm{~s}_{c}+1 \mathrm{~s}_{d}+1 \mathrm{~s}_{e}\left(A_{1}^{\prime}\right) ; 2\left(1 \mathrm{~s}_{c}\right)-1 \mathrm{~s}_{d}-1 \mathrm{~s}_{e}$ and $1 \mathrm{~s}_{d}-1 \mathrm{~s}_{e}$ ( $E^{\prime}$ symmetry). If we assume central atom A contributes $n \mathrm{~s}$ and $n$ p orbitals to bonding, we can easily arrive at the results summarized in Table 7.1.4. Note that we can further combine the two ligand linear combinations with $A_{1}^{\prime}$ symmetry by taking their sum and difference.
Finally, we treat the highly symmetrical octahedral molecule $\mathrm{AH}_{6}$ with $O_{\mathrm{h}}$ symmetry. A coordinate system for this molecule is shown in Fig. 7.1.10. If we assume that central atom A contributes $n \mathrm{~s}, n \mathrm{p}$, and $n \mathrm{~d}$ orbitals to bonding, the

Table 7.1.5. Formation of the molecular orbitals in $\mathrm{AH}_{6}$

| Symmetry | Orbital on A | Orbitals on H | Molecular Orbitals |
| :---: | :---: | :---: | :---: |
| $A_{1 g}$ | $n \mathrm{~s}$ | $(6)^{-1 / 2}\left(1 \mathrm{~s}_{a}+1 \mathrm{~s}_{b}+1 \mathrm{~s}_{c}+1 \mathrm{~s}_{d}+1 \mathrm{~s}_{e}+1 \mathrm{~s}_{f}\right)$ | $1 a_{1}, 2 a_{1}$ |
| $E_{g}$ | $\left\{\begin{array}{l}n \mathrm{~d}^{2} \\ n \mathrm{~d}_{x^{2}-y^{2}}\end{array}\right.$ | $\left\{\begin{array}{l}(12)^{-1 / 2}\left[\left(2\left(1 \mathrm{~s}_{e}\right)+2\left(1 \mathrm{~s}_{f}\right)-1 \mathrm{~s}_{a}-1 \mathrm{~s}_{b}\right.\right. \\ \left.-1 \mathrm{~s}_{c}-1 \mathrm{~s}_{d}\right) \\ \frac{1}{2}\left(1 \mathrm{~s}_{a}+1 \mathrm{~s}_{b}-1 \mathrm{~s}_{c}-1 \mathrm{~s}_{d}\right)\end{array}\right.$ | $1 e_{\mathrm{g}}, 2 e_{\mathrm{g}}$ |
| $T_{2 g}$ | $\left\{\begin{array}{l}n \mathrm{~d}_{x y} \\ n \mathrm{~d}_{y z} \\ n \mathrm{~d}_{x z}\end{array}\right.$ | $\begin{aligned} & - \\ & - \end{aligned}$ | $1 t_{2 \mathrm{~g}}$ |
| $T_{1 u}$ | $\left\{\begin{array}{l}n \mathrm{p}_{x} \\ n \mathrm{p}_{y} \\ n \mathrm{p}_{z}\end{array}\right.$ | $\left\{\begin{array}{l}(2)^{-1 / 2}\left(1 \mathrm{~s}_{a}-1 \mathrm{~s}_{b}\right) \\ (2)^{-1 / 2}\left(1 \mathrm{~s}_{c}-1 \mathrm{~s}_{d}\right) \\ (2)^{-1 / 2}\left(1 \mathrm{~s}_{e}-1 \mathrm{~s}_{f}\right)\end{array}\right.$ | $1 t_{1 \mathrm{u}}, 2 t_{\text {lu }}$ |

secular determinant has the dimensions $15 \times 15$. To obtain the symmetries of the six 1s orbital linear combinations:

| $O_{\mathrm{h}}$ | $\boldsymbol{E}$ | $8 \boldsymbol{C}_{3}$ | $6 \boldsymbol{C}_{2}$ | $6 \boldsymbol{C}_{4}$ | $3 \boldsymbol{C}_{2}=\mathbf{C}_{4}^{2}$ | $\boldsymbol{i}$ | $6 \boldsymbol{S}_{4}$ | $8 \boldsymbol{S}_{6}$ | $3 \boldsymbol{\sigma}_{\mathrm{h}}$ | $6 \boldsymbol{\sigma}_{\mathrm{d}}$ |  |
| :--- | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :--- |
| $\Gamma_{\mathrm{H}}$ | 6 | 0 | 0 | 2 | 2 | 0 | 0 | 0 | 4 | 2 | $\equiv A_{1 \mathrm{~g}}+E_{\mathrm{g}}+T_{1 \mathrm{u}}$ |

To derive the combinations, we need the following tabulation listing the effect of various symmetry operations of $O_{\mathrm{h}}$ on the 1 s orbital on hydrogen atom $\mathrm{H}_{a}$ :

| $O_{\mathrm{h}}$ | $\boldsymbol{E}$ | $8 \boldsymbol{C}_{3}$ | $6 \boldsymbol{C}_{2}$ | $6 \boldsymbol{C}_{4}$ | $3 \boldsymbol{C}_{2}=\mathbf{C}_{4}^{2}$ | $\boldsymbol{i}$ | $6 \boldsymbol{S}_{4}$ | $8 \boldsymbol{S}_{6}$ | $3 \sigma_{\mathrm{h}}$ | $6 \sigma_{\mathrm{d}}$ |
| :--- | :--- | :--- | :--- | :--- | :--- | :--- | :--- | :--- | :--- | :--- |
| $1 \mathrm{~s}_{a}$ | $1 \mathrm{~s}_{a}$ | $2\left(1 \mathrm{~s}_{c}\right)$, | $2\left(1 \mathrm{~s}_{b}\right)$, | $2\left(1 \mathrm{~s}_{a}\right)$, | $1 \mathrm{~s}_{a}$, | $1 \mathrm{~s}_{b}$ | $2\left(1 \mathrm{~s}_{b}\right)$, | $2\left(1 \mathrm{~s}_{c}\right)$, | $2\left(1 \mathrm{~s}_{a}\right)$, | $2\left(1 \mathrm{~s}_{a}\right)$, |
|  |  | $2\left(1 \mathrm{~s}_{d}\right)$, | $1 \mathrm{~s}_{c}, 1 \mathrm{~s}_{d}$, | $1 \mathrm{~s}_{c}, 1 \mathrm{~s}_{d}$, | $2\left(1 \mathrm{~s}_{b}\right)$ |  | $1 \mathrm{~s}_{c}, 1 \mathrm{~s}_{d}$, | $2\left(1 \mathrm{~s}_{d}\right)$, | $1 \mathrm{~s}_{b}$ | $1 \mathrm{~s}_{c}, 1 \mathrm{l}_{d}$, |
|  |  | $2\left(1 \mathrm{~s}_{e}\right)$, | $1 \mathrm{~s}_{e}, 1 \mathrm{~s}_{f}$ | $1 \mathrm{~s}_{e}, 1 \mathrm{~s}_{f}$ |  |  | $1 \mathrm{~s}_{e}, 1 \mathrm{~s}_{f}$ | $2\left(1 \mathrm{~s}_{e}\right)$, |  | $1 \mathrm{~s}_{e}, 1 \mathrm{~s}_{f}$ |
|  |  | $2\left(1 \mathrm{~s}_{f}\right)$ |  |  |  |  |  |  | $2\left(1 \mathrm{~s}_{f}\right)$ |  |
|  |  |  |  |  |  |  |  |  |  |  |

Now it is straightforward to derive the results summarized in Table 7.1.5. It is clear that the $15 \times 15$ secular determinant is block-factored into three $1 \times 1$ determinants that form a $T_{2 \mathrm{~g}}$ set, one $2 \times 2$ with $A_{1 \mathrm{~g}}$ symmetry, two $2 \times 2$ that form an $E_{\mathrm{g}}$ set, and three $2 \times 2$ that form a $T_{1 \mathrm{u}}$ set. In other words, we only need to solve one $1 \times 1$ and three $2 \times 2$ secular determinants for this highly symmetrical molecule. This example shows the great simplification that group theory brings to the solution of a large secular determinant.

### 7.1.2 Hückel theory for cyclic conjugated polyenes

Previously in Chapter 3 we introduced the Hückel molecular orbital theory and applied it to the $\pi$ system of a number of conjugated polyene chains. In this section we will apply this approximation to cyclic conjugated polyenes, taking advantage of the symmetry properties of these systems in the process.

Now let us take benzene as an example. The six 2 p atomic orbitals taking part in the $\pi$ bonding are labeled in the manner shown in Fig. 7.1.11. In the

Fig. 7.1.11.
Labeling of the 2 p orbitals taking part in the $\pi$ bonding of benzene. Also shown are the locations of the symmetry elements $C_{2}^{\prime}, C_{2}^{\prime \prime}, \sigma_{\mathrm{v}}$ and $\sigma_{\mathrm{d}}$.

## Symmetry in Chemistry

Hückel approximation, the $6 \times 6$ secular determinant has the form

$$
\left|\begin{array}{cccccc}
\alpha-E & \beta & 0 & 0 & 0 & \beta  \tag{7.1.21}\\
\beta & \alpha-E & \beta & 0 & 0 & 0 \\
0 & \beta & \alpha-E & \beta & 0 & 0 \\
0 & 0 & \beta & \alpha-E & \beta & 0 \\
0 & 0 & 0 & \beta & \alpha-E & \beta \\
\beta & 0 & 0 & 0 & \beta & \alpha-E
\end{array}\right|=0 .
$$

If we consider the $D_{6 \mathrm{~h}}$ symmetry of the system, we can determine the symmetries of the six $\pi$ molecular orbitals:

$$
\begin{array}{l|lllllllllllll}
D_{6 \mathrm{~h}} & \boldsymbol{E} & 2 \boldsymbol{C}_{6} & 2 \boldsymbol{C}_{3} & \boldsymbol{C}_{2} & 3 \boldsymbol{C}_{2}^{\prime} & 3 \boldsymbol{C}_{2}^{\prime \prime} & \boldsymbol{i} & 2 \boldsymbol{S}_{3} & 2 \boldsymbol{S}_{6} & \boldsymbol{\sigma}_{\mathrm{h}} & 3 \sigma_{\mathrm{d}} & 3 \sigma_{\mathrm{v}} & \\
\hline \Gamma_{\pi} & 6 & 0 & 0 & 0 & -2 & 0 & 0 & 0 & 0 & -6 & 0 & 2 & \equiv A_{2 \mathrm{u}}+B_{2 \mathrm{~g}}+E_{1 \mathrm{~g}}+E_{2 \mathrm{u}}
\end{array}
$$

Recall that the character of an operation is equal to the number of vectors unshifted by that operation. Previously, for $\mathrm{AH}_{n}$ molecules, in determining $\Gamma_{\mathrm{H}}$, the 1 s orbitals on the hydrogen atoms are spherically symmetric. In the present case, however, the 2 p orbitals have directional properties. Take $\sigma_{\mathrm{h}}$ as an example. Upon reflection, the direction of the $2 p$ orbitals is reversed. Hence $\chi\left(\sigma_{\mathrm{h}}\right)=-6$.

Upon decomposing $\Gamma_{\pi}$, we can conclude that the secular determinant in eq. (7.1.21) can be factored into six $1 \times 1$ blocks: one with $A_{2 u}$ symmetry, one with $B_{2 \mathrm{~g}}$ symmetry, two others composing an $E_{1 \mathrm{~g}}$ set (with the same root), and the remaining two forming an $E_{2 \mathrm{u}}$ set (also with the same root). To derive the six linear combinations, we make use of the following results:

| $D_{6 \mathrm{~h}}$ | E | $2 C_{6}$ | $2 C_{3}$ | $C_{2}$ | $3 C_{2}^{\prime}$ | $3 C_{2}^{\prime \prime}$ | $i$ | $2 S_{3}$ | $2 S_{6}$ | $\sigma_{\text {h }}$ | $3 \sigma_{\mathrm{d}}$ | $3 \sigma_{\mathrm{v}}$ |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| pa | $\mathrm{p} a$ | $\mathrm{p}_{b}, \mathrm{p}_{f}$ | $\mathrm{p}_{c}, \mathrm{p}_{e}$ | $\mathrm{p}_{d}$ | $\begin{gathered} -\mathrm{p} a,-\mathrm{p}_{c}, \\ -\mathrm{p}_{e} \end{gathered}$ | $\begin{gathered} -\mathrm{p}_{b},-\mathrm{p}_{d}, \\ -\mathrm{p}_{f} \end{gathered}$ | $-\mathrm{p}_{d}$ | $-\mathrm{p}_{c},-\mathrm{p} e$ | $-\mathrm{p}_{b},-\mathrm{p}_{f}$ |  | $\begin{gathered} \mathrm{p}_{b}, \mathrm{p}_{d} \\ \mathrm{p}_{f} \end{gathered}$ | $\begin{gathered} \mathrm{p}_{a}, \mathrm{p}_{c}, \\ \mathrm{p}_{e} \end{gathered}$ |

The derivation of the non-degenerate linear combinations are straightforward:

$$
\begin{array}{ll}
P^{A_{2 \mathrm{u}}}\left(\mathrm{p}_{a}\right)=(6)^{-1 / 2}\left(\mathrm{p}_{a}+\mathrm{p}_{b}+\mathrm{p}_{c}+\mathrm{p}_{d}+\mathrm{p}_{e}+\mathrm{p}_{f}\right) & \text { (after normalization). } \\
P^{B_{2 \mathrm{~g}}}\left(\mathrm{p}_{a}\right)=(6)^{-1 / 2}\left(\mathrm{p}_{a}-\mathrm{p}_{b}+\mathrm{p}_{c}-\mathrm{p}_{d}+\mathrm{p}_{e}-\mathrm{p}_{f}\right) \quad \text { (after normalization). } \tag{7.1.23}
\end{array}
$$

The first component of the $E_{1 \mathrm{~g}}$ set can also be derived easily:

$$
\begin{equation*}
P^{E_{1 \mathrm{~g}}}\left(\mathrm{p}_{a}\right)=(12)^{-1 / 2}\left[2\left(\mathrm{p}_{a}\right)+\mathrm{p}_{b}-\mathrm{p}_{c}-2\left(\mathrm{p}_{d}\right)-\mathrm{p}_{e}+\mathrm{p}_{f}\right] \tag{7.1.24}
\end{equation*}
$$

(after normalization).
For the second component, we operate $P^{E_{1 g}}$ on $\mathrm{p}_{b}$ an $\mathrm{p}_{c}$ :

$$
\begin{align*}
& P^{E_{1 \mathrm{~g}}}\left(\mathrm{p}_{b}\right)=\mathrm{p}_{a}+2\left(\mathrm{p}_{b}\right)+\mathrm{p}_{c}-\mathrm{p}_{d}-2\left(\mathrm{p}_{e}\right)-\mathrm{p}_{f},  \tag{7.1.25}\\
& P^{E_{\lg }}\left(\mathrm{p}_{c}\right)=-\mathrm{p}_{a}+\mathrm{p}_{b}+2\left(\mathrm{p}_{c}\right)+\mathrm{p}_{d}-\mathrm{p}_{e}-2\left(\mathrm{p}_{f}\right) . \tag{7.1.26}
\end{align*}
$$

Since subtracting eq. (7.1.26) from eq. (7.1.25) yields eq. (7.1.24) (aside from a normalization constant), we need to take the sum of these two equations:

Eq. (7.1.25) + Eq. (7.1.26) : $\frac{1}{2}\left(\mathrm{p}_{b}+\mathrm{p}_{c}-\mathrm{p}_{e}-\mathrm{p}_{f}\right) \quad$ (after normalization).

Similar manipulation leads to the following two linear combinations forming the $E_{2 \mathrm{u}}$ set:

$$
E_{2 \mathrm{u}}:\left\{\begin{array}{l}
(12)^{-1 / 2}\left[2\left(\mathrm{p}_{a}\right)-\mathrm{p}_{b}-\mathrm{p}_{c}+2\left(\mathrm{p}_{d}\right)-\mathrm{p}_{e}-\mathrm{p}_{f}\right]  \tag{7.1.28}\\
\frac{1}{2}\left(\mathrm{p}_{b}-\mathrm{p}_{c}+\mathrm{p}_{e}-\mathrm{p}_{f}\right)
\end{array}\right.
$$

The energy of the six molecular orbitals can now be calculated, using the Hückel approximation as discussed in Chapter 3:

$$
\begin{align*}
& E\left(a_{2 \mathrm{u}}\right)=\alpha+2 \beta,  \tag{7.1.30}\\
& E\left(e_{1 \mathrm{~g}}\right)=\alpha+\beta  \tag{7.1.31}\\
& E\left(e_{2 \mathrm{u}}\right)=\alpha-\beta,  \tag{7.1.32}\\
& E\left(b_{2 \mathrm{~g}}\right)=\alpha-2 \beta \tag{7.1.33}
\end{align*}
$$

The $\pi$ energy levels, along with the molecular orbital wavefunctions, are pictorially displayed in Fig. 7.1.12. Since there are six $\pi$ electrons in benzene, orbitals $a_{2 \mathrm{u}}$ and $e_{1 \mathrm{~g}}$ are filled, giving rise to a ${ }^{1} A_{1 \mathrm{~g}}$ ground state with the total $\pi$ energy

$$
\begin{equation*}
E_{\pi}=6 \alpha+8 \beta \tag{7.1.34}
\end{equation*}
$$

Fig. 7.1.12.
The energy level diagram and the wavefunctions of the six $\pi$ molecular orbitals in benzene.

## Symmetry in Chemistry

If the three $\pi$ bonds in benzene were independent of each other, i.e., localized, they would have energy $3(2 \alpha+2 \beta)=6 \alpha+6 \beta$. Hence the delocalization energy (DE) for benzene is

$$
\begin{equation*}
\mathrm{DE}=6 \alpha+8 \beta-6 \alpha-6 \beta=2 \beta \tag{7.1.35}
\end{equation*}
$$

Calculation of $\beta$ from first principles is a fairly complicated task. On the other hand, it can be approximated from experimental data:

$$
\begin{equation*}
|\beta| \sim 18 \mathrm{kcal} \mathrm{~mol}^{-1}=75 \mathrm{~kJ} \mathrm{~mol}^{-1} \tag{7.1.36}
\end{equation*}
$$

Another example of a cyclic conjugated polyene system is naphthalene. A coordinate system for this molecule, along with the labeling of the $\pi$ atomic orbitals, is shown in Fig. 7.1.13. The $10 \times 10$ secular determinant has the form:

$$
\left|\begin{array}{cccccccccc}
\alpha-E & \beta & 0 & 0 & 0 & 0 & 0 & 0 & \beta & 0  \tag{7.1.37}\\
\beta & \alpha-E & \beta & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\
0 & \beta & \alpha-E & \beta & 0 & 0 & 0 & 0 & 0 & 0 \\
0 & 0 & \beta & \alpha-E & 0 & 0 & 0 & 0 & 0 & \beta \\
0 & 0 & 0 & 0 & \alpha-E & \beta & 0 & 0 & 0 & \beta \\
0 & 0 & 0 & 0 & \beta & \alpha-E & \beta & 0 & 0 & 0 \\
0 & 0 & 0 & 0 & 0 & \beta & \alpha-E & \beta & 0 & 0 \\
0 & 0 & 0 & 0 & 0 & 0 & \beta & \alpha-E & \beta & 0 \\
\beta & 0 & 0 & 0 & 0 & 0 & 0 & \beta & \alpha-E & \beta \\
0 & 0 & 0 & \beta & \beta & 0 & 0 & 0 & \beta & \alpha-E
\end{array}\right|=0 .
$$

With the aid of the $D_{2 \mathrm{~h}}$ character table, we can determine the symmetries of the ten molecular orbitals of this system:

| $D_{2 \mathrm{~h}}$ | $\boldsymbol{E}$ | $\boldsymbol{C}_{2}(z)$ | $\boldsymbol{C}_{2}(y)$ | $\boldsymbol{C}_{2}(x)$ | $\boldsymbol{i}$ | $\boldsymbol{\sigma}(x y)$ | $\boldsymbol{\sigma}(x z)$ | $\boldsymbol{\sigma}(y z)$ |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :--- |
| $\Gamma_{\pi}$ | 10 | 0 | 0 | -2 | 0 | -10 | 2 | 0 | $\equiv 2 A_{\mathrm{u}}+3 B_{2 \mathrm{~g}}+2 B_{3 \mathrm{~g}}+3 B_{1 \mathrm{u}}$ |

In other words, the secular determinant in eq. (7.1.37) can be factored into two $2 \times 2$ and two $3 \times 3$ blocks. To obtain the explicit forms of these ten combinations, we need the results of each of the eight symmetry operations. Also, since the system now has three types of (structurally non-equivalent) carbon atoms, we need the operation results on the 2 p orbitals of these three kinds of atoms:

| $D_{2 \mathrm{~h}}$ | $\boldsymbol{E}$ | $\boldsymbol{C}_{2}(z)$ | $\boldsymbol{C}_{2}(y)$ | $\boldsymbol{C}_{2}(x)$ | $\boldsymbol{i}$ | $\boldsymbol{\sigma}(x y)$ | $\boldsymbol{\sigma}(x z)$ | $\boldsymbol{\sigma}(y z)$ |
| :--- | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| $\mathrm{p}_{a}$ | $\mathrm{p}_{a}$ | $\mathrm{p}_{e}$ | $-\mathrm{p}_{d}$ | $-\mathrm{p}_{h}$ | $-\mathrm{p}_{e}$ | $-\mathrm{p}_{a}$ | $\mathrm{p}_{h}$ | $\mathrm{p}_{d}$ |
| $\mathrm{p}_{b}$ | $\mathrm{p}_{b}$ | $\mathrm{p}_{f}$ | $-\mathrm{p}_{c}$ | $-\mathrm{p}_{g}$ | $-\mathrm{p}_{f}$ | $-\mathrm{p}_{b}$ | $\mathrm{p}_{g}$ | $\mathrm{p}_{c}$ |
| $\mathrm{p}_{i}$ | $\mathrm{p}_{i}$ | $\mathrm{p}_{j}$ | $-\mathrm{p}_{j}$ | $-\mathrm{p}_{i}$ | $-\mathrm{p}_{j}$ | $-\mathrm{p}_{i}$ | $\mathrm{p}_{i}$ | $\mathrm{p}_{j}$ |

The resultant combinations can be obtained easily:

$$
\begin{align*}
A_{\mathrm{u}}: \phi_{1} & =\frac{1}{2}\left(\mathrm{p}_{a}-\mathrm{p}_{d}+\mathrm{p}_{e}-\mathrm{p}_{h}\right),  \tag{7.1.38}\\
\phi_{2} & =\frac{1}{2}\left(\mathrm{p}_{b}-\mathrm{p}_{c}+\mathrm{p}_{f}-\mathrm{p}_{g}\right) \tag{7.1.39}
\end{align*}
$$

$$
\begin{align*}
B_{2 \mathrm{~g}}: \phi_{3} & =\frac{1}{2}\left(\mathrm{p}_{a}-\mathrm{p}_{d}-\mathrm{p}_{e}+\mathrm{p}_{h}\right)  \tag{7.1.40}\\
\phi_{4} & =\frac{1}{2}\left(\mathrm{p}_{b}-\mathrm{p}_{c}-\mathrm{p}_{f}+\mathrm{p}_{g}\right)  \tag{7.1.41}\\
\phi_{5} & =(2)^{-1 / 2}\left(\mathrm{p}_{i}-\mathrm{p}_{j}\right)  \tag{7.1.42}\\
B_{3 \mathrm{~g}}: \phi_{6} & =\frac{1}{2}\left(\mathrm{p}_{a}+\mathrm{p}_{d}-\mathrm{p}_{e}-\mathrm{p}_{h}\right)  \tag{7.1.43}\\
\phi_{7} & =\frac{1}{2}\left(\mathrm{p}_{b}+\mathrm{p}_{c}-\mathrm{p}_{f}-\mathrm{p}_{g}\right)  \tag{7.1.44}\\
B_{1 \mathrm{u}}: \phi_{8} & =\frac{1}{2}\left(\mathrm{p}_{a}+\mathrm{p}_{d}+\mathrm{p}_{e}+\mathrm{p}_{h}\right)  \tag{7.1.45}\\
\phi_{9} & =\frac{1}{2}\left(\mathrm{p}_{b}+\mathrm{p}_{c}+\mathrm{p}_{f}+\mathrm{p}_{g}\right)  \tag{7.1.46}\\
\phi_{10} & =(2)^{-1 / 2}\left(\mathrm{p}_{i}+\mathrm{p}_{j}\right) \tag{7.1.47}
\end{align*}
$$

Next we need to set up the four smaller secular determinants. Take the one with $A_{\mathbf{u}}$ symmetry as an example:

$$
\begin{align*}
H_{11} & =\int \phi_{1} \hat{H} \phi_{1} \mathrm{~d} \tau \\
& =\frac{1}{4} \int\left(\mathrm{p}_{a}-\mathrm{p}_{d}+\mathrm{p}_{e}-\mathrm{p}_{h}\right) \hat{H}\left(\mathrm{p}_{a}-\mathrm{p}_{d}+\mathrm{p}_{e}-\mathrm{p}_{h}\right) \mathrm{d} \tau=\alpha  \tag{7.1.48}\\
H_{12} & =\int \phi_{1} \hat{H} \phi_{2} \mathrm{~d} \tau \\
& =\frac{1}{4} \int\left(\mathrm{p}_{a}-\mathrm{p}_{d}+\mathrm{p}_{e}-\mathrm{p}_{h}\right) \hat{H}\left(\mathrm{p}_{b}-\mathrm{p}_{c}+\mathrm{p}_{f}-\mathrm{p}_{g}\right) \mathrm{d} \tau=\beta  \tag{7.1.49}\\
H_{22} & =\int \phi_{2} \hat{H} \phi_{2} \mathrm{~d} \tau \\
& =\frac{1}{4} \int\left(\mathrm{p}_{b}-\mathrm{p}_{c}+\mathrm{p}_{f}-\mathrm{p}_{g}\right) \hat{H}\left(\mathrm{p}_{b}-\mathrm{p}_{c}+\mathrm{p}_{f}-\mathrm{p}_{g}\right) \mathrm{d} \tau=\alpha-\beta \tag{7.1.50}
\end{align*}
$$

Thus the $A_{\mathrm{u}}$ secular determinant has the form

$$
A_{\mathrm{u}}:\left|\begin{array}{ll}
\alpha-E & \beta  \tag{7.1.51}\\
\beta & \alpha-\beta-E
\end{array}\right|=0
$$

The other three determinants can be obtained in a similar manner:

$$
\begin{align*}
& B_{2 \mathrm{~g}}:\left|\begin{array}{ccc}
\alpha-E & \beta & (2)^{1 / 2} \beta \\
\beta & \alpha-\beta-E & 0 \\
(2)^{1 / 2} \beta & 0 & \alpha-\beta-E
\end{array}\right|=0 .  \tag{7.1.52}\\
& B_{3 \mathrm{~g}}:\left|\begin{array}{cc}
\alpha-E & \beta \\
\beta & \alpha+\beta-E
\end{array}\right|=0 . \tag{7.1.53}
\end{align*}
$$

$$
B_{1 \mathrm{u}}:\left|\begin{array}{ccc}
\alpha-E & \beta & (2)^{1 / 2} \beta  \tag{7.1.54}\\
\beta & \alpha+\beta-E & 0 \\
(2)^{1 / 2} \beta & 0 & \alpha+\beta-E
\end{array}\right|=0
$$

Table 7.1.6. The Hückel energies and wavefunctions of the $\pi$ molecular orbitals in naphthalene

|  | Orbital | Energy | Wavefunction |
| :---: | :---: | :---: | :---: |
|  | $3 b_{2 \mathrm{~g}}$ | $\alpha-2.303 \beta$ | $0.3006\left(\mathrm{p}_{a}-p_{d}-\mathrm{p}_{e}+\mathrm{p}_{h}\right)-0.2307\left(\mathrm{p}_{b}-\mathrm{p}_{c}-\mathrm{p}_{f}+\mathrm{p}_{g}\right)-0.4614\left(\mathrm{p}_{i}-\mathrm{p}_{j}\right)$ |
|  | $2 a_{\text {u }}$ | $\alpha-1.618 \beta$ | $0.2629\left(\mathrm{p}_{a}-\mathrm{p}_{d}+\mathrm{p}_{e}-\mathrm{p}_{h}\right)-0.4253\left(\mathrm{p}_{b}-\mathrm{p}_{c}+\mathrm{p}_{f}-\mathrm{p}_{g}\right)$ |
|  | $3 b_{1 \mathrm{u}}$ | $\alpha-1.303 \beta$ | $0.3996\left(\mathrm{p}_{a}+\mathrm{p}_{d}+\mathrm{p}_{e}+\mathrm{p}_{h}\right)-0.1735\left(\mathrm{p}_{b}+\mathrm{p}_{c}+\mathrm{p}_{f}+\mathrm{p}_{g}\right)-0.3470\left(\mathrm{p}_{i}+\mathrm{p}_{j}\right)$ |
| $\uparrow$ | $2 b_{2 g}$ | $\alpha-\beta$ | $0.4082\left(\mathrm{p}_{b}-\mathrm{p}_{c}-\mathrm{p}_{f}+\mathrm{p}_{g}\right)-0.4082\left(\mathrm{p}_{i}-\mathrm{p}_{j}\right)$ |
| E | $2 b_{3 \mathrm{~g}}$ | $\alpha-0.618 \beta$ | $0.4253\left(\mathrm{p}_{a}+\mathrm{p}_{d}-\mathrm{p}_{e}-\mathrm{p}_{h}\right)-0.2629\left(\mathrm{p}_{b}+\mathrm{p}_{c}-\mathrm{p}_{f}-\mathrm{p}_{g}\right)$ |
|  | $1 a_{\mathrm{u}}$ | $\alpha+0.618 \beta$ | $0.4253\left(\mathrm{p}_{a}-\mathrm{p}_{d}+\mathrm{p}_{e}-\mathrm{p}_{h}\right)+0.2629\left(\mathrm{p}_{b}-\mathrm{p}_{c}+\mathrm{p}_{f}-\mathrm{p}_{g}\right)$ |
|  | $2 b_{1 \mathrm{u}}$ | $\alpha+\beta$ | $0.4082\left(\mathrm{p}_{b}+\mathrm{p}_{c}+\mathrm{p}_{f}+\mathrm{p}_{g}\right)-0.4082\left(\mathrm{p}_{i}-\mathrm{p}_{j}\right)$ |
|  | $1 b_{2 \mathrm{~g}}$ | $\alpha+1.303 \beta$ | $0.3996\left(\mathrm{p}_{a}-\mathrm{p}_{d}-\mathrm{p}_{e}+\mathrm{p}_{h}\right)+0.1735\left(\mathrm{p}_{b}-\mathrm{p}_{c}-\mathrm{p}_{f}+\mathrm{p}_{g}\right)+0.3470\left(\mathrm{p}_{i}-\mathrm{p}_{j}\right)$ |
|  | $1 b_{3 \mathrm{~g}}$ | $\alpha+1.618 \beta$ | $0.2629\left(\mathrm{p}_{a}+\mathrm{p}_{d}-\mathrm{p}_{e}-\mathrm{p}_{h}\right)+0.4253\left(\mathrm{p}_{b}+\mathrm{p}_{c}-\mathrm{p}_{f}-\mathrm{p}_{g}\right)$ |
|  | $1 b_{1 \mathrm{u}}$ | $\alpha+2.303 \beta$ | $0.3006\left(\mathrm{p}_{a}+\mathrm{p}_{d}+\mathrm{p}_{e}+\mathrm{p}_{h}\right)+0.2307\left(\mathrm{p}_{b}+\mathrm{p}_{c}+\mathrm{p}_{f}+\mathrm{p}_{g}\right)+0.4614\left(\mathrm{p}_{i}+\mathrm{p}_{j}\right)$ |

The solving of these determinants may be facilitated by the substitution $x=$ $(\alpha-E) / \beta$. In any event, the energies of the ten molecular orbitals can be obtained readily. With the energies we can then solve the corresponding secular equations for the coefficients. The energies and the wavefunctions of the ten $\pi$ molecular orbitals for naphthalene are summarized in Table 7.1.6. From these results, we can arrive at the following ground electronic configuration and state:

$$
\left(1 b_{1 \mathrm{u}}\right)^{2}\left(1 b_{3 \mathrm{~g}}\right)^{2}\left(1 b_{2 \mathrm{~g}}\right)^{2}\left(2 b_{1 \mathrm{u}}\right)^{2}\left(1 a_{\mathrm{u}}\right)^{2},{ }^{1} A_{\mathrm{g}} .
$$

By adding up the energies for all ten $\pi$ electrons, we get

$$
\begin{equation*}
E_{\pi}=10 \alpha+13.684 \beta, \tag{7.1.55}
\end{equation*}
$$

and

$$
\begin{equation*}
\mathrm{DE}=3.684 \beta \tag{7.1.56}
\end{equation*}
$$

In addition, we can obtain the following allowed electronic transitions:

$$
\begin{aligned}
& { }^{1} A_{g} \rightarrow\left[\ldots\left(1 a_{\mathrm{u}}\right)^{1}\left(2 b_{3 \mathrm{~g}}\right)^{1}\right],{ }^{1} B_{3 \mathrm{u}}, \quad x \text {-polarized; } \\
& { }^{1} A_{g} \rightarrow\left[\ldots\left(1 a_{\mathrm{u}}\right)^{1}\left(2 b_{2 \mathrm{~g}}\right)^{1}\right],{ }^{1} B_{2 \mathrm{u}}, \quad y \text {-polarized; } \\
& { }^{1} A_{g} \rightarrow\left[\ldots\left(2 b_{1 \mathrm{u}}\right)^{1}\left(1 a_{\mathrm{u}}\right)^{2}\left(2 b_{3 \mathrm{~g}}\right)^{1}\right],{ }^{1} B_{2 \mathrm{u}}, \quad y \text {-polarized. }
\end{aligned}
$$

Note that all three transitions are $\mathrm{g} \leftrightarrow \mathrm{u}$, in accordance with Laporte's rule.
In the previous section, we discussed the construction of the $\sigma$ molecular orbitals in $\mathrm{AH}_{n}$ systems. In this section, we confine our treatment to the $\pi$ molecular orbitals in cyclic conjugated polyenes. In most molecules, there are $\sigma$ bonds as well as $\pi$ bonds, and these systems can be treated by the methods introduced in these two sections.

Before concluding this section, it is noted that a fairly user-friendly SHMO (simple Hückel molecular orbital) calculator is now available on the Internet, http://www.chem.ucalgary.ca/shmo/. With this calculator, the Hückel energies and wavefunctions of planar conjugated molecules can be obtained "on the fly."

Table 7.1.7. Some useful steps in the derivation of the linear combinations of atomic orbitals for the $\pi$ system of $\left(\mathrm{NPX}_{2}\right)_{3}$.

| $D_{3 \mathrm{~h}}$ | $\boldsymbol{E}$ | $2 \boldsymbol{C}_{3}$ | $3 \boldsymbol{C}_{2}$ | $\boldsymbol{\sigma}_{\mathrm{h}}$ | $2 \boldsymbol{S}_{3}$ | $3 \boldsymbol{\sigma}_{\mathrm{v}}$ |  |
| :--- | :---: | :---: | :---: | :---: | :---: | :---: | :--- |
| $\Gamma_{\mathrm{p}}$ | 3 | 0 | -1 | -3 | 0 | 1 | $\equiv A_{2}^{\prime \prime}+E^{\prime \prime}$ |
| $\Gamma_{\mathrm{d}}$ | 3 | 0 | 1 | -3 | 0 | -1 | $\equiv A_{1}^{\prime \prime}+E^{\prime \prime}$ |
| $c$ | $c$ | $-a,-e$ | $a,-c, e$ | $-c$ | $a, e$ | $-a, c,-e$ |  |
| $d$ | $d$ | $-b,-f$ | $-b, d,-f$ | $-d$ | $b, f$ | $b,-d, f$ |  |

### 7.1.3 Cyclic systems involving d orbitals

Sometimes a cyclic $\pi$ system also involves d orbitals. An example of such a system is the inorganic phosphonitrilic halide $\left(\mathrm{NPX}_{2}\right)_{3}$, which has $D_{3 \mathrm{~h}}$ symmetry with a pair of out-of-plane halide groups $\sigma$-bonded to each phosphorous atom. Now the six atomic orbitals taking part in the $\pi$ bonding are the three $p$ orbitals on nitrogen and the three d orbitals on phosphorus. These orbitals and their signed lobes above the molecular plane are shown in Fig. 7.1.14. Note that the overlap of the six orbitals is not as efficient as that found in benzene. There is an inevitable "mismatch" of symmetry, here occurring between orbitals $a$ and $f$, among the six atomic orbitals.

The incorporation of the d orbitals complicates the group theoretic procedure to some extent. Table 7.1.7 gives some useful steps in the derivation of the linear combinations of six atomic orbitals. With the results in Table 7.1.7, the linear combination of the atomic orbitals can be readily derived:

$$
\begin{equation*}
P^{A_{2}^{\prime \prime}} c \Rightarrow(3)^{-1 / 2}(a-c+e) \quad \text { (after normalization). } \tag{7.1.57}
\end{equation*}
$$

For the degenerate $E^{\prime \prime}$ pair, we have

$$
\begin{aligned}
& P^{E^{\prime \prime}} a=2 a+c-e \\
& P^{E^{\prime \prime}} c=a+2 c+e \\
& P^{E^{\prime \prime}} e=-a+c+2 e
\end{aligned}
$$

Since the first expression is the difference of the last two expressions, we can select the first expression as well as the sum of the last two:

$$
E^{\prime \prime}:\left\{\begin{array}{l}
(6)^{-1 / 2}(2 a+c-e)  \tag{7.1.58}\\
(2)^{-1 / 2}(c+e)
\end{array} .\right.
$$

Similarly, for the phosphorus 3d orbitals, we have:

$$
\begin{align*}
& P^{A_{1}^{\prime \prime}} b \Rightarrow(3)^{-1 / 2}(b-d+f) \quad \text { (after normalization). }  \tag{7.1.59}\\
& E^{\prime \prime}:\left\{\begin{array}{l}
(6)^{-1 / 2}(b+2 d+f) \\
(2)^{-1 / 2}(b-f)
\end{array}\right. \tag{7.1.60}
\end{align*}
$$

It is not difficult to show that, when we form the $2 \times 2$ secular determinants with $E^{\prime \prime}$ symmetry, the first component of (7.1.58) interacts with the second component of (7.1.60). Analogously, the second component of (7.1.58) interacts

Fig. 7.1 .14.
Labeling of the N 2 p orbitals and P 3d orbitals taking part in the $\pi$ bonding of $\left(\mathrm{NPX}_{2}\right)_{3}$. Note that only the signed lobes above the molecular plane are shown. Also, a "mismatch," in this case occurring between orbitals $a$ and $f$, is inevitable.

Fig. 7.1.15.
The six pi molecular orbitals of $\left(\mathrm{NPX}_{2}\right)_{3}$.
with the first component of (7.1.60). Without further quantitative treatment, it is apparent that the six $\pi$ golecular orbitals have the energy ordering and nodal characters shown in Fig. 7.1.15.

Molecular orbitals $1 e^{\prime \prime}$ and $2 e^{\prime \prime}$ may be classified as bonding and antibonding, respectively, while $1 a_{2}^{\prime \prime}$ and $1 a_{1}^{\prime \prime}$ may be considered as nonbonding orbitals. The ground configuration for this system is $\left(1 e^{\prime \prime}\right)^{4}\left(1 a_{2}^{\prime \prime}\right)^{2}$. It is clear that the delocalization of the six $\pi$ electrons of this compound is not as extensive as that in benzene. As a result, the $\mathrm{P}_{3} \mathrm{~N}_{3}$ cycle is not as rigid as the benzene ring. Furthermore, it should be noted that the phosphorus d oribital participation in the bonding of this type of compounds has played an important role in the development of inorganic chemistry. Indeed, the phosphorus d orbitals can participate in the bonding of the $\left(\mathrm{NPX}_{2}\right)_{3}$ molecule in a variety of ways, as discussed in Chapter 15. The presentation here is mainly concerned with the symmetry properties of the $\pi$ molecular orbitals.

### 7.1.4 Linear combinations of ligand orbitals for $\mathrm{AL}_{4}$ molecules with $T_{\mathrm{d}}$ symmetry

In previous discussion, we constructed the symmetry-adapted linear combinations of the hydrogen 1s orbitals for $\mathrm{AH}_{n}$ molecules. In this section, we consider $\mathrm{AL}_{n}$ molecules, where L is a ligand capable of both $\sigma$ and $\pi$ bonding. For such systems, the procedure to derive the linear combinations of ligand orbitals can become fairly complicated. As an illustration, we take an $\mathrm{AL}_{4}$ molecule with $T_{\mathrm{d}}$ symmetry as an example.

The coordinate systems for all five atoms in $\mathrm{AL}_{4}$ are shown in Fig. 7.1.16. Note that all of them are right-handed. Also, $x_{1}$ and $x_{4}$ lie in the $\mathrm{AL}_{1} \mathrm{~L}_{4}$ plane, while $x_{2}$ and $x_{3}$ lie in the $\mathrm{AL}_{2} \mathrm{~L}_{3}$ plane.

The four linear combinations with $A_{1}$ and $T_{2}$ symmetries of the four vectors $z_{1}, \ldots, z_{4}$ forming $\sigma$ bonds with orbitals on atom A may be easily obtained by the technique of projection operators. Therefore, only the results are given in Table 7.1.8, where all linear combinations of ligand orbitals will be listed. It is noted that the four combinations of the $z_{1}$ vectors are identical to the combinations of hydrogen 1 s orbitals obtained for methane.

The remaining eight vectors, $x_{1}, \ldots, x_{4}$ and $y_{1}, \ldots, y_{4}$, will form eight linear combinations having symmetries $E, T_{1}$, and $T_{2}$. In order to see how these ligand vectors transform under the 24 symmetry operations of the $T_{\mathrm{d}}$ point group, the direction numbers of all the ligand vectors are required. They are

$$
\begin{array}{llll}
x_{1}(-1,-1,2) & x_{2}(-1,1,2) & x_{3}(1,-1,2) & x_{4}(1,1,2) \\
y_{1}(1,-1,0) & y_{2}(1,1,0) & y_{3}(-1,-1,0) & y_{4}(-1,1,0) \\
z_{1}(1,1,1) & z_{2}(-1,1,-1) & z_{3}(1,-1,-1) & z_{4}(-1,-1,1)
\end{array}
$$

Among these, the direction numbers of the four $z$ vectors are obvious. From these four vectors, any other vector may be generated by doing the cross product between an appropriate pair of vectors. For instance, $y_{1}=z_{1} \times z_{4}$, $x_{1}=y_{1} \times z_{1}$, etc.

Next we write down the transformation matrices for all the operations:
$\boldsymbol{C}_{3}(i)$ : A threefold axis passing through atoms A and $\mathrm{L}_{i}$

$$
\boldsymbol{C}_{3}(1)=\left|\begin{array}{lll}
0 & 0 & 1 \\
1 & 0 & 0 \\
0 & 1 & 0
\end{array}\right| \quad \boldsymbol{C}_{3}(2)=\left|\begin{array}{ccc}
0 & 0 & 1 \\
-1 & 0 & 0 \\
0 & -1 & 0
\end{array}\right| \quad \boldsymbol{C}_{3}(3)=\left|\begin{array}{ccc}
0 & 0 & -1 \\
-1 & 0 & 0 \\
0 & 1 & 0
\end{array}\right| \quad \boldsymbol{C}_{3}(4)=\left|\begin{array}{ccc}
0 & 0 & -1 \\
1 & 0 & 0 \\
0 & -1 & 0
\end{array}\right|
$$

Note that the matrix for $\boldsymbol{C}_{3}^{-1}(i)$, or $\boldsymbol{C}_{3}^{2}(i)$, is simply the transpose of $\boldsymbol{C}_{3}(i)$.
$\boldsymbol{C}_{2}(q)$ : A twofold axis which coincides with axis $q$ on atom A

$$
\boldsymbol{C}_{2}(X)=\left|\begin{array}{ccc}
1 & 0 & 0 \\
0 & -1 & 0 \\
0 & 0 & -1
\end{array}\right| \quad \boldsymbol{C}_{2}(Y)=\left|\begin{array}{ccc}
-1 & 0 & 0 \\
0 & 1 & 0 \\
0 & 0 & -1
\end{array}\right| \quad \boldsymbol{C}_{2}(Z)=\left|\begin{array}{ccc}
-1 & 0 & 0 \\
0 & -1 & 0 \\
0 & 0 & 1
\end{array}\right|
$$

Fig. 7.1.16.
Coordinate system for a tetrahedral $\mathrm{AL}_{4}$ molecule.

## Symmetry in Chemistry

$\boldsymbol{S}_{4}(q)$ : Again, the axis of this operation coincides with axis $q$ on atom A

$$
\boldsymbol{S}_{4}(X)=\left|\begin{array}{ccc}
-1 & 0 & 0 \\
0 & 0 & -1 \\
0 & 1 & 0
\end{array}\right| \quad \boldsymbol{S}_{4}(Y)=\left|\begin{array}{ccc}
0 & 0 & 1 \\
0 & -1 & 0 \\
-1 & 0 & 0
\end{array}\right| \quad \boldsymbol{S}_{4}(Z)=\left|\begin{array}{ccc}
0 & -1 & 0 \\
1 & 0 & 0 \\
0 & 0 & 1
\end{array}\right| .
$$

Note that the matrix for $\boldsymbol{S}_{4}^{-1}(q)$, or $\boldsymbol{S}_{4}^{3}(q)$, is also simply the transpose of $\boldsymbol{S}_{4}(q)$. $\sigma(i j)$ : A symmetry plane passing through atoms $\mathrm{A}, \mathrm{L}_{i}$, and $\mathrm{L}_{j}$

$$
\begin{gathered}
\sigma(12)=\left|\begin{array}{ccc}
0 & 0 & 1 \\
0 & 1 & 0 \\
1 & 0 & 0
\end{array}\right| \quad \sigma(13)=\left|\begin{array}{ccc}
1 & 0 & 0 \\
0 & 0 & 1 \\
0 & 1 & 0
\end{array}\right| \quad \sigma(14)=\left|\begin{array}{ccc}
0 & 1 & 0 \\
1 & 0 & 0 \\
0 & 0 & 1
\end{array}\right| . \\
\sigma(23)=\left|\begin{array}{ccc}
0 & -1 & 0 \\
-1 & 0 & 0 \\
0 & 0 & 1
\end{array}\right| \quad \sigma(24)=\left|\begin{array}{ccc}
1 & 0 & 0 \\
0 & 0 & -1 \\
0 & -1 & 0
\end{array}\right| \quad \sigma(34)=\left|\begin{array}{ccc}
0 & 0 & -1 \\
0 & 1 & 0 \\
-1 & 0 & 0
\end{array}\right| .
\end{gathered}
$$

So now we have the transformation matrices of all the symmetry operations in the $T_{\mathrm{d}}$ point group, except the identity operation $\boldsymbol{E}$, which is simply a unit matrix with the dimensions $3 \times 3$.

When we carry out mathematically a symmetry operation on a ligand vector, we perform a matrix multiplication between the symmetry operation matrix and the vector composed of its directional numbers. For instance, when we operate $\boldsymbol{C}_{3}(1)$ on $x_{1}$, we do the following:

$$
\boldsymbol{C}_{3}(1) x_{1}=\left|\begin{array}{lll}
0 & 0 & 1 \\
1 & 0 & 0 \\
0 & 1 & 0
\end{array}\right|\left|\begin{array}{c}
-1 \\
-1 \\
2
\end{array}\right|=\left|\begin{array}{c}
2 \\
-1 \\
-1
\end{array}\right| .
$$

Since operation $\boldsymbol{C}_{3}(1)$ does not change the position of ligand $L_{1}$, the above resultant new vector $(2,-1,-1)$ may be resolved along the $x_{1}$ and $y_{1}$ directions by taking the dot products

$$
\begin{gathered}
(6)^{-1 / 2}(2,-1,-1) \cdot(6)^{-1 / 2}(-1,-1,2)=-\frac{1}{2} x_{1} \\
(6)^{-1 / 2}(2,-1,-1) \cdot(2)^{-1 / 2}(1,-1,0)=\frac{1}{2}(3)^{1 / 2} y_{1} .
\end{gathered}
$$

In other words, $\boldsymbol{C}_{3}(1) x_{1}=-\frac{1}{2} x_{1}+\frac{1}{2}(3)^{1 / 2} y_{1}$. Note that when we resolve the new vector along the $x_{1}$ and $y_{1}$ directions, all vectors involved need to be normalized first.

Similarly, when we operate $\boldsymbol{C}_{3}(2)$ on $x_{1}$, we get $\boldsymbol{C}_{3}(2) x_{1}=(2,1,1)$. Since operation $\boldsymbol{C}_{3}(2)$ on ligand $\mathrm{L}_{1}$ yields $\mathrm{L}_{3}$, the resultant vector $(2,1,1)$ is to be resolved along the $x_{3}$ and $y_{3}$ directions. Now it is easy to show $\boldsymbol{C}_{3}(2) x_{1}=$ $\frac{1}{2} x_{3}-\frac{1}{2}(3)^{1 / 2} y_{3}$.

When we carry out all 24 symmetry operations in the $T_{\mathrm{d}}$ point group on vector $x_{1}$, we get

$$
\begin{aligned}
& \boldsymbol{C}_{3}(1):-\frac{1}{2} x_{1}+\frac{1}{2}(3)^{1 / 2} y_{1}, \quad \boldsymbol{C}_{3}^{-1}(1):-\frac{1}{2} x_{1}-\frac{1}{2}(3)^{1 / 2} y_{1} \\
& \boldsymbol{C}_{3}(2): \frac{1}{2} x_{3}-\frac{1}{2}(3)^{1 / 2} y_{3}, \quad \boldsymbol{C}_{3}^{-1}(2):-\frac{1}{2} x_{4}-\frac{1}{2}(3)^{1 / 2} y_{4}
\end{aligned}
$$

$$
\begin{aligned}
& \boldsymbol{C}_{3}(3):-\frac{1}{2} x_{4}+\frac{1}{2}(3)^{1 / 2} y_{4}, \quad \boldsymbol{C}_{3}^{-1}(3): \frac{1}{2} x_{2}+\frac{1}{2}(3)^{1 / 2} y_{2} \\
& \boldsymbol{C}_{3}(4): \frac{1}{2} x_{2}-\frac{1}{2}(3)^{1 / 2} y_{2}, \quad \boldsymbol{C}_{3}^{-1}(4): \frac{1}{2} x_{3}+\frac{1}{2}(3)^{1 / 2} y_{3} .
\end{aligned}
$$

After summing up, $8 \boldsymbol{C}_{3} x_{1}=-x_{1}+x_{2}+x_{3}-x_{4}$.

$$
\boldsymbol{C}_{2}(X):-x_{3}, \quad \boldsymbol{C}_{2}(Y):-x_{2}, \quad \boldsymbol{C}_{2}(Z): x_{4}
$$

After summing up, $3 \boldsymbol{C}_{2} x_{1}=-x_{2}-x_{3}+x_{4}$.

$$
\begin{aligned}
& S_{4}(X):-\frac{1}{2} x_{4}-\frac{1}{2}(3)^{1 / 2} y_{4}, \quad S_{4}^{-1}(X): \frac{1}{2} x_{2}+\frac{1}{2}(3)^{1 / 2} y_{2} \\
& S_{4}(Y): \frac{1}{2} x_{3}-\frac{1}{2}(3)^{1 / 2} y_{3}, \quad S_{4}^{-1}(Y):-\frac{1}{2} x_{4}+\frac{1}{2}(3)^{1 / 2} y_{4} \\
& S_{4}(Z):-x_{2}, \quad S_{4}^{-1}(Z):-x_{3}
\end{aligned}
$$

After summing up, $6 \boldsymbol{S}_{4} x_{1}=-\frac{1}{2} x_{2}-\frac{1}{2} x_{3}-x_{4}+\frac{1}{2}(3)^{1 / 2} y_{2}-\frac{1}{2}(3)^{1 / 2} y_{3}$.

$$
\begin{aligned}
& \sigma(12):-\frac{1}{2} x_{1}+\frac{1}{2}(3)^{1 / 2} y_{1}, \quad \sigma(13):-\frac{1}{2} x_{1}-\frac{1}{2}(3)^{1 / 2} y_{1}, \sigma(14): x_{1} \\
& \sigma(23): x_{4}, \quad \sigma(24): \frac{1}{2} x_{3}+\frac{1}{2}(3)^{1 / 2} y_{3}, \quad \sigma(34): \frac{1}{2} x_{2}-\frac{1}{2}(3)^{1 / 2} y_{2} .
\end{aligned}
$$

After summing up, $6 \sigma_{d} x_{1}=\frac{1}{2} x_{2}+\frac{1}{2} x_{3}+x_{4}-\frac{1}{2}(3)^{1 / 2} y_{2}+\frac{1}{2}(3)^{1 / 2} y_{3}$.
Finally, for the identity operation $\boldsymbol{E}$, we have $\boldsymbol{E}, \boldsymbol{E} x_{1}=x_{1}$.
If we carry out the same 24 symmetry operations on vector $y_{1}$, we get

$$
\begin{aligned}
\boldsymbol{E} y_{1} & =y_{1} \\
8 \boldsymbol{C}_{3} y_{1} & =-y_{1}+y_{2}+y_{3}-y_{4} . \\
3 \boldsymbol{C}_{2} y_{1} & =-y_{2}-y_{3}+y_{4} . \\
6 \boldsymbol{S}_{4} y_{1} & =\frac{1}{2} y_{2}+\frac{1}{2} y_{3}+y_{4}+\frac{1}{2}(3)^{1 / 2} x_{2}-\frac{1}{2}(3)^{1 / 2} x_{3} . \\
6 \boldsymbol{\sigma}_{\mathrm{d}} y_{1} & =-\frac{1}{2} y_{2}-\frac{1}{2} y_{3}-y_{4}-\frac{1}{2}(3)^{1 / 2} x_{2}+\frac{1}{2}(3)^{1 / 2} x_{3} .
\end{aligned}
$$

Now we are in a position to apply the projection operator to obtain the linear combinations of ligand orbitals with the desired symmetry. For instance, for the two linear combinations that form the degenerate set with $E$ symmetry, we carry out the operations

$$
P^{E} x_{1}=3 x_{1}-3 x_{2}-3 x_{3}+3 x_{4}, \quad \text { or } \quad \frac{1}{2}\left(x_{1}-x_{2}-x_{3}+x_{4}\right) .
$$

Similarly, $P^{E} y_{1}=\frac{1}{2}\left(y_{1}-y_{2}-y_{3}+y_{4}\right)$. All linear combinations may be obtained in an analogous manner. Table 7.1.8 lists the 16 linear combinations of ligand orbitals for an $\mathrm{AL}_{4}$ molecule with $T_{\mathrm{d}}$ symmetry.

Table 7.1.8. The symmetry-adapted linear combinations of ligand orbitals for an $\mathrm{AL}_{4}$ molecule with $T_{\mathrm{d}}$ symmetry

| Symmetry | Orbital on A | Orbitals on ligands | Molecular orbitals |
| :---: | :---: | :---: | :---: |
| $A_{1}$ | S | $\frac{1}{2}\left(\mathrm{~s}_{1}+\mathrm{s}_{2}+\mathrm{s}_{3}+\mathrm{s}_{4}\right) ; \quad \frac{1}{2}\left(z_{1}+z_{2}+z_{3}+z_{4}\right)$ | $1 a_{1}, 2 a_{1}, 3 a_{1}$ |
| $E$ | $\left\{\begin{array}{c} \mathrm{d}_{z^{2}} \\ \mathrm{~d}_{x^{2}-y^{2}} \end{array}\right.$ | $\left\{\begin{array}{l}\frac{1}{2}\left(x_{1}-x_{2}-x_{3}+x_{4}\right) \\ \frac{1}{2}\left(y_{1}-y_{2}-y_{3}+y_{4}\right)\end{array}\right.$ | $1 e, 2 e$ |
| $T_{1}$ |  | $\left\{\begin{array}{l} \frac{1}{4}\left[(3)^{\frac{1}{2}}\left(x_{1}+x_{2}-x_{3}-x_{4}\right)+\left(y_{1}+y_{2}-y_{3}-y_{4}\right)\right] \\ \frac{1}{4}\left[(3)^{\frac{1}{2}}\left(x_{1}-x_{2}+x_{3}-x_{4}\right)+\left(y_{1}-y_{2}+y_{3}-y_{4}\right)\right] \\ \frac{1}{2}\left(y_{1}+y_{2}+y_{3}+y_{4}\right) \end{array}\right.$ | $1 t_{1}$ |
| $T_{1}$ | $\left\{\begin{array}{l}\mathrm{p}_{x} \\ \mathrm{p}_{y} \\ \mathrm{p}_{z}\end{array}\right.$ | $\left\{\begin{array} { l }  { \frac { 1 } { 2 } ( \mathrm { s } _ { 1 } - \mathrm { s } _ { 2 } + \mathrm { s } _ { 3 } - \mathrm { s } _ { 4 } ) } \\ { \frac { 1 } { 2 } ( \mathrm { s } _ { 1 } + \mathrm { s } _ { 2 } - \mathrm { s } _ { 3 } - \mathrm { s } _ { 4 } ) } \\ { \frac { 1 } { 2 } ( \mathrm { s } _ { 1 } - \mathrm { s } _ { 2 } - \mathrm { s } _ { 3 } + \mathrm { s } _ { 4 } ) } \end{array} \quad \left\{\begin{array}{l} \frac{1}{2}\left(z_{1}-z_{2}+z_{3}-z_{4}\right) \\ \frac{1}{2}\left(z_{1}+z_{2}-z_{3}-z_{4}\right) \\ \frac{1}{2}\left(z_{1}-z_{2}-z_{3}+z_{4}\right) \end{array}\right.\right.$ | $1 t_{2}, 2 t_{2}, 3 t_{2}, 4 t_{2}, 5 t_{2}$ |
|  | $\left\{\begin{array}{l}\mathrm{d}_{y z} \\ \mathrm{~d}_{x z} \\ \mathrm{~d}_{x y}\end{array}\right.$ | $\left\{\begin{array}{l}\frac{1}{4}\left[\left(x_{1}+x_{2}-x_{3}-x_{4}\right)+(3)^{\frac{1}{2}}\left(-y_{1}-y_{2}+y_{3}+y_{4}\right)\right] \\ \frac{1}{4}\left[\left(x_{1}-x_{2}+x_{3}-x_{4}\right)+(3)^{\frac{1}{2}}\left(y_{1}-y_{2}+y_{3}-y_{4}\right)\right] \\ \frac{1}{2}\left(x_{1}+x_{2}+x_{3}+x_{4}\right)\end{array}\right.$ |  |

For an $\mathrm{AL}_{4}$ molecule with $T_{\mathrm{d}}$ symmetry, if we assume that nine atomic orbitals on A and four atomic orbitals on each L participate in bonding, there will be 25 molecular orbitals in total. Based on symmetry arguments, as shown in Table 7.1.8, among the molecular orbitals formed, there will be three with $a_{1}$ symmetry, two doubly degenerate sets with $E$ symmetry, one triply degenerate set with $T_{1}$ symmetry (which is nonbonding, i.e., localized on the ligands), and five triply degenerate set with $T_{2}$ symmetry. Clearly, for such a complex system, it is not straightforward to come up with a qualitative energy level diagram.

### 7.2 Construction of hybrid orbitals

As introduced in Chapter 3, for $\mathrm{AX}_{n}$ systems, the hybrid orbitals are the linear combinations of atomic orbitals on central atom A that point toward the X atoms. In addition, the construction of the $\mathrm{sp}^{n}$ hybrids was demonstrated. In this section, we will consider hybrids that have d-orbital contributions, as well as the relationship between the hybrid orbital coefficient matrix and that of the molecular orbitals, all from the viewpoint of group theory.

### 7.2.1 Hybridization schemes

As is well known, if we construct four equivalent hybrid orbitals using one s and three p atomic orbitals, the hybrids would point toward the four corners of a tetrahedron. However, is this the only way to construct four such hybrids? If not, what other atomic orbitals can be used to form such hybrid orbitals? To answer these questions, we need to determine the representations spanned by the four hybrid orbitals that point toward the corners of a tetrahedron:

| $T_{\mathrm{d}}$ | $\boldsymbol{E}$ | $8 \boldsymbol{C}_{3}$ | $3 \boldsymbol{C}_{2}$ | $6 \boldsymbol{S}_{4}$ | $6 \boldsymbol{\sigma}_{\mathrm{d}}$ |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :--- |
| $\Gamma_{\sigma}$ | 4 | 1 | 0 | 0 | 2 | $\equiv A_{1}+T_{2}$ |

This result implies that, among the four required atomic orbitals (on the central atom), one must have $A_{1}$ symmetry and the other three must form a $T_{2}$ set. From Areas III and IV of the $T_{\mathrm{d}}$ character table, we know that the $s$ orbital has $A_{1}$ symmetry, while the three p orbitals, or the $\mathrm{d}_{x y}, \mathrm{~d}_{y z}$, and $\mathrm{d}_{x z}$ orbitals, collectively form a $T_{2}$ set. In other words, the hybridization scheme can be either the well-known $\mathrm{sp}^{3}$ or the less familiar $\mathrm{sd}^{3}$, or a combination of these two schemes.

On symmetry grounds, the $\mathrm{sp}^{3}$ and $\mathrm{sd}^{3}$ schemes are entirely equivalent to each other. However, for a particular molecule, we can readily see that one scheme is favored over the other. For instance, in $\mathrm{CH}_{4}$, carbon can use the 2 s and three 2 p orbitals to form a set of $\mathrm{sp}^{3}$ hybrids. It is also clear that carbon is unlikely to use its 2 s orbital and three 3 d orbitals (which lie above the 2 p orbitals by about $950 \mathrm{~kJ} \mathrm{~mol}^{-1}$ ) to form the hybrids. On the other hand, for tetrahedral transition metal ions such as $\mathrm{MnO}_{4}^{-}$, it is likely that Mn would use three 3d orbitals, instead of the three higher energy $4 p$ orbitals, for the formation of the hybrids.

We now list the possible hybridization schemes for several important molecular types.
(1) $\mathrm{AX}_{3}$, trigonal planar, $D_{3 \mathrm{~h}}$ symmetry:

$$
\begin{array}{l|ccccccl}
D_{3 \mathrm{~h}} & \boldsymbol{E} & 2 \boldsymbol{C}_{3} & 3 \boldsymbol{C}_{2} & \sigma_{\mathrm{h}} & 2 \boldsymbol{S}_{3} & 3 \sigma_{\mathrm{v}} & \\
\hline \Gamma_{\sigma} & 3 & 0 & 1 & 3 & 0 & 1 & \equiv A_{1}^{\prime}\left(\mathrm{s} ; \mathrm{d}_{z^{2}}\right)+E!\left[\left(\mathrm{p}_{x}, \mathrm{p}_{y}\right) ;\left(\mathrm{d}_{x y}, \mathrm{~d}_{x^{2}-y^{2}}\right)\right]
\end{array}
$$

Hence the possible schemes include $\mathrm{sp}^{2}, \mathrm{sd}^{2}, \mathrm{dp}^{2}$, and $\mathrm{d}^{3}$.
(2) $\mathrm{AX}_{4}$, square planar, $D_{4 \mathrm{~h}}$ symmetry:

$$
\begin{array}{l|ccccccccccl}
D_{4 \mathrm{~h}} & E & 2 C_{4} & C_{2} & 2 C_{2^{\prime}} & 2 C_{2^{\prime \prime}} & i & 2 S_{4} & \sigma_{\mathrm{h}} & 2 \sigma_{\mathrm{v}} & 2 \sigma_{\mathrm{d}} & \\
\hline \Gamma_{\sigma} & 4 & 0 & 0 & 2 & 0 & 0 & 0 & 4 & 2 & 0 & \equiv A_{1 g}\left(\mathrm{~s}, \mathrm{~d}_{z^{2}}\right)+B_{1 \mathrm{~g}}\left(\mathrm{~d}_{x^{2}-y^{2}}\right)+E_{u}\left(\mathrm{p}_{x}, \mathrm{p}_{y}\right)
\end{array}
$$

Hence the possible schemes include $\mathrm{dsp}^{2}$ and $\mathrm{d}^{2} \mathrm{p}^{2}$.
(3) AX ${ }_{5}$, trigonal bipyramidal, $D_{3 \mathrm{~h}}$ symmetry:

| $D_{3 \mathrm{~h}}$ | $E$ | $2 \boldsymbol{C}_{3}$ | $3 \boldsymbol{C}_{2}$ | $\sigma_{\mathrm{h}}$ | $2 \boldsymbol{S}_{3}$ | $3 \sigma_{\mathrm{v}}$ |  |
| :--- | :---: | :---: | :---: | :---: | :---: | :---: | :--- |
| $\Gamma_{\sigma}$ | 5 | 2 | 1 | 3 | 0 | 3 | $\equiv 2 A_{1}^{\prime}\left(\mathrm{s} ; \mathrm{d}_{z^{2}}\right)+A_{2}^{\prime \prime}\left(\mathrm{p}_{z}\right)+E!\left(\mathrm{p}_{x}, \mathrm{p}_{y}\right) ;\left(\mathrm{d}_{x y}, \mathrm{~d}_{\left.\left.x^{2}-y^{2}\right)\right]}\right.$ |

Hence the possible schemes include dsp ${ }^{3}$ and $d^{3}$ sp.
(4) $\mathrm{AX}_{6}$, octahedral, $O_{\mathrm{h}}$ symmetry:

| $O_{\mathrm{h}}$ | $E$ | $8 C_{3}$ | $6 C_{2}$ | $6 C_{4}$ | $3 C_{2}$ | $i$ | $6 S_{4}$ | $8 S_{6}$ | $3 \sigma_{\mathrm{h}}$ | $6 \sigma_{\mathrm{d}}$ |  |
| :--- | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| $\Gamma_{\sigma}$ | 6 | 0 | 0 | 2 | 2 | 0 | 0 | 0 | 4 | 2 | $\equiv A_{1 \mathrm{~g}}(\mathrm{~s})+E_{\mathrm{g}}\left(\mathrm{d}_{\mathrm{z}} 2, \mathrm{~d}_{x^{2}-y^{2}}\right)+T_{\mathrm{lu}}\left(\mathrm{p}_{\mathrm{x}}, \mathrm{p}_{\mathrm{y}}, \mathrm{p} \mathrm{p}\right)$ |

So the only possible scheme is $\mathrm{d}^{2} \mathrm{sp}^{3}$.
Once we have determined the atomic orbitals taking part in the formation of the hybrids, we can employ the method outlined in Chapter 3 to obtain the explicit expressions of the hybrid orbitals.

### 7.2.2 Relationship between the coefficient matrices for the hybrid and molecular orbital wavefunctions

As has been mentioned more than once already, to construct the hybrid orbitals for an $\mathrm{AX}_{n}$ molecule, we linearly combine the atomic orbitals on A so that the

## Symmetry in Chemistry

resultant hybrid orbitals point toward the X ligands. On the other hand, to form the molecular orbitals for the $\mathrm{AX}_{n}$ molecule, we linearly combine the orbitals on the ligands such that the combinations match in symmetry with the orbitals on A. Upon studying these two statements, we would not be surprised to find that the coefficient matrices for the hybrid orbitals and for the ligand orbital linear combinations are related to each other. The basis for this relationship is that both matrices are derived by considering the symmetry properties of the molecule. Indeed, this relationship is obvious if we take up a specific example.

From eq. (3.4.31), the $\mathrm{sp}^{2}$ hybrids for an $\mathrm{AX}_{3}\left(\right.$ or $\left.\mathrm{AH}_{3}\right)$ molecule with $D_{3 \mathrm{~h}}$ symmetry is:

$$
\left|\begin{array}{l}
h_{1}  \tag{7.2.1}\\
h_{2} \\
h_{3}
\end{array}\right|=\left|\begin{array}{ccc}
(3)^{-1 / 2} & (2 / 3)^{1 / 2} & 0 \\
(3)^{-1 / 2} & -(6)^{-1 / 2} & (2)^{-1 / 2} \\
(3)^{-1 / 2} & -(6)^{-1 / 2} & -(2)^{-1 / 2}
\end{array}\right|\left|\begin{array}{c}
\mathrm{s} \\
\mathrm{p}_{x} \\
\mathrm{p}_{y}
\end{array}\right| .
$$

From Table 7.1.2, the linear combinations of ligand orbitals for $\mathrm{BH}_{3}$ have the form

$$
\left|\begin{array}{ccc}
(3)^{-1 / 2} & (3)^{-1 / 2} & (3)^{-1 / 2}  \tag{7.2.2}\\
(2 / 3)^{1 / 2} & -(6)^{-1 / 2} & -(6)^{-1 / 2} \\
0 & (2)^{-1 / 2} & -(2)^{-1 / 2}
\end{array}\right|\left|\begin{array}{c}
1 \mathrm{~s}_{a} \\
1 \mathrm{~s}_{b} \\
1 \mathrm{~s}_{c}
\end{array}\right|
$$

It is now obvious that the matrix in eq. (7.2.1) is simply the transpose of the matrix in expression (7.2.2), and vice versa. In addition, it can be easily checked that the coefficient matrix for the $\mathrm{sp}^{3}$ hybrids given in eq. (3.4.35) and the coefficient matrix for the linear combinations of ligand orbitals in $\mathrm{CH}_{4}$ (Table 7.1.3) have the same relationship.

To conclude, there are two ways to determine the explicit expressions of a set of hybrid orbitals. The first one is that outlined in Chapter 3, taking advantage of the orthonormality relationship among the hybrids as well as the geometry and symmetry of the system. The second method is to apply the appropriate projection operators to the ligand orbitals, which are placed at the ends of the hybrids, to obtain the linear combinations of the ligand orbitals. The coefficient matrix for the hybrids is simply the transpose of the coefficient matrix for the linear combinations. These two methods are naturally closely related to one another. The only difference is that the latter formally makes use of group theory techniques, such as projection operator application and decomposition of a reducible representation, whereas the former does not.

### 7.2.3 Hybrids with d-orbital participation

In Section 7.2.1, we have seen that many hybridization schemes involve d orbitals. In fact, we do not anticipate any technical difficulty in the construction of hybrids that have d orbital participation. Let us take octahedral $\mathrm{d}^{2} \mathrm{sp}^{3}$ hybrids, directed along Cartesian axes (Fig. 7.1.10), as an example. From Table 7.1.5,
we have the coefficient matrix for the linear combinations of ligand orbitals:

$$
\left|\begin{array}{cccccc}
(6)^{-1 / 2} & (6)^{-1 / 2} & (6)^{-1 / 2} & (6)^{-1 / 2} & (6)^{-1 / 2} & (6)^{-1 / 2} \\
-(12)^{-1 / 2} & -(12)^{-1 / 2} & -(12)^{-1 / 2} & -(12)^{-1 / 2} & 2(12)^{-1 / 2} & 2(12)^{-1 / 2} \\
1 / 2 & 1 / 2 & -1 / 2 & -1 / 2 & 0 & 0 \\
(2)^{-1 / 2} & -(2)^{-1 / 2} & 0 & 0 & 0 & 0 \\
0 & 0 & (2)^{-1 / 2} & -(2)^{-1 / 2} & 0 & 0 \\
0 & 0 & 0 & 0 & (2)^{-1 / 2} & -(2)^{-1 / 2}
\end{array}\right|\left|\begin{array}{c}
1 s_{a} \\
1 s_{b} \\
1 s_{c} \\
1 s_{d} \\
1 s_{e} \\
1 s_{f}
\end{array}\right|
$$

With these results, we can easily obtain the hybrid wavefunctions

$$
\left|\begin{array}{l}
h_{a}  \tag{7.2.3}\\
h_{b} \\
h_{c} \\
h_{d} \\
h_{e} \\
h_{f}
\end{array}\right|=\left|\begin{array}{cccccc}
(6)^{-1 / 2} & -(12)^{-1 / 2} & 1 / 2 & (2)^{-1 / 2} & 0 & 0 \\
(6)^{-1 / 2} & -(12)^{-1 / 2} & 1 / 2 & -(2)^{-1 / 2} & 0 & 0 \\
(6)^{-1 / 2} & -(12)^{-1 / 2} & -1 / 2 & 0 & (2)^{-1 / 2} & 0 \\
(6)^{-1 / 2} & -(12)^{-1 / 2} & -1 / 2 & 0 & -(2)^{-1 / 2} & 0 \\
(6)^{-1 / 2} & 2(12)^{-1 / 2} & 0 & 0 & 0 & (2)^{-1 / 2} \\
(6)^{-1 / 2} & 2(12)^{-1 / 2} & 0 & 0 & 0 & -(2)^{-1 / 2}
\end{array}\right|\left|\begin{array}{c}
\mathrm{s} \\
\mathrm{~d}_{z^{2}} \\
\mathrm{~d}_{x^{2}-y^{2}} \\
\mathrm{p}_{x} \\
\mathrm{p}_{y} \\
\mathrm{p}_{z}
\end{array}\right| .
$$

In eq. (7.2.3), hybrids $h_{a}, h_{b}, \ldots, h_{f}$ point toward orbitals $1 \mathrm{~s}_{a}, 1 \mathrm{~s}_{b}, \ldots, 1 \mathrm{~s}_{f}$, respectively (Fig. 7.1.10).

Lastly, we consider a system with non-equivalent positions. An example of such a system is the trigonal bipyramidal molecule $\mathrm{AX}_{5}$ with $D_{3 \mathrm{~h}}$ symmetry. As discussed previously, one possible scheme is the dsp ${ }^{3}$ hybridization, where $\mathrm{d}_{z^{2}}$ is the only d orbital participating.

If we use the $\mathrm{d}_{z^{2}}$ and $\mathrm{p}_{z}$ orbitals for the construction of axial hybrids $h_{a}$ and $h_{b}$, and the $\mathrm{s}, \mathrm{p}_{x}$, and $\mathrm{p}_{y}$ orbitals for the equatorial hybrids $h_{c}, h_{d}$, and $h_{e}$ (Fig. 7.1.8), we can readily write down the wavefunctions of these hybrids:

$$
\left|\begin{array}{c}
h_{a}  \tag{7.2.4}\\
h_{b} \\
h_{c} \\
h_{d} \\
h_{e}
\end{array}\right|=\left|\begin{array}{ccccc}
(2)^{-1 / 2} & (2)^{-1 / 2} & 0 & 0 & 0 \\
(2)^{-1 / 2} & -(2)^{-1 / 2} & 0 & 0 & 0 \\
0 & 0 & (3)^{-1 / 2} & 2(6)^{-1 / 2} & 0 \\
0 & 0 & (3)^{-1 / 2} & -(6)^{-1 / 2} & (2)^{-1 / 2} \\
0 & 0 & (3)^{-1 / 2} & -(6)^{-1 / 2} & -(2)^{-1 / 2}
\end{array} \|\left|\begin{array}{c}
\mathrm{d}_{z^{2}} \\
\mathrm{p}_{z} \\
\mathrm{~s} \\
\mathrm{p}_{x} \\
\mathrm{p}_{y}
\end{array}\right|\right.
$$

However, there is no reason at all to assume $h_{a}$ and $h_{b}$ are made up of only $\mathrm{p}_{z}$ and $\mathrm{d}_{z^{2}}$ orbitals: The $\mathrm{d}_{z^{2}}$ orbital can also contribute to the equatorial hybrids, and the s orbital can also contribute to the axial hybrids. In fact, if we use only the s and $\mathrm{p}_{z}$ orbitals for the axial hybrids, and the $\mathrm{d}_{z^{2}}, \mathrm{p}_{x}$, and $\mathrm{p}_{y}$ for the equatorial hybrids, we then have

$$
\left|\begin{array}{l}
h_{a}  \tag{7.2.5}\\
h_{b} \\
h_{c} \\
h_{d} \\
h_{e}
\end{array}\right|=\left|\begin{array}{ccccc}
0 & (2)^{-1 / 2} & (2)^{-1 / 2} & 0 & 0 \\
0 & -(2)^{-1 / 2} & (2)^{-1 / 2} & 0 & 0 \\
-(3)^{-1 / 2} & 0 & 0 & 2(6)^{-1 / 2} & 0 \\
-(3)^{-1 / 2} & 0 & 0 & -(6)^{-1 / 2} & (2)^{-1 / 2} \\
-(3)^{-1 / 2} & 0 & 0 & -(6)^{-1 / 2} & -(2)^{-1 / 2}
\end{array}\right|\left|\begin{array}{c}
\mathrm{d}_{z^{2}} \\
\mathrm{p}_{z} \\
\mathrm{~s} \\
\mathrm{p}_{x} \\
\mathrm{p}_{y}
\end{array}\right| .
$$

Obviously, both of the matrices in eqs. (7.2.4) and (7.2.5) are limiting cases. A general expression encompassing these two cases is

To obtain eqs. (7.2.4) and (7.2.5) from eq. (7.2.6), we only need to set angle $\alpha$ to be $90^{\circ}$ and $0^{\circ}$, respectively. It is not difficult to show that the five hybrids form an orthonormal set of wavefunctions. The parameter $\alpha$ in the coefficient matrix in eq. (7.2.6) may be determined in a number of ways, such as by the maximization of overlap between the hybrids and the ligand orbitals, or by the minimization of the energy of the system. In any event, such procedures are clearly beyond the scope of this chapter (or this book) and we will not deal with them any further.

### 7.3 Molecular vibrations

Molecular vibrations, as detected in infrared and Raman spectroscopy, provide useful information on the geometric and electronic structures of a molecule. As mentioned earlier, each vibrational wavefunction of a molecule must have the symmetry of an irreducible representation of that molecule's point group. Hence the vibrational motion of a molecule is another topic that may be fruitfully treated by group theory.

### 7.3.1 The symmetries and activities of the normal modes

A molecule composed of $N$ atoms has in general $3 N$ degrees of freedom, which include three each for translational and rotational motions, and $(3 N-6)$ for the normal vibrations. During a normal vibration, all atoms execute simple harmonic motion at a characteristic frequency about their equilibrium positions. For a linear molecule, there are only two rotational degrees of freedom, and hence $(3 N-5)$ vibrations. Note that normal vibrations that have the same symmetry and frequency constitute the equivalent components of a degenerate normal mode; hence the number of normal modes is always equal to or less than the number of normal vibrations. In the following discussion, we shall demonstrate how to determine the symmetries and activities of the normal modes of a molecule, using $\mathrm{NH}_{3}$ as an example.

Step 1. For a molecule belonging to a certain point group, we first determine the representation $\Gamma\left(N_{0}\right)$ whose characters are the number of atoms that are unshifted by the operations in the group. Taking the $\mathrm{NH}_{3}$ molecule as an example,

Step 2 . Multiply each character of $\Gamma\left(N_{0}\right)$ by the appropriate factor $f(\boldsymbol{R})$ to obtain $\Gamma_{3 N}$. Now we show how to determine factor $f(\boldsymbol{R})$ for operation $\boldsymbol{R}$. When $\boldsymbol{R}$ is a rotation of angle $\phi, \boldsymbol{C}_{\phi}$, we use

$$
\begin{equation*}
f\left(\boldsymbol{C}_{\phi}\right)=1+2 \cos \phi \tag{7.3.1}
\end{equation*}
$$

Thus, $f(\boldsymbol{E})=3 ; f\left(\boldsymbol{C}_{2}\right)=-1 ; f\left(\boldsymbol{C}_{3}\right)=f\left(\boldsymbol{C}_{3}^{2}\right)=0 ; f\left(\boldsymbol{C}_{4}\right)=f\left(\boldsymbol{C}_{4}^{3}\right)=1$; $f\left(\boldsymbol{C}_{6}\right)=f\left(\boldsymbol{C}_{6}^{5}\right)=2$; etc. When $\boldsymbol{R}$ is an improper rotation of angle $\phi, \boldsymbol{S}_{\phi}$, we have

$$
\begin{equation*}
f\left(\boldsymbol{S}_{\phi}\right)=-1+2 \cos \phi \tag{7.3.2}
\end{equation*}
$$

Thus, $f\left(\boldsymbol{S}_{1}\right)=f(\boldsymbol{\sigma})=1 ; f\left(\boldsymbol{S}_{2}\right)=f(\boldsymbol{i})=-3 ; f\left(\boldsymbol{S}_{3}\right)=-2 ; f\left(\boldsymbol{S}_{4}\right)=f\left(\boldsymbol{S}_{4}^{3}\right)=$ $-1 ; f\left(\boldsymbol{S}_{6}\right)=f\left(\boldsymbol{S}_{6}^{5}\right)=0$; etc. So, for $\mathrm{NH}_{3}$,

| $C_{3 \mathrm{v}}$ | $\boldsymbol{E}$ | $\mathbf{2} \boldsymbol{C}_{3}$ | $3 \boldsymbol{\sigma}_{\mathrm{v}}$ |
| :--- | :--- | :--- | :--- |
| $f(\boldsymbol{R})$ | 3 | 0 | 1 |
| $\Gamma_{3 N}=f(\boldsymbol{R}) \times \Gamma\left(N_{0}\right)$ | 12 | 0 | 2 |

Note that the values of $f(\boldsymbol{R})$ can also be obtained from the characters of the symmetry species $\Gamma_{x y z}$ (representation based on $x, y$, and $z$ ). For point group $C_{3 \mathrm{v}}, \Gamma_{x y z}=\Gamma_{x y}($ based on $x$ and $y)+\Gamma_{z}($ based on $z)=E+A_{2}$.

Upon decomposing $\Gamma_{3 N}$ using e.g. (6.4.3), we get

$$
\Gamma_{3 N}\left(\mathrm{NH}_{3}\right)=3 A_{1}+A_{2}+4 E .
$$

Step 3. From $\Gamma_{3 N}$ subtract the symmetry species $\Gamma_{\text {trans }}\left(=\Gamma_{x y z}\right)$ for the translation of the molecule as a whole and $\Gamma_{\text {rot }}$ (based on $R_{x}, R_{y}$, and $R_{z}$ ) for the rotational motion to obtain the representation for molecular vibration, $\Gamma_{\mathrm{vib}}$ :

$$
\begin{equation*}
\Gamma_{\mathrm{vib}}=\Gamma_{3 N}-\Gamma_{\text {trans }}-\Gamma_{\mathrm{rot}} . \tag{7.3.3}
\end{equation*}
$$

For $\mathrm{NH}_{3}$, we have

$$
\begin{aligned}
\Gamma_{\mathrm{vib}}\left(\mathrm{NH}_{3}\right) & =\left(3 A_{1}+A_{2}+4 E\right)-\left(A_{1}+E\right)-\left(A_{2}+E\right) \\
& =2 A_{1}+2 E .
\end{aligned}
$$

In other words, among the six normal vibrations of $\mathrm{NH}_{3}$, two have $A_{1}$ symmetry, two others form a degenerate $E$ set, and the remaining two form another $E$ set.

Step 4. For a vibrational mode to be infrared (IR) active, it must bring about a change in the molecule's dipole moment. Since the symmetry species of the dipole moment's components are the same as $\Gamma_{x}, \Gamma_{y}$, and $\Gamma_{z}$, a normal mode having the same symmetry as $\Gamma_{x}, \Gamma_{y}$, or $\Gamma_{z}$ will be infrared active. The argument employed here is very similar to that used in the derivation of the selection rules for electric dipole transitions (Section 7.1.3). So, of the six vibrations of $\mathrm{NH}_{3}$, all are infrared active, and they comprise four normal modes with distinct fundamental frequencies.

Fig. 7.3.1.
The vibrational modes of $\mathrm{NH}_{3}$ and observed frequencies. Note that only one component is shown for the $E$ modes.

On the other hand, for a vibrational mode to be Raman (R) active, it must bring about a change in the polarizability of the molecule. As the components of the polarizability tensor (based on the quadratic products of the coordinates) have the symmetry of $\Gamma_{x^{2}}, \Gamma_{y^{2}}, \Gamma_{z^{2}}, \Gamma_{x y}, \Gamma_{x z}$, and $\Gamma_{y z}$, a normal mode having one of these symmetries will be Raman active. So, for $\mathrm{NH}_{3}$, we again will observe four fundamentals in its Raman spectrum. In other words,

$$
\Gamma_{\mathrm{vib}}\left(\mathrm{NH}_{3}\right)=2 A_{1}(\mathrm{R} / \mathrm{IR})+2 E(\mathrm{R} / \mathrm{IR})
$$

The four observed frequencies and the pictorial representations of the normal modes for $\mathrm{NH}_{3}$ are displayed in Fig. 7.3.1. From this figure, we can see that $\nu_{1}$ and $\nu_{3}$ are stretching modes, while $\nu_{2}$ and $\nu_{4}$ are bending modes. Note that the number of stretching vibrations is equal to the number of bonds. Also, the stretching modes have higher frequencies than the bending ones.

Before discussing other examples, we note here that, for a centrosymmetric molecule (one with an inversion center), $\Gamma_{x}, \Gamma_{y}$, and $\Gamma_{z}$ are "u" (from the German word ungerade, meaning odd) species, while binary products of $x, y$, and $z$ have "g" (gerade, meaning even) symmetry. Thus infrared active modes will be Raman forbidden, and Raman active modes will be infrared forbidden. In other words, there are no coincident infrared and Raman bands for a centrosymmetric molecule. This relationship is known as the rule of mutual exclusion.

Another useful relationship: As the totally symmetric irreducible representation $\Gamma_{\mathrm{TS}}$ in every group is always associated with one or more binary products of $x, y$, and $z$ and it follows that totally symmetric vibrational modes are always Raman active.

Besides being always Raman active, the totally symmetric vibrational modes can also be readily identified in the spectrum. As shown in Fig. 7.3.2, the scattered Raman radiation can be resolved into two intensity components, $I_{\perp}$ and $I_{\|}$. The ratio of these two intensities is called the depolarization ratio $\rho$ :

$$
\begin{equation*}
\rho=I_{\perp} / I_{\|} . \tag{7.3.4}
\end{equation*}
$$

If the incident radiation is plane-polarized, such as that produced by lasers in Raman spectroscopy, scattering theory predicts that totally symmetric modes
will have $0<\rho<3 / 4$ and all other (non-totally symmetric) modes will have $\rho=3 / 4$. A vibrational band with $0<\rho<3 / 4$ is said to be polarized, and one with $\rho=3 / 4$ is said to be depolarized. In fact, for highly symmetric molecules, the polarized bands often have $\rho \sim 0$, which makes identifying totally symmetric modes relatively simple. For the $\mathrm{NH}_{3}$ molecule, the two $A_{1}$ modes are polarized.

Figure 7.3.2 shows the intensities $I_{\perp}$ and $I_{\|}$for the $\nu_{1}\left(A_{1}\right)$ and $\nu_{2}(E)$ Raman bands of $\mathrm{CCl}_{4}$. It is seen that $I_{\perp}$ of $\nu_{1}\left(A_{1}\right)$ is essentially zero. Precise measurements yield $\rho=0.005 \pm 0.002$ for $\nu_{1}\left(A_{1}\right)$ and $\rho=0.72 \pm 0.002$ for $\nu_{2}(E)$. These results are consistent with scattering theory.

### 7.3.2 Some illustrative examples

In this section, we will attempt to illustrate the various principles and techniques introduced in the previous section with several simple examples. Special emphasis will be on the stretching modes of a molecule.

## (1) trans- $\mathrm{N}_{2} \mathrm{~F}_{2}$

The molecule $\mathrm{N}_{2} \mathrm{~F}_{2}$ can exist in two geometrical forms, namely, cis and trans. Here we are only concerned with the trans isomer with $C_{2 \mathrm{~h}}$ symmetry. The methodical derivation of the symmetry species of the vibrational modes is best conducted in tabular form, as shown below.

| $C_{2 \mathrm{~h}}$ | $\boldsymbol{E}$ | $\boldsymbol{C}_{2}$ | $\boldsymbol{i}$ | $\boldsymbol{\sigma}_{\mathrm{h}}$ | Remark |
| :--- | :---: | :---: | :---: | :---: | :--- |
| $\Gamma\left(N_{0}\right)$ | 4 | 0 | 0 | 4 | row 1 (atoms not moved by $\boldsymbol{R})$ |
| $\Gamma_{3 N}$ | 12 | 0 | 0 | 4 | row $2=$ row $1 \times$ row 3 |
| $\Gamma_{\text {trans }}=f(\boldsymbol{R})$ | 3 | -1 | -3 | 1 | row $3, \Gamma_{\text {trans }}$ based on $(x, y, z)$ |
| $\Gamma_{\text {rot }}$ | 3 | -1 | 3 | -1 | row $4, \Gamma_{\text {rot }}$ based on $\left(R_{x}, R_{y}, R_{z}\right)$ |
| $\Gamma_{\text {vib }}$ | 6 | 2 | 0 | 4 | row $5=$ row $2-$ row $3-$ row 4 |

Hence $\Gamma_{3 N}\left(\mathrm{~N}_{2} \mathrm{~F}_{2}\right)=4 A_{\mathrm{g}}+2 B_{\mathrm{g}}+2 A_{\mathrm{u}}+4 B_{\mathrm{u}}$, and

$$
\Gamma_{\mathrm{vib}}\left(\mathrm{~N}_{2} \mathrm{~F}_{2}\right)=3 A_{\mathrm{g}}(\mathrm{R})+A_{\mathrm{u}}(\mathrm{IR})+2 B_{\mathrm{u}}(\mathrm{IR})
$$

So trans $-\mathrm{N}_{2} \mathrm{~F}_{2}$ has three bands in both its infrared spectrum and its Raman spectrum. However, none of the bands are coincident, as this is a centrosymmetric molecule. The normal modes, as well as their observed frequencies, of trans- $\mathrm{N}_{2} \mathrm{~F}_{2}$ are shown in Fig. 7.3.3. Note that this molecule has three bonds and hence has three stretching modes: $\nu_{1}\left(A_{\mathrm{g}}\right)$ is the symmetric stretch of two N-F bonds, $\nu_{2}\left(A_{\mathrm{g}}\right)$ is the $\mathrm{N}=\mathrm{N}$ stretching, while $\nu_{4}\left(B_{\mathrm{u}}\right)$ is the asymmetric stretch of the two $\mathrm{N}-\mathrm{F}$ bonds. As the symmetric $\mathrm{N}-\mathrm{F}$ stretch and $\mathrm{N}=\mathrm{N}$ stretch have the same symmetry $\left(A_{\mathrm{g}}\right), \nu_{1}$ and $\nu_{2}$ are both mixtures of these two types of stretch motion. Among the three modes, $\nu_{2}\left(A_{\mathrm{g}}\right)$ has the highest energy, as $\mathrm{N}=\mathrm{N}$ is a double bond and $\mathrm{N}-\mathrm{F}$ is a single bond.

Fig. 7.3.2.
Raman band intensities $I_{\perp}$ and $I_{\|}$of $\mathrm{CCl}_{4}$ for $\nu_{1}\left(A_{1}\right)$ (top) and $\nu_{2}(E)$ (bottom). The splitting in the $\nu_{1}$ band is due to the isotopic effect of Cl .

## 240

## Fig. 7.3.3.

The vibrational modes and the corresponding frequencies of trans $-\mathrm{N}_{2} \mathrm{~F}_{2}$. Note that only $\nu_{1}, \nu_{2}$, and $\nu_{4}$ are stretching modes.

## Fig. 7.3.4.

The vibrational modes and their frequencies of $\mathrm{CF}_{4}$. Note that only one component is shown for the degenerate modes.

## Symmetry in Chemistry

## (2) $\mathrm{CF}_{4}$

This is a tetrahedral molecule with $T_{\mathrm{d}}$ symmetry. The derivation of the vibrational modes is summarized below.

| $T_{\mathrm{d}}$ | $\boldsymbol{E}$ | $8 \boldsymbol{C}_{3}$ | $3 \boldsymbol{C}_{2}$ | $6 \boldsymbol{S}_{4}$ | $6 \boldsymbol{\sigma}_{\mathrm{d}}$ |  |
| :--- | :---: | :---: | :---: | :---: | :---: | :--- |
| $\Gamma\left(N_{0}\right)$ | 5 | 2 | 1 | 1 | 3 |  |
| $f(\boldsymbol{R})$ | 3 | 0 | -1 | -1 | 1 |  |
| $\Gamma_{3 N}$ | 15 | 0 | -1 | -1 | 3 | $\equiv A_{1}+E+T_{1}+3 T_{2}$ |

$$
\Gamma_{\mathrm{vib}}\left(\mathrm{CF}_{4}\right)=A_{1}(\mathrm{R})+E(\mathrm{R})+2 T_{2}(\mathrm{IR} / \mathrm{R})
$$

So $\mathrm{CF}_{4}$ has two infrared bands and four Raman bands, and there are two coincident absorptions. The normal modes and their respective frequencies are given in Fig. 7.3.4. Note that $\nu_{1}\left(A_{1}\right)$ and $\nu_{3}\left(T_{2}\right)$ are the stretching bands. Also, this is an example that illustrates the "rule" that a highly symmetrical molecule has very few infrared active vibrations. The basis of the "rule" is that, in a point group with very high symmetry, $x, y$, and $z$ often combine to form degenerate representations.
(3) $\mathbf{P}_{4}$

The atoms in the $\mathrm{P}_{4}$ molecule occupy the corners of a regular tetrahedron. In point group $T_{\mathrm{d}}$, following the previous procedure, we have

$$
\left.\begin{array}{c|ccccc}
T_{\mathrm{d}} & \boldsymbol{E} & 8 \boldsymbol{C}_{3} & 3 \boldsymbol{C}_{2} & 6 \boldsymbol{S}_{4} & 6 \boldsymbol{\sigma}_{\mathrm{d}} \\
\hline \Gamma\left(N_{0}\right) & 4 & 1 & 0 & 0 & 2 \\
f(\boldsymbol{R}) & 3 & 0 & -1 & -1 & 1 \\
\Gamma_{3 N} & 12 & 0 & 0 & 0 & 2
\end{array} \equiv A_{1}+E+T_{1}+2 T_{2}\right)
$$

If the molecule were to adopt a hypothetical square-planar structure in point group $D_{4 \mathrm{~h}}$, the normal modes would be

$$
\Gamma_{\mathrm{vib}}\left(\mathrm{P}_{4}, D_{4 \mathrm{~h}}\right)=A_{1 \mathrm{~g}}(\mathrm{R})+B_{1 \mathrm{~g}}(\mathrm{R})+B_{2 \mathrm{~g}}(\mathrm{R})+B_{2 \mathrm{u}}+E_{\mathrm{u}}(\mathrm{IR})
$$

Both models have the same numbers of infrared, Raman, and polarized Raman bands. However, they can be distinguished by the fact that the $T_{2}$ mode in the $T_{\mathrm{d}}$ structure is both IR and Raman active (there is one coincidence), whereas the rule of mutual exclusion holds for the centrosymmetric $D_{4 \mathrm{~h}}$ structure.
The normal modes of $\mathrm{P}_{4}$ and their observed Raman frequencies are shown in Fig. 7.3.5. Here $A_{1}$ is called the breathing mode, since all $\mathrm{P}-\mathrm{P}$ bonds are stretching and contracting in unison. In the $\nu_{2}(E)$ mode, two bonds are contracting while the other four are lengthening; in the $\nu_{3}\left(T_{2}\right)$ mode, three bonds are contracting while the other three are lengthening. It is of interest to note that all six vibrations of $\mathrm{P}_{4}$ are stretching motions.

## (4) $\mathrm{XeF}_{4}$

This molecule has a square-planar structure with $D_{4 \mathrm{~h}}$ symmetry. With reference to the coordinate system displayed in Fig. 7.3.6, the symmetry of the vibrational modes may be derived in the following manner:

| $D_{4 \mathrm{~h}}$ | $\boldsymbol{E}$ | $2 \boldsymbol{C}_{4}$ | $\boldsymbol{C}_{2}$ | $2 \boldsymbol{C}_{2}^{\prime}$ | $2 \boldsymbol{C}_{2}^{\prime \prime}$ | $\boldsymbol{i}$ | $2 \boldsymbol{S}_{4}$ | $\boldsymbol{\sigma}_{\mathrm{h}}$ | $2 \boldsymbol{\sigma}_{\mathrm{v}}$ | $2 \boldsymbol{\sigma}_{\mathrm{d}}$ |
| :--- | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| $\Gamma\left(N_{0}\right)$ | 5 | 1 | 1 | 3 | 1 | 1 | 1 | 5 | 3 | 1 |
| $f(\mathbf{R})$ | 3 | 1 | -1 | -1 | -1 | -3 | -1 | 1 | 1 | 1 |
| $\Gamma_{3 N}$ | 15 | 1 | -1 | -3 | -1 | -3 | -1 | 5 | 3 | 1 |
| $\Gamma_{3 N}\left(\mathrm{XeF}_{4}\right)=A_{1 \mathrm{~g}}+A_{2 \mathrm{~g}}+B_{1 \mathrm{~g}}+B_{2 \mathrm{~g}}+E_{\mathrm{g}}+2 A_{2 \mathrm{u}}+B_{2 \mathrm{u}}+3 E_{\mathrm{u}}$. |  |  |  |  |  |  |  |  |  |  |
| $\Gamma_{\text {vib }}\left(\mathrm{XeF}_{4}\right)=A_{1 \mathrm{~g}}(\mathrm{R})+B_{1 \mathrm{~g}}(\mathrm{R})+B_{2 \mathrm{~g}}(\mathrm{R})+A_{2 \mathrm{u}}(\mathrm{IR})+B_{2 \mathrm{u}}+2 E_{\mathrm{u}}(\mathrm{IR})$. |  |  |  |  |  |  |  |  |  |  |

So $\mathrm{XeF}_{4}$ has three bands in its infrared spectrum as well as in its Raman spectrum. None of the bands are coincident, as this molecule is centrosymmetric. In addition, there is a "silent" mode, with $B_{2 u}$ symmetry, which does not show up in either spectrum. The normal modes and their frequencies are given in Fig. 7.3.6.

Fig. 7.3.5.
The normal modes and Raman frequencies of $\mathrm{P}_{4}$. Only one component is shown for the degenerate modes.

## 242

Fig. 7.3.6.
Normal modes and vibrational frequencies of $\mathrm{XeF}_{4}$. Note that the $x$ and $y$ axes are equivalent, and only one component is shown for the degenerate modes. The coordinate system of locations of secondary twofold axes and mirror planes are shown in the lower part of the figure.

## Symmetry in Chemistry

Among the normal modes shown in Fig. 7.3.6, $v_{1}\left(A_{1 \mathrm{~g}}\right), v_{2}\left(B_{1 \mathrm{~g}}\right)$, and $v_{6}\left(E_{\mathrm{u}}\right)$, are the stretching modes. It is appropriate here to note that it is straightforward to come up with these pictorial representations. If we call the four $\mathrm{Xe}-\mathrm{F}$ bonds $a, b, c$, and $d$, the $\nu_{1}\left(A_{1 \mathrm{~g}}\right)$ mode may be denoted as $a+b+c+d$, with " + " indicating contracting motion and " - " indicating stretching motion. The combination $a+b+c+d$ is what we will get if we apply the projection operator $P^{A_{1 \mathrm{~g}}}$ to $a$. Similarly, if we apply $P^{B_{1 g}}$ to $a$, we will get $a-b+c-d$, which translates to $\nu_{2}\left(B_{1 \mathrm{~g}}\right)$ in Fig. 7.3.6. If we apply $P^{E_{\mathrm{u}}}$ to $a$, we get $a-c$; similarly, applying $P^{E_{\mathrm{u}}}$ to $b$ will yield $b-d$. When we combine these combination further, $(a-c) \pm(b-d)$ are the results. One of these combinations is shown in Fig. 7.3.6, while the other is not. The stretching motions of a molecule can usually be derived in this manner.

If the $x$ and $y$ axes are chosen to bisect the $\mathrm{F}-\mathrm{Xe}-\mathrm{F}$ bond angles, the symmetry of the normal modes is expressed as

$$
\begin{equation*}
\Gamma_{\mathrm{vib}}\left(\mathrm{XeF}_{4}\right)=A_{1 \mathrm{~g}}(\mathrm{R})+B_{1 \mathrm{~g}}(\mathrm{R})+B_{2 \mathrm{~g}}(\mathrm{R})+A_{2 \mathrm{u}}(\mathrm{IR})+B_{1 \mathrm{u}}+2 E_{\mathrm{u}}(\mathrm{IR}) \tag{7.3.6}
\end{equation*}
$$

As compared to eq. (7.3.5), the only difference is that the silent mode $B_{2 u}$ in that expression is converted to $B_{1 \mathrm{u}}$ here, and now $\nu_{2}$ has $B_{2 \mathrm{~g}}$ symmetry and $\nu_{4}$ has $B_{1 \mathrm{~g}}$ symmetry. All deductions concerning infrared and Raman activities remain unchanged.

Given the illustrations of the normal modes of a molecule, it is possible to identify their symmetry species from the character table. Each non-degenerate normal mode can be regarded as a basis, and the effects of all symmetry operations of the molecular point group on it are to be considered. For instance, the $v_{1}$ mode of $\mathrm{XeF}_{4}$ is invariant to all symmetry operations, i.e. $\boldsymbol{R}\left(v_{1}\right)=(1) \nu_{1}$ for all values of $\boldsymbol{R}$. Since the characters are all equal to $1, \nu_{1}$ belongs to symmetry species $A_{1 \mathrm{~g}}$. For $\nu_{2}$, the symmetry operation $C_{4}$ leads to a character of -1 , as shown below:

Working through all symmetry operations in the various classes by inspection, we can readily identify the symmetry species of $\nu_{2}$ as $B_{1 \mathrm{~g}}$.

For a doubly degenerate normal mode, both components must be used together as the basis of a two-dimensional irreducible representation. For example, the operations $\boldsymbol{C}_{2}$ and $\boldsymbol{\sigma}_{\mathrm{v}}$ on the two normal vibrations that constitute the $\nu_{6}$ mode lead to the character (sum of the diagonal elements of the corresponding $2 \times 2$ matrix) of -2 and 0 , respectively, as illustrated below. Working through the remaining symmetry operations, the symmetry species of $v_{6}$ can be identified as $E_{\mathrm{u}}$.

## (5) $\mathrm{SF}_{4}$

As shown below, this molecule has $C_{2 \mathrm{v}}$ symmetry with two types of $S-F$ bonds, equatorial and axial. The vibrational modes can be derived in the following way:

| $C_{2 \mathrm{v}}$ | $\boldsymbol{E}$ | $\boldsymbol{C}_{2}$ | $\boldsymbol{\sigma}_{\mathrm{v}}(x z)$ | $\boldsymbol{\sigma}_{\mathrm{v}}^{\prime}(y z)$ |
| :--- | :---: | :---: | :---: | :---: |
| $\Gamma\left(N_{0}\right)$ | 5 | 1 | 3 | 3 |
| $f(\boldsymbol{R})$ | 3 | -1 | 1 | 1 |
| $\Gamma_{3 N}$ | 15 | -1 | 3 | 3 |

Fig. 7.3.7.
Normal modes of $\mathrm{SF}_{4}$ and observed frequencies. The + and - symbols refer to motions of "coming out" and "going into" the paper, respectively.

$v_{1}\left(A_{1}\right)(\mathrm{IR} / \mathrm{R})$ $892 \mathrm{~cm}^{-1}$

$v_{7}\left(B_{1}\right)(\mathrm{IR} / \mathrm{R})$
$532 \mathrm{~cm}^{-1}$

${ }_{8}\left(B_{2}\right)(\mathrm{IR} / \mathrm{R})$
$867 \mathrm{~cm}^{-1}$
$v_{9}\left(B_{2}\right)(\mathrm{IR} / \mathrm{R})$
$353 \mathrm{~cm}^{-1}$

So there are nine Raman lines and eight infrared lines. All eight infrared bands may be found in the Raman spectrum. The normal modes and their frequencies for $\mathrm{SF}_{4}$ are shown in Fig. 7.3.7. From this figure, it may be seen that stretching modes include $\nu_{1}$ (symmetric stretch for equatorial bonds), $\nu_{2}$ (symmetric stretch for axial bonds), $\nu_{6}$ (asymmetric stretch for axial bonds), and $\nu_{8}$ (asymmetric stretch for equatorial bonds).

It is worth noting that we have so far discussed the vibrational spectra of three five-atom molecules: $\mathrm{CF}_{4}, \mathrm{XeF}_{4}$, and $\mathrm{SF}_{4}$, with $T_{\mathrm{d}}, D_{4 \mathrm{~h}}$, and $C_{2 \mathrm{v}}$ symmetry, respectively. In their infrared spectra, two, three, and eight bands are observed, respectively. These results are consistent with the expectation that more symmetrical molecules have less infrared bands.

## (6) $\mathrm{PF}_{5}$

This well-known molecule assumes a trigonal bipyramidal structure with $D_{3 \mathrm{~h}}$ symmetry. As in the case of $\mathrm{SF}_{4}, \mathrm{PF}_{5}$ also has two types of bonds, equatorial and

axial P-F bonds. The vibrational modes for this molecule can be determined in the following way:

$$
\begin{array}{l|cccccc}
D_{3 \mathrm{~h}} & \boldsymbol{E} & 2 \boldsymbol{C}_{3} & 3 \boldsymbol{C}_{2} & \boldsymbol{\sigma}_{\mathrm{h}} & 2 \boldsymbol{S}_{3} & 3 \sigma_{\mathrm{v}} \\
\hline \Gamma\left(N_{0}\right) & 6 & 3 & 2 & 4 & 1 & 4 \\
f(\boldsymbol{R}) & 3 & 0 & -1 & 1 & -2 & 1 \\
\Gamma_{3 N} & 18 & 0 & -2 & 4 & -2 & 4 \\
\\
\Gamma_{\mathrm{vib}}\left(\mathrm{PF}_{5}\right)=2 A_{1}^{\prime}(\mathrm{R})+3 A_{1}^{\prime}+A_{2}^{\prime}(\mathrm{IR} / \mathrm{R})+2 A_{2}^{\prime \prime}(\mathrm{IR})+E^{\prime}+3 A_{2}^{\prime \prime}(\mathrm{R}) .
\end{array}
$$

So there are five infrared and six Raman bands, three of which are coincident. The normal modes and their frequencies are shown in Fig. 7.3.8. From this figure, it is seen that $\nu_{1}\left(A_{1}^{\prime}\right)$ and $\nu_{5}\left(E^{\prime}\right)$ are the stretching modes for the equatorial bonds, while $\nu_{2}\left(A_{1}^{\prime}\right)$ and $\nu_{3}\left(A_{2}^{\prime \prime}\right)$ are the symmetric and asymmetric stretches for the axial bonds. Recall that in the derivation of the linear combinations for three equivalent functions $a, b$, and $c$, the results are $a+b+c ; 2 a-b-c$, and $b-c$, with the last two being degenerate. Mode $\nu_{1}\left(A_{1}^{\prime}\right)$ in Fig. 7.3.8 is equivalent to $a+b+c$, while $v_{5}\left(E^{\prime}\right)$ is $2 a-b-c$. The remaining combination, $b-c$, is not shown in this figure.

## (7) $\mathrm{SF}_{6}$

This highly symmetrical molecule has an octahedral structure with $O_{\mathrm{h}}$ symmetry. Contrary to $\mathrm{SF}_{4}$ and $\mathrm{PF}_{5}$, where there are two types of bonds, all six bonds in $\mathrm{SF}_{6}$ are equivalent to each other. The vibrational modes of this molecule can be determined in the following manner:

| $O_{\mathrm{h}}$ | $\boldsymbol{E}$ | $8 \boldsymbol{C}_{3}$ | $6 \boldsymbol{C}_{2}$ | $6 \boldsymbol{C}_{4}$ | $3 \boldsymbol{C}_{2}=\boldsymbol{C}_{4}^{2}$ | $\boldsymbol{i}$ | $6 \boldsymbol{S}_{4}$ | $8 \boldsymbol{S}_{6}$ | $3 \boldsymbol{\sigma}_{\mathrm{h}}$ | $6 \boldsymbol{\sigma}_{\mathrm{d}}$ |
| ---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| $\Gamma\left(N_{0}\right)$ | 7 | 1 | 1 | 3 | 3 | 1 | 1 | 1 | 5 | 3 |
| $f(\boldsymbol{R})$ | 3 | 0 | -1 | 1 | -1 | -3 | -1 | 0 | 1 | 1 |
| $\Gamma_{3 N}$ | 21 | 0 | -1 | 3 | -3 | -3 | -1 | 0 | 5 | 3 |
|  | $\Gamma_{3 N}\left(\mathrm{SF}_{6}\right)=A_{1 \mathrm{~g}}+E_{\mathrm{g}}+T_{1 \mathrm{~g}}+T_{2 \mathrm{~g}}+3 T_{1 \mathrm{u}}+T_{2 \mathrm{u}}$. |  |  |  |  |  |  |  |  |  |
|  | $\Gamma_{\mathrm{vib}}\left(\mathrm{SF}_{6}\right)=A_{1 \mathrm{~g}}(\mathrm{R})+E_{\mathrm{g}}(\mathrm{R})+2 T_{1 \mathrm{u}}(\mathrm{IR})+T_{2 \mathrm{~g}}(\mathrm{R})+T_{2 \mathrm{u}}$. |  |  |  |  |  |  |  |  |  |

Fig. 7.3.8.
Normal modes of $\mathrm{PF}_{5}$ and their frequencies. Note that only one component is shown for each degenerate mode.

So there are three Raman and two infrared bands, none of which are coincident. Also, the $T_{2 \mathrm{u}}$ mode is silent. The normal modes and their frequencies are shown in Fig. 7.3.9. It is clear now that $\nu_{1}\left(A_{1 \mathrm{~g}}\right), \nu_{2}\left(E_{\mathrm{g}}\right)$, and $\nu_{3}\left(T_{1 \mathrm{u}}\right)$ are the stretching modes.

If we call the six bonds $a, b, \ldots, f$, with $a$ and $b$ colinear, and so are $c$ and $d$, as well as $e$ and $f$, then $\nu_{1}\left(A_{1 \mathrm{~g}}\right)$ is equivalent to $a+b+c+d+e+f ; \nu_{2}\left(E_{\mathrm{g}}\right)$ is equivalent to $2 e+2 f-a-b-c-d ; \nu_{3}\left(T_{1 \mathrm{u}}\right)$ is equivalent to $e-f$. The ones not shown in Fig. 7.3.9 are the remaining component of $E_{\mathrm{g}}, a+b-c-d$, and the last two components of $T_{1 \mathrm{u}}, a-b$ and $c-d$. These six combinations are identical to those listed in Table 7.1.5, the combinations of ligand orbitals in $\mathrm{AH}_{6}$.

### 7.3.3 CO stretch in metal carbonyl complexes

In the previous examples for molecules with relatively few atoms, we studied and presented the results of all $3 N-6$ vibrations of the molecules. However, for molecules composed of a large number of atoms, often it is convenient to concentrate on a certain type of vibration. The prime example of this kind of investigation is the enumeration of the CO stretching modes in metal carbonyl complexes.

Most metal carbonyl complexes exhibit sharp and intense CO bands in the range $1800-2100 \mathrm{~cm}^{-1}$. Since the CO stretch motions are rarely coupled with other modes and CO absorption bands are not obscured by other vibrations, measurement of the CO stretch bands alone often provides valuable information about the geometric and electronic structures of the carbonyl complexes. As we may recall, free CO absorbs strongly at $2155 \mathrm{~cm}^{-1}$, which corresponds to the stretching motion of a $\mathrm{C} \equiv \mathrm{O}$ triple bond. On the other hand, most ketones and aldehyde exhibit bands near $1715 \mathrm{~cm}^{-1}$, which corresponds formally to

the stretching of a $\mathrm{C}=\mathrm{O}$ double bond. In other words, the CO bonds in metal carbonyls have a bond order somewhere between 2 and 3 . This observation may be rationalized by the simple bonding model illustrated in Fig. 7.3.10.

The M-C $\sigma$ bond is formed by donating the lone electrons on C to the empty $\mathrm{d}_{z^{2}}$ orbital on M (upper portion of Fig. 7.3.10). The $\pi$ bond is formed by back donation of the metal $\mathrm{d} \pi$ electrons to the $\pi^{*}$ orbital (introduced in Chapter 3) of CO. Populating the $\pi^{*}$ orbital of CO tends to decrease the CO bond order, thus lowering the CO stretch frequency (lower portion of Fig. 7.3.10). These two components of metal-carbonyl bonding may be expressed by the two resonance structures

(I)

Thus structure (I), with higher CO frequencies, tends to build up electron density on M and is thus favored by systems with positive charges accumulated on the metal. On the other hand, structure (II), with lower CO frequencies, is favored by those with negative charge (which enhances back donation) on metal. In other words, net charges on carbonyl compounds have a profound effect on the CO stretch frequencies, as illustrated by the following two isoelectronic series:

| Importance of resonance structure |  |  |  |
| :--- | :---: | :---: | :---: |
| $\nu\left(\mathrm{in} \mathrm{cm}^{-1}\right)$ | $\mathrm{V}(\mathrm{CO}-\mathrm{C} \equiv)_{6}^{-}$ | $\mathrm{Cr}(\mathrm{CO})_{6}$ | $\mathrm{Mn}(\mathrm{CO})_{6}^{+}$ |
| $\nu\left(A_{1 \mathrm{~g}}\right)$ | 2020 | 2119 | 2192 |
| $v\left(E_{\mathrm{g}}\right)$ | 1895 | 2027 | 2125 |
| $v\left(T_{1 \mathrm{u}}\right)$ | 1858 | 2000 | 2095 |
|  | $\mathrm{Fe}(\mathrm{CO})_{4}^{2-}$ | $\mathrm{Co}(\mathrm{CO})_{4}^{-}$ | $\mathrm{Ni}(\mathrm{CO})_{4}$ |
| $\nu\left(A_{1}\right)$ | 1788 | 2002 | 2125 |
| $v\left(T_{2}\right)$ | 1786 | 1888 | 2045 |
| Importance of resonance structure $\mathrm{M}=\mathrm{C}=\mathrm{O}$ |  |  |  |

The identification of the symmetries of the CO stretching modes and the determination of their activities may be accomplished by the usual group theory techniques. Take the trigonal bipyramidal $\mathrm{Fe}(\mathrm{CO})_{5}$ (with $D_{3 \mathrm{~h}}$ symmetry) as an example. The representation spanned by the five CO stretching motions, $\Gamma_{\mathrm{CO}}$, is once again derived by counting the number of CO groups unshifted by each operation in the $D_{3 \mathrm{~h}}$ point group.

Fig. 7.3.10.
The $\sigma$ and $\pi$ bonding in metal carbonyls. Note that electrons flow from the shaded orbital to the unshaded orbital in both instances.
frequencies for $\mathrm{Fe}(\mathrm{CO})_{5}$. Note that only one component is shown for $v_{10}\left(E^{\prime}\right)$.
Fig. 7.3.11.
Carbonyl stretching modes and their

$$
\begin{array}{c|cccccc}
D_{3 \mathrm{~h}} & \boldsymbol{E} & 2 \boldsymbol{C}_{3} & 3 \boldsymbol{C}_{2} & \boldsymbol{\sigma}_{\mathrm{h}} & 2 \boldsymbol{S}_{3} & 3 \boldsymbol{\sigma}_{\mathrm{v}} \\
\hline \Gamma_{\mathrm{CO}} & 5 & 2 & 1 & 3 & 0 & 3
\end{array}
$$

$$
\Gamma_{\mathrm{CO}}\left[\mathrm{Fe}(\mathrm{CO})_{5}\right]=2 A_{1}^{\prime}(\mathrm{R})+A_{2}^{\prime \prime}(\mathrm{IR})+E^{\prime}(\mathrm{IR} / \mathrm{R})
$$

So there are two and three CO stretch bands in the infrared and Raman spectra, respectively. The CO stretching modes and their frequencies are given in Fig. 7.3.11.

The CO stretching modes shown in Fig. 7.3.11 may be easily obtained using the standard group theory technique. If we call the equatorial CO groups $a, b$, and $c$, and the axial groups $d$ and $e$, the combinations for these five entities are simply $A_{1}^{\prime}, a+b+c ; E^{\prime}, 2 a-b-c$ and $b-c ; A_{1}^{\prime}, d+e ; A_{2}^{\prime \prime}, d-e ;$ where + denotes stretching and - denotes contracting. Since there are two $A_{1}^{\prime}$ combinations, we can combine them further to form $k(a+b+c)+d+e$ and $k^{\prime}(-a-b-c)+d+e$, where $k$ and $k^{\prime}$ are the combination coefficients. The stretching modes shown in Fig. 7.3.11 are simply graphical representations of these five linear combinations, except that one component of the $E^{\prime}$ mode, $b-c$, is not shown. Again, $\nu_{1}\left(A_{1}^{\prime}\right)$ is called the breathing mode, since all carbonyl groups are stretching and contracting
in unison. For metal-carbonyl complexes, the breathing mode often has the highest energy, as in the case of $\mathrm{Fe}(\mathrm{CO})_{5}$.

Now it is straightforward to show that, for tetrahedral carbonyl complexes $\mathrm{M}(\mathrm{CO})_{4}$ with $T_{\mathrm{d}}$ symmetry,

$$
\Gamma_{\mathrm{CO}}\left[\mathrm{M}(\mathrm{CO})_{4}\right]=A_{1}(\mathrm{R})+T_{2}(\mathrm{IR} / \mathrm{R})
$$

For octahedral carbonyl complexes $\mathrm{M}(\mathrm{CO})_{6}$ with $O_{\mathrm{h}}$ symmetry,

$$
\Gamma_{\mathrm{CO}}\left[\mathrm{M}(\mathrm{CO})_{6}\right]=A_{1 \mathrm{~g}}(\mathrm{R})+E_{\mathrm{g}}(\mathrm{R})+T_{1 \mathrm{u}}(\mathrm{IR})
$$

Since there is a direct relationship between the structure of a metal-carbonyl complex and the number of CO stretching bands, it is often possible to deduce the arrangement of the CO groups in a complex when we compare its spectrum with the number of CO stretch bands predicted for each of the possible structures using group theory techniques. As an illustrative example, consider the cis and trans isomers of an octahedral $\mathrm{M}(\mathrm{CO})_{4} \mathrm{~L}_{2}$ complex. For the trans isomer, with $D_{4 \mathrm{~h}}$ symmetry, we have

$$
\Gamma_{\mathrm{CO}}\left[\text { trans }-\mathrm{M}(\mathrm{CO})_{4} \mathrm{~L}_{2}\right]=A_{1 \mathrm{~g}}(\mathrm{R})+B_{1 \mathrm{~g}}(\mathrm{R})+E_{\mathrm{u}}(\mathrm{IR})
$$

So there are two CO stretching bands in the Raman spectrum and only one in infrared. Also, there are no coincident bands. For the cis isomer, with $C_{2 v}$ symmetry, we have

$$
\Gamma_{\mathrm{CO}}\left[c i s-\mathrm{M}(\mathrm{CO})_{4} \mathrm{~L}_{2}\right]=2 A_{1}(\mathrm{IR} / \mathrm{R})+B_{1}(\mathrm{IR} / \mathrm{R})+B_{2}(\mathrm{IR} / \mathrm{R})
$$

So there are four infrared/Raman coincident lines for the cis isomer. When M is Mo and L is $\mathrm{PCl}_{3}$, the trans isomer has indeed only one infrared CO stretch band, while there are four for the cis isomer. These results are summarized in Fig. 7.3.12, along with the pictorial illustrations of the CO stretching modes. It appears that the two $A_{1}$ modes of the cis isomer do not couple strongly. Also, this is another example for the general rule that a more symmetrical molecule will have fewer infrared bands.

In some cases, two isomers may have the same number of CO stretching bands, yet they may still be distinguished by the relative intensities of the bands. Take the cis- and trans- $\left[\left(\eta^{5}-\mathrm{C}_{5} \mathrm{H}_{5}\right) \mathrm{Mo}(\mathrm{CO})_{2} \mathrm{PPh}_{3} \mathrm{C}_{4} \mathrm{H}_{6} \mathrm{O}\right]^{+}$and their spectra as an example. The structural formulas of these complex ions and their infrared spectra are shown in Fig. 7.3.13. In both spectra, the two bands are the symmetric and asymmetric CO stretch modes. As shown in the previous example of cis-[ $\left.\mathrm{Mo}(\mathrm{CO})_{4}\left(\mathrm{PCl}_{3}\right)_{2}\right]$, the symmetric modes has a slightly higher energy. Also, as shown below, the intensity ratio is related to the angle formed by the two groups.

Referring to Fig. 7.3.14, the dipole vector $\mathbf{R}$ for a stretching mode is simply the sum or difference of the two individual CO group dipoles. Since the intensities of the symmetric and asymmetric stretches are proportional to $\mathbf{R}_{\mathrm{sym}}^{2}$ and

cis:

$v\left(A_{1}^{(1)}\right)(\mathrm{IR} / \mathrm{R})$ $2072 \mathrm{~cm}^{-1}$

$v\left(A_{1 \mathrm{~g}}\right)(\mathrm{R})$

$v\left(B_{1 \mathrm{~g}}\right)(\mathrm{R})$

trans:

$\mathbf{R}_{\text {sym }}=2 \mathbf{r} \cos \theta \quad \mathbf{R}_{\text {asym }}=2 \mathbf{r} \sin \theta$
$\mathbf{R}_{\text {asym }}^{2}$, respectively, the ratio of these two intensities is simply

$$
\begin{aligned}
I(1) / I(2) & =\mathbf{R}_{\mathrm{sym}}^{2} / \mathbf{R}_{\mathrm{asym}}^{2} \\
& =\left(2 \mathbf{r} \cos \theta^{2}\right) /(2 \mathbf{r} \sin \theta)^{2} \\
& =\cot ^{2} \theta,
\end{aligned}
$$

where $2 \theta$ is the angle formed by the two CO groups. For the left spectrum in Fig. 7.3.13, $I(1) / I(2)=1.44$, and $2 \theta$ is $79^{\circ}$, indicating this spectrum is that of the cis isomer. For the spectrum on the right, $I(1) / I(2)=0.32$, and $2 \theta$ is $121^{\circ}$, signifying this spectrum is that of the trans isomer.

In polynuclear carbonyls, i.e., those carbonyl complexes with two or more metal atoms, the CO ligands may bond to the metal(s) in different ways. In addition to the terminal carbonyl groups, those we have studied so far, we may also have $\mu_{n}$ bridging carbonyls, which bond to $n$ metal atoms. In the case of $\mu_{2}$ bridging, it may be assumed that a CO group donates one electron to each metal. Also, both metals back-donate to the CO ligand, thus leading to vibrational frequencies lower than those of terminal COs. Indeed, most $\mu_{2}-$ bridging CO groups absorb in the range of $1700-1860 \mathrm{~cm}^{-1}$. In the following we consider the dinulclear complex $\mathrm{Co}_{2}(\mathrm{CO})_{8}$ which, in the solid state, has the following structure with $C_{2 \mathrm{v}}$ symmetry:

To derive the CO stretching modes, we may consider the bridging and terminal groups separately.

$$
\begin{gathered}
C_{2 \mathrm{v}} \\
\boldsymbol{E}
\end{gathered} \boldsymbol{C}_{2} \quad \boldsymbol{\sigma}_{\mathrm{v}}(x z) \quad \boldsymbol{\sigma}_{\mathrm{v}}^{\prime}(y z),
$$

So there are seven CO stretching bands in the infrared spectrum, as found experimentally. The terminal CO stretching frequencies are at 2075, 2064, 2047, 2035, and $2028 \mathrm{~cm}^{-1}$, and the two bridging CO stretch peaks are at 1867 and $1859 \mathrm{~cm}^{-1}$.

## Symmetry in Chemistry

As another example, consider the highly symmetrical $\mathrm{Fe}_{2}(\mathrm{CO})_{9}$, with $D_{3 h}$ symmetry, as shown above. The symmetries of the CO stretching modes can be determined readily:

$$
\begin{aligned}
& \left(\Gamma_{\mathrm{CO}}\right)_{\text {brid }}\left[\mathrm{Fe}_{2}(\mathrm{CO})_{9}\right]=A_{1}^{\prime}(\mathrm{R})+E^{\prime}(\mathrm{IR} / \mathrm{R}) \text {, } \\
& \left(\Gamma_{\mathrm{CO}}\right)_{\text {term }}\left[\mathrm{Fe}_{2}(\mathrm{CO})_{9}\right]=A_{1}^{\prime}(\mathrm{R})+A_{2}^{\prime \prime}(\mathrm{IR})+E^{\prime}(\mathrm{IR} / \mathrm{R})+E^{\prime \prime}(\mathrm{R}) .
\end{aligned}
$$

So there are three infrared absorption bands: $2066\left(A_{2}^{\prime \prime}\right), 2038$ ( $E^{\prime}$, terminal), and 1855 ( $E^{\prime}$, bridging) $\mathrm{cm}^{-1}$.

In this section, using purely qualitative symmetry arguments, we have discussed the kind of information regarding structure and bonding we can obtain from vibrational spectroscopy. Obviously, treatments of this kind have their limitations, such as their failure to make reliable assignments for the observed vibrational bands. To carry out this type of tasks with confidence, we need to make use of quantitative methods, which are beyond the scope of this book.

### 7.3.4 Linear molecules

In this section, we examine the vibrational spectra of a few linear molecules to illustrate the principles we have discussed.

## (1) Hydrogen cyanide and carbon dioxide

Both HCN and $\mathrm{CO}_{2}$, with $C_{\infty v}$ and $D_{\infty h}$ symmetry, respectively, have two bonds and, hence, have two stretching modes and one (doubly degenerate) bending mode. In $\mathrm{CO}_{2}$, the two bonds are equivalent and they may couple in a symmetric and an antisymmetric way, giving rise to symmetric and asymmetric stretching modes. However, for HCN , we simply have the $\mathrm{C}-\mathrm{H}$ and $\mathrm{C} \equiv \mathrm{N}$ stretching modes. The observed frequencies and their assignments for these two triatomic molecules are summarized in Tables 7.3.1 and 7.3.2.

Table 7.3.1. The normal modes of HCN and their observed frequencies

| Symmetry | $\mathrm{cm}^{-1}$ | Normal mode | Activity | Description |
| :---: | :---: | :---: | :---: | :---: |
| $\Pi$ | 712 |  | IR/R | bending |
| $\Sigma^{+}$ | 2089 | $\overleftarrow{\mathrm{H}}-\overleftarrow{\mathrm{C}} \equiv \overrightarrow{\mathrm{~N}}$ | IR/R | $\mathrm{C} \equiv \mathrm{N}$ stretch |
| $\Sigma^{+}$ | 3312 | $\stackrel{\mathrm{H}}{ }-\overrightarrow{\mathrm{C}} \equiv \overrightarrow{\mathrm{~N}}$ | IR/R | C-H stretch |

## (2) Cyanogen

Cyanogen, $\mathrm{N} \equiv \mathrm{C}-\mathrm{C} \equiv \mathrm{N}$, is a symmetric linear molecule. It has three stretching modes and two (doubly degenerate) bending modes. Just as in the case of $\mathrm{CO}_{2}$,

Table 7.3.2. The normal modes of $\mathrm{CO}_{2}$ and their observed frequencies

| Symmetry | $\mathrm{cm}^{-1}$ | Normal mode | Activity | Description |
| :---: | :---: | :---: | :---: | :---: |
| $\Pi_{u}$ | 667 |  | IR | bending |
| $\Sigma_{\mathrm{g}}^{+}$ | 1388 | $\stackrel{+}{\mathrm{O}}=\mathrm{C}=\overrightarrow{\mathrm{O}}$ | R | symmetric stretch |
| $\Sigma_{\text {u }}^{+}$ | 2349 | $\overrightarrow{\mathrm{O}}=\stackrel{\leftarrow}{\mathrm{C}}=\overrightarrow{\mathrm{O}}$ | IR | asymmetric stretch |

there are no coincident bands. Hence, the assignments are fairly straightforward, as summarized in Table 7.3.3.

Table 7.3.3. The normal modes of cyanogen and their observed frequencies

| Symmetry | $\mathrm{cm}^{-1}$ | Normal mode | Activity | Description |
| :---: | :---: | :---: | :---: | :---: |
| $\Pi_{u}$ | 226 |  | IR | asymmetric $\mathrm{C}-\mathrm{C}-\mathrm{N}$ bending |
| $\Pi_{g}$ | 506 |  | R | symmetric bending |
| $\Sigma_{g}^{+}$ | 848 | $\overleftarrow{\mathrm{N}} \equiv \stackrel{\leftarrow}{\mathrm{C}}-\overrightarrow{\mathrm{C}} \overline{\mathrm{C}} \overrightarrow{\mathrm{~N}}$ | R | C-C stretch |
| $\Sigma_{\text {u }}^{+}$ | 2149 | $\overleftarrow{\mathrm{N}} \equiv \overrightarrow{\mathrm{C}}-\overrightarrow{\mathrm{C}} \equiv \stackrel{\leftarrow}{\mathrm{~N}}$ | IR | asymmetric $\mathrm{C} \equiv \mathrm{N}$ stretch |
| $\Sigma_{g}^{+}$ | 2322 | $\overleftarrow{\mathrm{N}} \overline{\equiv \mathrm{C}}-\overleftarrow{\mathrm{C}} \overline{\overline{\mathrm{~N}}}$ | R | symmetric $\mathrm{C} \equiv \mathrm{N}$ stretch |

## (3) Carbon suboxide

Carbon suboxide, $\mathrm{O}=\mathrm{C}=\mathrm{C}=\mathrm{C}=\mathrm{O}$, has four stretching modes and three (doubly degenerate) bending modes. The spectral assignments can be made in a similar manner, as summarized in Table 7.3.4.

While most of the assignments given in Tables 7.3.1 to 7.3 .4 may be made by qualitative arguments, it should be stressed that quantitative treatments are indispensable in making certain that the assignments are correct.

Finally, it is useful to mention here a "systematic" way to derive the symmetries of the vibrational modes for a linear molecule. Even though formally carbon suboxide has $D_{\infty h}$ symmetry, its vibrational modes may be derived by using the $D_{2 \mathrm{~h}}$ character table. The procedure is illustrated below for the carbon suboxide molecule:

| $D_{2 \mathrm{~h}}$ | $\boldsymbol{E}$ | $\boldsymbol{C}_{2}(z)$ | $\boldsymbol{C}_{2}(y)$ | $\boldsymbol{C}_{2}(x)$ | $\boldsymbol{i}$ | $\boldsymbol{\sigma}(x y)$ | $\boldsymbol{\sigma}(x z)$ | $\boldsymbol{\sigma}(y z)$ |
| :--- | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| $\Gamma\left(N_{0}\right)$ | 5 | 5 | 1 | 1 | 1 | 1 | 5 | 5 |
| $f(\boldsymbol{R})$ | 3 | -1 | -1 | -1 | -3 | 1 | 1 | 1 |
| $\Gamma_{3 N}$ | 15 | -5 | -1 | -1 | -3 | 1 | 5 | 5 |

Table 7.3.4. The normal modes of carbon suboxide and their observed frequencies

| Symmetry | $\mathrm{cm}^{-1}$ | Normal mode | Activity | Description |
| :---: | :---: | :---: | :---: | :---: |
| $\Pi_{u}$ | 557 |  | IR | asymmetric $\mathrm{C}-\mathrm{C}-\mathrm{O}$ bending |
| $\Pi_{g}$ | 586 |  | R | symmetric bending |
| $\Pi_{u}$ | 637 |  | IR | asymmetric $\mathrm{C}-\mathrm{C}-\mathrm{C}$ bending |
| $\Sigma_{\mathrm{g}}^{+}$ | 843 | $\overrightarrow{\mathrm{o}}=\overrightarrow{\mathrm{C}}=\mathrm{C}=\overleftarrow{\mathrm{C}}=\overleftarrow{\mathrm{O}}$ | R | symmetric $\mathrm{C}=\mathrm{C}$ stretch |
| $\Sigma_{u}^{+}$ | 1570 | $\overleftarrow{\mathrm{O}}=\overleftarrow{\mathrm{C}}=\overrightarrow{\mathrm{C}}=\overleftarrow{\mathrm{C}}=\overleftarrow{\mathrm{O}}$ | IR | asymmetric $\mathrm{C}=\mathrm{C}$ stretch |
| $\Sigma_{g}^{+}$ | 2200 | $\overrightarrow{\mathrm{o}}=\overleftarrow{\mathrm{C}}=\mathrm{C}=\overrightarrow{\mathrm{C}}=\overleftarrow{\mathrm{O}}$ | R | symmetric $\mathrm{C}=\mathrm{O}$ stretch |
| $\Sigma_{\text {u }}^{+}$ | 2290 | $\overleftarrow{\mathrm{o}}=\overrightarrow{\mathrm{C}}=\overrightarrow{\mathrm{C}}=\overrightarrow{\mathrm{C}}=\stackrel{\leftarrow}{\mathrm{o}}$ | IR | asymmetric $\mathrm{C}=\mathrm{O}$ stretch |

$$
\begin{aligned}
& \Gamma_{3 N}=2 A_{\mathrm{g}}+2 B_{2 \mathrm{~g}}+2 B_{3 \mathrm{~g}}+3 B_{1 \mathrm{u}}+3 B_{2 \mathrm{u}}+3 B_{3 \mathrm{u}} \\
& \Gamma_{\mathrm{vib}}\left(\mathrm{C}_{3} \mathrm{O}_{2}, D_{2 \mathrm{~h}}\right)=2 A_{\mathrm{g}}+B_{2 \mathrm{~g}}+B_{3 \mathrm{~g}}+2 B_{1 \mathrm{u}}+2 B_{2 \mathrm{u}}+2 B_{3 \mathrm{u}}
\end{aligned}
$$

Note that in deriving these results, we have considered $\Gamma_{\text {vib }}\left(\mathrm{C}_{3} \mathrm{O}_{2}, D_{2 \mathrm{~h}}\right)=$ $\Gamma_{3 N}-\Gamma_{\text {trans }}-\Gamma\left(R_{x}\right)-\Gamma\left(R_{y}\right)$, which gives rise to a total of 10 vibrations for this linear molecule. There is no need to take rotation $R_{z}$ (with $B_{1 g}$ symmetry) into account here as we have assigned the molecular axis to be the $z$ axis.

To convert the symmetry species in point group $D_{2 \mathrm{~h}}$ to those of $D_{\infty \mathrm{h}}$, we make use of the correlation diagram shown below, which can be easily deduced from the pair of character tables:

So, in terms of the symmetry species of point group $D_{\infty h}$, we have

$$
\Gamma_{\mathrm{vib}}\left(\mathrm{C}_{3} \mathrm{O}_{2}\right)=2 \Sigma_{\mathrm{g}}^{+}+\Pi_{\mathrm{g}}+2 \Sigma_{\mathrm{u}}^{+}+2 \Pi_{\mathrm{u}}
$$

### 7.3.5 Benzene and related molecules

In the final section of this chapter, we discuss the vibrational spectra of benzene, its isostructural species $\mathrm{C}_{6} \mathrm{O}_{6}^{2-}$ (rhodizonate dianion), and dibenzene metal complexes.

## (1) Benzene

Historically, the cyclic structure of benzene with $D_{6 \mathrm{~h}}$ symmetry, as shown in Fig. 7.3.15, was deduced by enumerating the derivatives formed in the mono-, di-, tri-substitution reactions of benzene. The structure can also be established directly using physical methods such as X-ray and neutron diffraction, NMR, and vibrational spectroscopy. We now discuss the infrared and Raman spectral data of benzene.

The symmetries of the 30 normal vibrations can be derived in the usual way. The symmetry elements $C_{2}^{\prime}, C_{2}^{\prime \prime}, \sigma_{\mathrm{d}}$, and $\sigma_{\mathrm{v}}$ are taken as those shown in Fig. 7.3.15.

$$
\begin{array}{r|cccccccccccc}
D_{6 \mathrm{~h}} & \boldsymbol{E} & 2 \boldsymbol{C}_{6} & 2 \boldsymbol{C}_{3} & \boldsymbol{C}_{2} & 3 \boldsymbol{C}_{2}^{\prime} & 3 \boldsymbol{C}_{2}^{\prime \prime} & \boldsymbol{i} & 2 \boldsymbol{S}_{3} & 2 \boldsymbol{S}_{6} & \boldsymbol{\sigma}_{\mathrm{h}} & 3 \boldsymbol{\sigma}_{\mathrm{d}} & 3 \boldsymbol{\sigma}_{\mathrm{v}} \\
\hline \Gamma\left(N_{0}\right) & 12 & 0 & 0 & 0 & 4 & 0 & 0 & 0 & 0 & 12 & 0 & 4 \\
f(\boldsymbol{R}) & 3 & 2 & 0 & -1 & -1 & -1 & -3 & -2 & 0 & 1 & 1 & 1 \\
\Gamma_{3 N} & 36 & 0 & 0 & 0 & -4 & 0 & 0 & 0 & 0 & 12 & 0 & 4 \\
& \Gamma_{3 N}= & 2 A_{1 \mathrm{~g}}+2 A_{2 \mathrm{~g}}+2 B_{2 \mathrm{~g}}+2 E_{1 \mathrm{~g}}+4 E_{2 \mathrm{~g}}+2 A_{2 \mathrm{u}}+2 B_{1 \mathrm{u}}+2 B_{2 \mathrm{u}} \\
& +4 E_{1 \mathrm{u}}+2 E_{2 \mathrm{u} .} \\
\Gamma_{\mathrm{vib}}\left(\mathrm{C}_{6} \mathrm{H}_{6}\right)= & 2 A_{1 \mathrm{~g}}(\mathrm{R})+A_{2 \mathrm{~g}}+2 B_{2 \mathrm{~g}}+E_{1 \mathrm{~g}}(\mathrm{R})+4 E_{2 \mathrm{~g}}(\mathrm{R})+A_{2 \mathrm{u}}(\mathrm{IR}) \\
& +2 B_{1 \mathrm{u}}+2 B_{2 \mathrm{u}}+3 E_{1 \mathrm{u}}(\mathrm{IR})+2 E_{2 \mathrm{u}} .
\end{array}
$$

So four bands are expected in the IR spectrum (one with $A_{2 u}$ symmetry and three sets with $E_{1 \mathrm{u}}$ symmetry), while there should be seven bands in the Raman spectrum (two with $A_{2 \mathrm{u}}$ symmetry, one set having $E_{1 \mathrm{~g}}$ symmetry, and four sets with $E_{2 \mathrm{~g}}$ symmetry).

The 20 vibrational modes of benzene are pictorially illustrated in Fig. 7.3.16. Also shown are the observed frequencies. In this figure, $\nu(\mathrm{CH})$ and $v(\mathrm{CC})$ represent $\mathrm{C}-\mathrm{H}$ and $\mathrm{C}-\mathrm{C}$ stretching modes, respectively, while $\delta$ and $\pi$ denote in-plane and out-of-plane bending modes, respectively. For each $E$ mode, only one component is shown.

The 20 vibrational modes illustrated in Fig. 7.3.16 may be broken down into various types of vibrations. In the following tabulation, the representation generated by the 12 vibrations of the carbon ring skeleton is denoted by $\Gamma_{\mathrm{C} 6}$, and $\Gamma_{\mathrm{C}-\mathrm{C}}$ and $\Gamma_{\mathrm{C}-\mathrm{H}}$ are the representations for the stretching motions of C-C and $\mathrm{C}-\mathrm{H}$ bonds, respectively.

| $D_{6 \mathrm{~h}}$ | $\boldsymbol{E}$ | $2 \boldsymbol{C}_{6}$ | $2 \boldsymbol{C}_{3}$ | $\boldsymbol{C}_{2}$ | $3 \boldsymbol{C}_{2}^{\prime}$ | $3 \boldsymbol{C}_{2}^{\prime}$ | $\boldsymbol{i}$ | $2 \boldsymbol{S}_{3}$ | $2 \boldsymbol{S}_{6}$ | $\boldsymbol{\sigma}_{\mathrm{h}}$ | $3 \boldsymbol{\sigma}_{\mathrm{d}}$ | $3 \boldsymbol{\sigma}_{\mathrm{v}}$ |
| :--- | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| $\Gamma\left(N_{0}\right)(\mathrm{C} 6)$ | 6 | 0 | 0 | 0 | 2 | 0 | 0 | 0 | 0 | 6 | 0 | 2 |
| $f(\boldsymbol{R})$ | 3 | 2 | 0 | -1 | -1 | -1 | -3 | -2 | 0 | 1 | 1 | 1 |
| $\Gamma_{3 N}(\mathrm{C} 6)$ | 18 | 0 | 0 | 0 | -2 | 0 | 0 | 0 | 0 | 6 | 0 | 2 |
| $\Gamma_{\mathrm{C}-\mathrm{C}}$ | 6 | 0 | 0 | 0 | 0 | 2 | 0 | 0 | 0 | 6 | 2 | 0 |
| $\Gamma_{\mathrm{C}-\mathrm{H}}$ | 6 | 0 | 0 | 0 | 2 | 0 | 0 | 0 | 0 | 6 | 0 | 2 |

$$
\begin{aligned}
\Gamma_{3 N}(\mathrm{C} 6) & =A_{1 \mathrm{~g}}+A_{2 \mathrm{~g}}+B_{2 \mathrm{~g}}+E_{1 \mathrm{~g}}+2 E_{2 \mathrm{~g}}+A_{2 \mathrm{u}}+B_{1 \mathrm{u}} \\
& +B_{2 \mathrm{u}}+2 E_{1 \mathrm{u}}+E_{2 \mathrm{u}} .
\end{aligned}
$$

Fig. 7.3.16.
Vibrational modes and their observed frequencies (in $\mathrm{cm}^{-1}$ ) of benzene.

Now,
$\Gamma_{\mathrm{C} 6}$ (vibration of the carbon ring)

$$
\begin{aligned}
= & \Gamma_{3 N}(\mathrm{C} 6)-\Gamma(\text { translation })-\Gamma \text { (rotation) } \\
= & A_{1 \mathrm{~g}}+A_{2 \mathrm{~g}}+B_{2 \mathrm{~g}}+E_{1 \mathrm{~g}}+2 E_{2 \mathrm{~g}}+A_{2 \mathrm{u}}+B_{1 \mathrm{u}}+B_{2 \mathrm{u}} \\
& +2 E_{1 \mathrm{u}}+E_{2 \mathrm{u}}-\left(A_{2 \mathrm{u}}+E_{1 \mathrm{u}}\right)-\left(A_{2 \mathrm{~g}}+E_{1 \mathrm{~g}}\right) \\
= & A_{1 \mathrm{~g}}+B_{2 \mathrm{~g}}+2 E_{2 \mathrm{~g}}+B_{1 \mathrm{u}}+B_{2 \mathrm{u}}+E_{1 \mathrm{u}}+E_{2 \mathrm{u}}
\end{aligned}
$$

Also,
$\Gamma_{\mathrm{C}-\mathrm{C}}=A_{1 \mathrm{~g}}+E_{2 \mathrm{~g}}+B_{2 \mathrm{u}}+E_{1 \mathrm{u}}, \quad$ which are the $\mathrm{C}-\mathrm{C}$ stretching modes;
$\Gamma_{\mathrm{C}-\mathrm{H}}=A_{1 \mathrm{~g}}+E_{2 \mathrm{~g}}+B_{1 \mathrm{u}}+E_{1 \mathrm{u}}, \quad$ which are the $\mathrm{C}-\mathrm{H}$ stretching modes.

The vibrations that involve the distortion of the carbon ring are therefore $\Gamma_{\mathrm{C} 6}-\Gamma_{\mathrm{C}-\mathrm{C}}=B_{2 \mathrm{~g}}+E_{2 \mathrm{~g}}+B_{1 \mathrm{u}}+E_{2 \mathrm{u}}$.

Another way to analyse $\Gamma_{\text {vib }}\left(\mathrm{C}_{6} \mathrm{H}_{6}\right)$ is to separate the in-plane vibration representation $\Gamma_{\text {vib }}(x, y)$ from the out-of-plane vibration representation $\Gamma_{\text {vib }}(z)$. To do this, we need to first derive the representation based on the $x$ and $y$ coordinates of all 12 atoms, $\Gamma_{2 N}(x, y)$ :

| $D_{6 \mathrm{~h}}$ | $\boldsymbol{E}$ | $2 \boldsymbol{C}_{6}$ | $2 \boldsymbol{C}_{3}$ | $\boldsymbol{C}_{2}$ | $3 \boldsymbol{C}_{2}^{\prime}$ | $3 \boldsymbol{C}_{2}^{\prime \prime}$ | $\boldsymbol{i}$ | $2 \boldsymbol{S}_{3}$ | $2 \boldsymbol{S}_{6}$ | $\boldsymbol{\sigma}_{\mathrm{h}}$ | $3 \boldsymbol{\sigma}_{\mathrm{d}}$ | $3 \boldsymbol{\sigma}_{\mathrm{v}}$ |
| :--- | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| $\Gamma_{2 N}(x, y)$ | 24 | 0 | 0 | 0 | 0 | 0 | 0 | 0 | 0 | 24 | 0 | 0 |
| $\Gamma(x, y)=E_{\mathrm{lu}}$ | 2 | 1 | -1 | -2 | 0 | 0 | -2 | -1 | 1 | 2 | 0 | 0 |
| $R_{z}=A_{2 \mathrm{~g}}$ | 1 | 1 | 1 | 1 | -1 | -1 | 1 | 1 | 1 | 1 | -1 | -1 |

Now, the representation of the in-plane vibrations of benzene is simply $\Gamma_{2 N}(x, y)-E_{1 \mathrm{u}}-A_{2 \mathrm{~g}}$, which is

$$
\Gamma_{\mathrm{vib}}(x, y)=2 A_{1 \mathrm{~g}}+A_{2 \mathrm{~g}}+4 E_{2 \mathrm{~g}}+2 B_{1 \mathrm{u}}+2 B_{2 \mathrm{u}}+3 E_{1 \mathrm{u}}
$$

The dimension of $\Gamma_{\mathrm{vib}}(x, y)$ is 24 (total number of degrees of freedom for motion in the $x y$-plane) - 2 (translation of the molecule in the $x$ and $y$ directions) - 1 (rotation of the molecule about the $z$ axis, $R_{z}$ ) $=21$. Furthermore, the representation of the out-of-plane vibrations of benzene can be easily obtained:

$$
\Gamma_{\mathrm{vib}}(z)=\Gamma_{\mathrm{vib}}\left(\mathrm{C}_{6} \mathrm{H}_{6}\right)-\Gamma_{\mathrm{vib}}(x, y)=2 B_{2 \mathrm{~g}}+E_{1 \mathrm{~g}}+A_{2 \mathrm{u}}+2 E_{2 \mathrm{u}}
$$

The infrared and Raman spectra of benzene are shown in Fig. 7.3.17. It is seen that the Raman lines at 991 and $3062 \mathrm{~cm}^{-1}$ represent $A_{1 \mathrm{~g}}$ vibrations, with $\rho=I_{\perp} / I_{\|} \ll 3 / 4$ while all remaining lines have $\rho=3 / 4$. Note that there are also weak bands arising from $2 v_{i}$ (first harmonic or overtone), $v_{i}-v_{j}$ (difference band), or $v_{i}+v_{j}$ (combination band) frequencies. These are not to be discussed here.

## Symmetry in Chemistry

Fig. 7.3.17.
Infrared (upper) and Raman (lower) spectra of benzene.

## (2) Rhodizonate dianion

Benzene and the rhodizonate dianion $\left(\mathrm{C}_{6} \mathrm{O}_{6}{ }^{2-}\right.$, structure shown above; also see Section 20.4.4) are isostructural species. Hence all the symmetry arguments and results given in the previous section for benzene are applicable here. The results for $\mathrm{C}_{6} \mathrm{O}_{6}{ }^{2-}$ are summarized in Table 7.3.5.

## (3) Dibenzene metal complexes

Dibenzene chromium, $\left[\mathrm{Cr}\left(\mathrm{C}_{6} \mathrm{H}_{6}\right)_{2}\right]$, has an eclipsed sandwich structure with $D_{6 \mathrm{~h}}$ symmetry. It has $3 \times 25-6=69$ normal vibrations:

$$
\begin{aligned}
\Gamma_{\mathrm{vib}}\left[\mathrm{Cr}\left(\mathrm{C}_{6} \mathrm{H}_{6}\right)_{2}\right]= & 4 A_{1 \mathrm{~g}}(\mathrm{R})+A_{2 \mathrm{~g}}+2 B_{1 \mathrm{~g}}+4 B_{2 \mathrm{~g}}+5 E_{1 \mathrm{~g}}(\mathrm{R})+6 E_{2 \mathrm{~g}}(\mathrm{R}) \\
& +2 A_{1 \mathrm{u}}+4 A_{2 \mathrm{u}}(\mathrm{IR})+4 B_{1 \mathrm{u}}+2 B_{2 \mathrm{u}}+6 E_{1 \mathrm{u}}(\mathrm{IR})+6 E_{2 \mathrm{u}}
\end{aligned}
$$

So it is anticipated that there are 15 Raman and 10 infrared spectral lines for complexes of this type. Listed in Table 7.3.6 are the 10 infrared frequencies for some group VIA dibenzene complexes.

In Table 7.3.6, the term "ring slant" describes a vibration that causes the rings to be inclined (non-parallel) to each other, $v$ ( M -ring) is a vibration that changes the distance between the metal and the rings, while $\delta$ (ring-M-ring) is a twisting

Table 7.3.5. The normal modes of the rhodizonate dianion and observed frequencies

## Bonding in Coordination Compounds

Coordination compounds are often referred to as metal complexes. They consist of one or more coordination centers (metal atom or ion), each of which is surrounded by a number of anions (monatomic or polyatomic) or neutral molecules called ligands. The set of ligands L constitutes the coordination sphere around a metal center M. The term coordination geometry is used to describe the spatial arrangement of the ligands, and the number of ligand atoms directly bonded to M is called its coordination number. If all ligands are of the same type, the complex is homoleptic; otherwise it is heteroleptic. A metal complex may be cationic, anionic, or neutral, depending on the sum of the charges on the metal centers and the ligands. It may take the form of a discrete mononuclear, dinuclear, or polynuclear molecule, or exist as a coordination polymer of the chain, layer, or network type. Dinuclear and polynuclear complexes stabilized by bonding interactions between metal centers (i.e., metal-metal bonds) are covered in Chapter 19, and some examples of coordination polymers are described in Chapter 20.

In this chapter, we discuss mostly the bonding in mononuclear homoleptic complexes $\mathrm{ML}_{n}$ using two simple models. The first, called crystal field theory (CFT), assumes that the bonding is ionic; i.e., it treats the interaction between the metal ion (or atom) and ligands to be purely electrostatic. In contrast, the second model, namely the molecular orbital theory, assumes the bonding to be covalent. A comparison between these models will be made.

### 8.1 Crystal field theory: d-orbital splitting in octahedral and tetrahedral complexes

By considering the electrostatic interaction between the central atom and the surrounding ligands, the CFT shows how the electronic state of a metal atom is affected by the presence of the ligands. Let us first consider the highly symmetrical case of a metal ion $\mathrm{M}^{m+}$ surrounded by six octahedrally arranged ligands, as shown in Fig. 8.1.1. If the metal ion has one lone d electron, this electron is equally likely to occupy any of the five degenerate d orbitals, in the absence of the ligands. However, in the presence of the ligands, the $d$ orbitals are no longer degenerate, or equivalent. Specifically, as Fig. 8.1.2 shows, the $\mathrm{d}_{z^{2}}$ and $\mathrm{d}_{x^{2}-y^{2}}$ orbitals have lobes pointing directly at the ligands, while the lobes of the $\mathrm{d}_{x y}, \mathrm{~d}_{y z}$, and $\mathrm{d}_{x z}$ are pointing between the ligands. As the ligands are negatively

Fig. 8.1.1.
The octahedral arrangement of six ligands surrounding a central metal ion.

## Fig. 8.1.2.

The electron density functions of the five d orbitals relative to the ligand positions in an octahedral complex. The gray and white regions in each orbital bear positive and negative signs, respectively.

Fig. 8.1.3.
Arrangement of the four ligands in a tetrahedral complex.

Fig. 8.1.4.
Orientations of the $\mathrm{d}_{x^{2}-y^{2}}$ and $\mathrm{d}_{x y}$ orbitals with respect to the four ligands in a tetrahedral complex, looking down the $z$ axis. Both d orbitals lie in the $x y$ plane. Filled and open circles represent ligands that lie above and below the $x y$ plane, respectively. It is obvious that the $\mathrm{d}_{x^{2}-y^{2}}$ orbital is more favored for electron occupation in a tetrahedral complex.

charged (or at least have the negative end of the dipole moment pointing at the metal), the $\mathrm{d}_{x y}, \mathrm{~d}_{y z}$, and $\mathrm{d}_{x z}$ orbitals should be more favored for electron occupation than the other two. Moreover, the $\mathrm{d}_{x y}, \mathrm{~d}_{y z}$, and $\mathrm{d}_{x z}$ orbitals are equally likely for electron occupation and hence are degenerate orbitals. On the other hand, the $\mathrm{d}_{z^{2}}$ and $\mathrm{d}_{x^{2}-y^{2}}$ are less likely to accommodate the single d electron. Furthermore, as pointed out in Chapter 6, it is easy to show that the $\mathrm{d}_{z^{2}}$ is simply the sum of $\mathrm{d}_{z^{2}-x^{2}}$ and $\mathrm{d}_{z^{2}-y^{2}}$ functions (aside from a constant), each of which is clearly equivalent to the $\mathrm{d}_{x^{2}-y^{2}}$ orbital, i.e.,

$$
\begin{equation*}
\mathrm{d}_{z^{2}-x^{2}}+\mathrm{d}_{z^{2}-y^{2}} \propto z^{2}-x^{2}+z^{2}-y^{2}=3 z^{2}-r^{2}=r^{2}\left(3 \cos ^{2} \theta-1\right) \propto \mathrm{d}_{z^{2}} \tag{8.1.1}
\end{equation*}
$$

Similarly, when a metal ion is surrounded by four tetrahedrally arranged ligands, as shown in Figs. 8.1.3 and 8.1.4, it is not difficult to see that in this case the electrons tend to occupy the $\mathrm{d}_{z^{2}}$ and $\mathrm{d}_{x^{2}-y^{2}}$ orbitals in preference to the other three orbitals, $\mathrm{d}_{x y}, \mathrm{~d}_{y z}$, and $\mathrm{d}_{x z}$. The splitting patterns for a set of d orbitals in octahedral and tetrahedral complexes are summarized in Fig. 8.1.5.
In Fig. 8.1.5(a), it is seen that, in an octahedral complex, the pair of $\mathrm{d}_{z^{2}}$ and $\mathrm{d}_{x^{2}-y^{2}}$ orbitals are grouped together and called the $e_{\mathrm{g}}$ orbitals, while the $\mathrm{d}_{x y}, \mathrm{~d}_{y z}$, and $\mathrm{d}_{x z}$ orbitals are called the $t_{2 g}$ orbitals. The energy difference between these two sets of orbitals is denoted as $\Delta_{0}$, where the subscript o is the abbreviation for octahedral. In order to retain the "center of gravity" of the d orbitals before and after splitting, i.e., the gain in energy by one set of orbitals $\left(t_{2 g}\right.$ in this case) is offset by the loss in stability by the other set ( $e_{\mathrm{g}}$ here), the $t_{2 \mathrm{~g}}$ orbitals lie $(2 / 5) \Delta_{\mathrm{o}}$ below the set of unsplit d orbitals and the $e_{\mathrm{g}}$ orbitals lie (3/5) $\Delta_{\mathrm{o}}$ above it. Finally, it is noted that $t_{2 \mathrm{~g}}$ and $e_{\mathrm{g}}$ are simply two of the irreducible representations in the $O_{\mathrm{h}}$ group.

In Fig. 8.1.5(b), for tetrahedral complexes, the $\mathrm{d}_{z^{2}}$ and $\mathrm{d}_{x^{2}-y^{2}}$ pair is now called the $e$ orbitals, and the $\mathrm{d}_{x y}, \mathrm{~d}_{y z}$, and $\mathrm{d}_{x z}$ trio is called the $t_{2}$ orbitals. Once again, $e$ and $t_{2}$ are two of the irreducible representations of the $T_{\mathrm{d}}$ point group.
$\Delta_{\mathrm{t}}=\frac{4}{9} \Delta_{\mathrm{o}}$

The energy difference between these two sets of orbitals is $\Delta_{t}(t$ for tetrahedral). Also, due to the "center of gravity" condition, the $t_{2}$ orbitals lie (2/5) $\Delta_{\mathrm{t}}$ above the unperturbed d orbitals and $e$ orbitals lie (3/5) $\Delta_{\mathrm{t}}$ below. When the metal ion, the ligands, and the metal-ligand distance are the same for both the octahedral and tetrahedral systems, it can be shown that

$$
\Delta_{\mathrm{t}}=\frac{4}{9} \Delta_{\mathrm{o}} .
$$

However, since CFT is a rather crude model, such an exact relationship is seldom of use. Instead, it is instructive and convenient to realize that, with all conditions being equal, the crystal field splitting for a tetrahedral complex is about half of that for an octahedral complex.

Finally, it is of interest to note that, in the purturbative treatment of CFT, $\Delta_{\mathrm{o}}$ has a quantum mechanical origin:

$$
\begin{equation*}
\Delta_{\mathrm{o}}=10 D q \tag{8.1.2}
\end{equation*}
$$

where

$$
\begin{align*}
D & =\frac{35 Z e^{2}}{4 a^{5}}  \tag{8.1.3}\\
q & =\frac{2}{105} \int_{0}^{\infty} R_{n \mathrm{~d}} r^{4} R_{n \mathrm{~d}} r^{2} \mathrm{~d} r \tag{8.1.4}
\end{align*}
$$

In the above expressions for $D$ and $q, \mathrm{Z}$ is the charge on each ligand, $a$ is the metal-ligand distance, $R_{n \mathrm{~d}}$ is the radial function for the $n$ d orbital on the metal. The crystal field splittings, $\Delta_{\mathrm{o}}$ and $\Delta_{\mathrm{t}}$ (or in terms of $D q$ ), are seldom determined by direct calculations. Rather, they are usually deduced from spectroscopic measurements.

### 8.2 Spectrochemical series, high spin and low spin complexes

We now briefly examine the factors that influence the magnitude of the crystal field splitting $\Delta_{\mathrm{o}}$ ( or 10 Dq ). In general, $\Delta_{\mathrm{o}}$ increases for similar transition metals as we go down the Periodic Table, i.e., first row $<$ second row $<$ third row.

Fig. 8.1.5.
The d orbitals splitting patterns in (a) octahedral and (b) tetrahedral complexes.

## Symmetry in Chemistry

Also, $\Delta_{\mathrm{o}}$ increases with the charge on the metal ion, i.e., $\mathrm{M}^{2+}<\mathrm{M}^{3+}$, etc. As far as the ligands are concerned, $\Delta_{\mathrm{o}}$ increases according to the spectrochemical series

$$
\begin{aligned}
& \mathrm{I}^{-}<\mathrm{Br}^{-}<\mathrm{S}^{2-}<\mathrm{SCN}^{-}<\mathrm{Cl}^{-}<\mathrm{NO}_{3}^{-}<\mathrm{F}^{-}<\mathrm{OH}^{-}<\mathrm{C}_{2} \mathrm{O}_{4}^{2-}<\mathrm{H}_{2} \mathrm{O}< \\
& \mathrm{NCS}^{-}<\mathrm{CH}_{3} \mathrm{CN}<\mathrm{NH}_{3}<\operatorname{en}\left(\mathrm{H}_{2} \mathrm{NCH}_{2} \mathrm{CH}_{2} \mathrm{NH}_{2}\right)<\operatorname{bipy}\left(2,2^{\prime}\right. \text {-bipyridine } \\
& \text { or 2, 2'dipyridine })<\operatorname{phen}(o \text {-phenanthroline })<\mathrm{NO}_{2}^{2-}<\mathrm{CN}^{-}<\mathrm{CO} .
\end{aligned}
$$

It is not easy to rationalize this series with the point charge model. For instance, on the basis of ionic bonding, it is difficult to see that a neutral ligand, CO, yields the largest (or at least one of the largest) $\Delta_{\mathrm{o}}$. However, this point may be readily understood once we consider covalent bonding between the metal ion and the ligands.

With the aid of the aufbau principle and Hund's rule, we are now in position to determine the ground electronic configuration of a given octahedral complex. As shown in Fig. 8.2.1 there is only one electronic assignment for $\mathrm{d}^{1}-\mathrm{d}^{3}$ and $d^{8}-d^{10}$ complexes, which have the ground configurations

$$
\mathrm{d}^{1}: t_{2 \mathrm{~g}}^{1} ; \mathrm{d}^{2}: t_{2 \mathrm{~g}}^{2} ; \mathrm{d}^{3}: t_{2 \mathrm{~g}}^{3} ; \mathrm{d}^{8}: t_{2 \mathrm{~g}}^{6} e_{\mathrm{g}}^{2} ; \mathrm{d}^{9}: t_{2 \mathrm{~g}}^{6} e_{\mathrm{g}}^{3} ; \mathrm{d}^{10}: t_{2 \mathrm{~g}}^{6} e_{\mathrm{g}}^{4}
$$

However, for $\mathrm{d}^{4}$ to $\mathrm{d}^{7}$ complexes, there are high-spin and low-spin configurations. In the high-spin complexes, we have $\Delta_{\mathrm{o}}$ smaller than the pairing energy; i.e., electrons avoid pairing by occupying both the $t_{2 \mathrm{~g}}$ and $e_{\mathrm{g}}$ orbitals. For lowspin complexes, $\Delta_{\mathrm{o}}$ is greater than the pairing energy; i.e., electrons prefer pairing in the $t_{2 \mathrm{~g}}$ orbitals to occupying the less stable $e_{\mathrm{g}}$ orbitals.

For a first transition series octahedral complex, whether it has a high-spin or low-spin configuration depends largely on the nature of the ligand or the charge on the metal ion. For second- or third-row complexes, low-spin configuration is favored, since now $\Delta_{0}$ is larger and pairing energy becomes smaller. In the larger 4d and 5d orbitals, the electronic repulsion, which contributes to pairing energy, is less than that for the smaller 3d orbital.

For tetrahedral complexes, with their crystal field splitting $\Delta_{t}$ being only about half of $\Delta_{0}$, the high-spin configuration is heavily favored. Indeed, lowspin tetrahedral complexes are rarely observed.

Fig. 8.2.1.
Electronic configurations of octahedral complexes for $d^{1}-d^{10}$ metals ions. The high-spin (HS) complexes have $\Delta_{0}$ smaller than pairing energy, while the low-spin (LS) complexes have $\Delta_{\mathrm{O}}$ larger than pairing energy.

Fig. 8.3.1.
Two examples of tetragonal distortion for an octahedral complex: (a) axial elongation and (b) axial compression. Note that the center of symmetry of the octahedral system is preserved after the distortion.

### 8.3 Jahn-Teller distortion and other crystal fields

Among the 14 configurations for octahedral complexes shown in Fig. 8.3.1, only five actually exist in the strictest sense. The non-existence of the other nine configurations is due to Jahn-Teller distortion. According to the theory put forth by physicists H. A. Jahn and E. Teller in 1937, any non-linear molecule with a degenerate electronic state, i.e., with orbital degeneracy, will undergo distortion to remove the degeneracy. Furthermore, if the "original" system is centrosymmetric, the center of symmetry will be retained after the distortion. When the 14 configurations shown in Fig. 8.2.1 are examined, it can be readily seen that only those of $d^{3}, d^{5}$ high spin, $d^{6}$ low spin, $d^{8}$, and $d^{10}$ have nondegenerate ground state and hence are not subjected to Jahn-Teller distortion. On the other hand, the remaining nine systems will distort from its octahedral geometry in order to remove the orbital degeneracy.

In octahedral complexes, the Jahn-Teller distortion is small when $t_{2 g}$ orbitals are involved; this distortion becomes larger when there is uneven electronic occupancy in the $e_{\mathrm{g}}$ orbitals. Let us take a d ${ }^{9}$ octahedral complex as an example: for configuration $t_{2 \mathrm{~g}}^{6} e_{\mathrm{g}}^{3}$, the orbital degeneracy occurs in the $e_{\mathrm{g}}$ orbitals. In order to preserve the center of symmetry, the complex will undergo a tetragonal distortion: the two ligands lying along the $z$ axis will be either compressed or pulled away from the metal, while the four ligands on the $x y$ plane retain their original positions, as shown in Fig. 8.3.1. The crystal field splitting pattern of a tetragonal distortion on an octahedral complex, deformed by either stretching or compressing two ligands along the $z$ axis, is summarized in Fig. 8.3.2. From this figure, it is clear that either configuration $e_{\mathrm{g}}^{4} b_{2 \mathrm{~g}}^{2} a_{1 \mathrm{~g}}^{2} b_{1 \mathrm{~g}}^{1}$ (for an axially elongated complex) or $b_{2 \mathrm{~g}}^{2} e_{\mathrm{g}}^{4} b_{1 \mathrm{~g}}^{2} a_{1 \mathrm{~g}}^{1}$ (for an axially compressed complex) will be energetically more favorable than the $t_{2 \mathrm{~g}}^{6} e_{\mathrm{g}}^{3}$ configuration of an octahedral complex. It is this energy stabilization that leads to the Jahn-Teller distortion. Well-known examples of axial elongation are found in $\mathrm{Cu}(\mathrm{II})$ halides. In these systems, each $\mathrm{Cu}^{2+}$ ion is surrounded by six halide ions, four of them lying closer to the cation and the remaining two farther away. The structural data for these halides are summarized in Fig. 8.3.3.

Referring to the orbital splitting pattern for an axially elongated tetragonal complex shown in Fig. 8.3.2, if we continue the elongation, the splittings

Fig. 8.3.2.

Fig. 8.3.3.
Examples of Jahn-Teller distortion: $\mathrm{Cu}(\mathrm{II})$ halides with two long bonds and four short ones.

Fig. 8.3.4.
Correlation between the orbital splitting patterns of octahedral $\mathrm{ML}_{6}$ and square-planar $\mathrm{ML}_{4}$ complexes.

denoted by $\delta_{1}$ and $\delta_{2}$ will become larger and larger. Eventually this will lead to the removal of two ligands, forming a square-planar complex in the process. The orbital splitting pattern of such a complex is shown in Fig. 8.3.4.

$\begin{array}{lll} & \mathrm{Cu}-\mathrm{X} & \mathrm{Cu}-\mathrm{X}^{\prime} \\ \mathrm{X}=\mathrm{C} 1 & 230 \mathrm{pm} & 295 \mathrm{pm} \\ \mathrm{X}=\mathrm{Br} & 240 & 318 \\ \mathrm{X}=\mathrm{F} & 193 & 227\end{array}$

Most square-planar complexes have the $\mathrm{d}^{8}$ configuration, and there are also some with the $\mathrm{d}^{9}$ configuration. Practically all $\mathrm{d}^{8}$ square-planar complexes are diamagnetic, with a vacant $b_{1 \mathrm{~g}}$ level (cf. Fig. 8.3.4). Also, most d ${ }^{8}$ square-planar complexes with first-row transition metals have strong field ligands. Since the energy gap between the $b_{1 \mathrm{~g}}$ and $b_{2 \mathrm{~g}}$ levels is (exactly) $\Delta_{\mathrm{o}}$, strong field ligands would produce a large $\Delta_{o}$, favoring a low-spin, i.e., diamagnetic, configuration. For example, $\mathrm{Ni}^{2+}$ ion forms square-planar complexes with strong field ligands (e.g., $\left[\mathrm{Ni}(\mathrm{CN})_{4}\right]^{2-}$ ), and it forms tetrahedral, paramagnetic complexes with weak field ligands (e.g., $\left[\mathrm{NiCl}_{4}\right]^{2-}$ ). For second- and third-row transition metals, the $\Delta_{\mathrm{o}}$ splittings are much larger and square-planar complexes are formed even with relatively weak field ligands (e.g., $\left[\mathrm{PtCl}_{4}\right]^{2-}$ ).

### 8.4 Octahedral crystal field splitting of spectroscopic terms

As shown in previous sections, under an octahedral crystal field, the five d orbitals are split into two sets of orbitals, $t_{2 \mathrm{~g}}$ and $e_{\mathrm{g}}$. In terms of spectroscopic states, we can readily see that the ${ }^{2} D$ term arising from configuration $\mathrm{d}^{1}$ will split into ${ }^{2} T_{2 \mathrm{~g}}$ and ${ }^{2} E_{\mathrm{g}}$ states, arising from configurations $t_{2 \mathrm{~g}}^{1}$ and $e_{\mathrm{g}}^{1}$, respectively. But what about the spectroscopic terms such as $F$ and $G$ arising from other $\mathrm{d}^{n}$ configurations? In this section, we will see how these terms split in an octahedral crystal field.

Octahedral complex $\mathrm{ML}_{6}$ has $O_{\mathrm{h}}$ symmetry. However, for simplicity, we may work with the $O$ point group, which has only rotations as its symmetry operations and five irreducible representations, $A_{1}, A_{2}, \ldots, T_{2}$. The character table for this group is shown in Table 8.4.1. It is seen that the main difference between the $O_{\mathrm{h}}$ and $O$ groups is that the former has inversion center $i$, while the latter does not. As a result, the $O_{\mathrm{h}}$ group has ten symmetry species: $A_{1 \mathrm{~g}}$, $A_{1 \mathrm{u}}, A_{2 \mathrm{~g}}, A_{2 \mathrm{u}}, \ldots, T_{2 \mathrm{~g}}, T_{2 \mathrm{u}}$.

To see how an octahedral crystal field reduces the ( $2 L+1$ )-fold degeneracy of a spectroscopic term, we first need to determine the character of a rotation operating on an atomic state defined by the orbital angular momentum quantum number $L$. It can be shown that the character $\chi$ for a rotation of angle $\alpha$ about the $z$ axis is simply

$$
\begin{equation*}
\chi(\alpha)=\left[\sin \left(L+\frac{1}{2}\right) \alpha\right] / \sin \frac{\alpha}{2} \tag{8.4.1}
\end{equation*}
$$

In particular, for the identity operation, i.e., when $\alpha=0$, we have

$$
\begin{equation*}
\chi(\alpha=0)=2 L+1 . \tag{8.4.2}
\end{equation*}
$$

With these formulas, it is now straightforward to obtain the $\chi$ values for all the rotations in the $O$ group and for any $L$ value. Furthermore, we can then reduce the representations with these $\chi$ values as characters into the irreducible representations of the $O$ group. All these results are summarized in Table 8.4.2.

To illustrate how the results are obtained, let us take the $F$ term, with $L=3$, as an example. With eq. (8.4.2), we get

$$
\begin{equation*}
\chi(\boldsymbol{E})=7 . \tag{8.4.3}
\end{equation*}
$$

Table 8.4.2. Representations of atomic terms in the $O$ point group and the states these terms generate

| Term | $L$ | $\boldsymbol{E}$ | $6 \boldsymbol{C}_{4}$ | $3 \boldsymbol{C}_{2}\left(=\boldsymbol{C}_{4}^{2}\right)$ | $8 \boldsymbol{C}_{3}$ | $6 \boldsymbol{C}_{2}$ | States generated |
| :--- | :---: | :---: | :---: | :---: | ---: | :---: | :---: |
| $S$ | 0 | 1 | 1 | 1 | 1 | 1 | $A_{1}$ |
| $P$ | 1 | 3 | 1 | -1 | 0 | -1 | $T_{1}$ |
| $D$ | 2 | 5 | -1 | 1 | -1 | 1 | $E+T_{2}$ |
| $F$ | 3 | 7 | -1 | -1 | 1 | -1 | $A_{2}+T_{1}+T_{2}$ |
| $G$ | 4 | 9 | 1 | 1 | 0 | 1 | $A_{1}+E+T_{1}+T_{2}$ |
| $H$ | 5 | 11 | 1 | -1 | -1 | -1 | $E+2 T_{1}+T_{2}$ |
| $I$ | 6 | 13 | -1 | 1 | 1 | 1 | $A_{1}+A_{2}+E+T_{1}+2 T_{2}$ |

With eq. (8.4.1), we have

$$
\begin{align*}
& \chi\left(\boldsymbol{C}_{4}\right)=\left[\sin \left(3+\frac{1}{2}\right)\left(90^{\circ}\right)\right] / \sin 45^{\circ}=-1 .  \tag{8.4.4}\\
& \chi\left(\boldsymbol{C}_{2}\right)=\left[\sin \left(3+\frac{1}{2}\right)\left(180^{\circ}\right)\right] / \sin 90^{\circ}=-1 .  \tag{8.4.5}\\
& \chi\left(\boldsymbol{C}_{3}\right)=\left[\sin \left(3+\frac{1}{2}\right)\left(120^{\circ}\right)\right] / \sin 60^{\circ}=1 . \tag{8.4.6}
\end{align*}
$$

Combining the results of eqs. (8.4.3) to (8.4.6), we obtain the following representation for the $F$ term:

$$
\begin{array}{c|ccccc}
O & \boldsymbol{E} & 6 \boldsymbol{C}_{4} & 3 \boldsymbol{C}_{2}\left(=\boldsymbol{C}_{4}^{2}\right) & 8 \boldsymbol{C}_{3} & 6 \boldsymbol{C}_{2} \\
\hline F, L=3 & 7 & -1 & -1 & 1 & -1
\end{array}
$$

This representation can be easily reduced to the irreducible representations $A_{2}+T_{1}+T_{2}$. Note that if this $F$ term arises from a configuration with electrons occupying d orbitals, which are even functions, the electronic states split from this term in an octahedral crystal field are then $A_{2 \mathrm{~g}}, T_{1 \mathrm{~g}}$, and $T_{2 \mathrm{~g}}$. (On the other hand, if the $F$ term comes from a configuration with f electron(s) such as $\mathrm{f}^{1}$, the electronic states in an octahedral crystal field will then be $A_{2 \mathrm{u}}, T_{1 \mathrm{u}}$, and $T_{2 \mathrm{u}}$. This is because f orbitals are odd functions.) All the results given in Table 8.4.2 can be obtained in a similar fashion.

### 8.5 Energy level diagrams for octahedral complexes

After determining what levels are present for an octahedral complex with a given electronic configuration, we are now ready to discuss the energy level diagrams for these spectroscopic terms.

### 8.5.1 Orgel diagrams

Let us first consider an octahedral complex $\mathrm{ML}_{6}$ with one single d electron. Configuration d ${ }^{1}$ has only one term, ${ }^{2} D$, which splits into ${ }^{2} E_{\mathrm{g}}$ and ${ }^{2} T_{2 \mathrm{~g}}$ levels in a crystal field with $O_{\mathrm{h}}$ symmetry. Levels ${ }^{2} E_{\mathrm{g}}$ and ${ }^{2} T_{2 \mathrm{~g}}$ arise from configurations
$e_{\mathrm{g}}^{1}$ and $t_{2 \mathrm{~g}}^{1}$, respectively. Also, from Fig. 8.1.5(a), we see that the energy of the $e_{\mathrm{g}}$ orbitals are higher than that of the $d$ orbitals by (3/5) $\Delta_{\mathrm{o}}$ (or $6 D q$ ), and the energy of the $t_{2 \mathrm{~g}}$ orbitals is lower than that of the d orbitals by $(2 / 5) \Delta_{\mathrm{o}}$ (or $4 D q$ ). Combining these results we can readily arrive at the energy level diagram shown in Fig. 8.5.1. In this diagram, we plot the energies of the spectroscopic levels against $D q$, one tenth of the octahedral crystal field splitting $\Delta_{\mathrm{o}}$. Furthermore, the energy difference between the ${ }^{2} E_{\mathrm{g}}$ and ${ }^{2} T_{2 \mathrm{~g}}$ level is always $10 D q$. Such a diagram is called an Orgel diagram, named after chemist L. E. Orgel, who popularized these diagrams in the 1950's.
For the $\mathrm{d}^{6}$ configuration, the ground term is ${ }^{5} D$, which splits into ${ }^{5} E_{\mathrm{g}}$ and ${ }^{5} T_{2 \mathrm{~g}}$ in an $O_{\mathrm{h}}$ field. For a high-spin d ${ }^{6}$ complex, the only quintet term arising from configuration $t_{2 \mathrm{~g}}^{4} e_{\mathrm{g}}^{2}$ is ${ }^{5} T_{2 \mathrm{~g}}$ and that arising from $t_{2 \mathrm{~g}}^{3} e_{\mathrm{g}}^{3}$ is ${ }^{5} E_{\mathrm{g}}$. These states correspond exactly to the $\mathrm{d}^{1}$ case, except now the states are spin quintets. In other words, for such a complex there is only one spin-allowed transition, ${ }^{5} T_{2 \mathrm{~g}} \rightarrow{ }^{5} E_{\mathrm{g}}$. Hence the d ${ }^{1}$ and high spin d ${ }^{6}$ octahedral complexes have the same Orgel diagram. (Note that the $\mathrm{d}^{6}$ configuration has a total of 16 terms, and ${ }^{5} D$ is the only quintet term. The remaining 15 terms are triplets and singlets and they are ignored in the current discussion.)

As mentioned in Chapter 2, both $\mathrm{d}^{9}$ and $\mathrm{d}^{1}$ configurations have only one term, ${ }^{2} D$. For a d ${ }^{9}$ octahedral complex, the ${ }^{2} D$ term once again splits into ${ }^{2} T_{2 \mathrm{~g}}$ and ${ }^{2} E_{\mathrm{g}}$ states, with the energy difference between them being 10 Dq . However, for the $\mathrm{d}^{9}$ configuration, which is equivalent to the one-hole, or one-positron, case, the energy ordering is just the opposite of that for the $\mathrm{d}^{1}$ configuration. In other words, for the $\mathrm{d}^{9}$ octahedral complex, we have the ${ }^{2} E_{\mathrm{g}}$ state lower than the ${ }^{2} T_{2 \mathrm{~g}}$ state, and the energy difference between the states is again 10 Dq .

Similarly, $\mathrm{d}^{4}$ is the hole-counterpart of $\mathrm{d}^{6}$, both of which have the ground term ${ }^{5} D$. As have been mentioned many times already, this term splits into ${ }^{5} T_{2 \mathrm{~g}}$ and ${ }^{5} E_{\mathrm{g}}$ states in an $O_{\mathrm{h}}$ crystal field. For the d ${ }^{4}$ case, these quintet states arise from the high-spin configurations $t_{2 \mathrm{~g}}^{2} e_{\mathrm{g}}^{2}$ and $t_{2 \mathrm{~g}}^{3} e_{\mathrm{g}}^{1}$, respectively. As may be surmised by the configurations from which they arise, the ${ }^{5} E_{\mathrm{g}}$ state is now lower than the ${ }^{5} T_{2 \mathrm{~g}}$ state for a $\mathrm{d}^{4}$ complex, which is just the opposite for a high-spin $\mathrm{d}^{6}$ octahedral complex. The energy difference between the states is once again $10 \mathrm{D} q$.

The foregoing results for $\mathrm{d}^{1}$, high-spin $\mathrm{d}^{4}$ and $\mathrm{d}^{6}$, as well as $\mathrm{d}^{9}$ octahedral complexes can be summarized by the fairly simple Orgel diagram shown in Fig. 8.5.2.

Additionally, we note that octahedral and tetrahedral complexes have opposite energy orderings (Fig. 8.1.5). Hence $d^{1}$ octahedral and $d^{9}$ tetrahedral have the same Orgel diagram; the same is true for $d^{6}$ octahedral and $d^{4}$ tetrahedral complexes. In other words, the Orgel diagram in Fig. 8.5.2 is also applicable to $d^{1}, d^{4}, d^{6}$, and $d^{9}$ tetrahedral complexes. Since tetrahedral complexes are not centrosymmetric, their states do not have $g$ or $u$ designations. States in Fig. 8.5.2 do not carry subscripts; they should be put back on for octahedral complexes.

Now we turn our attention to the $\mathrm{d}^{2}$ octahedral complexes. For this configuration, there are two triplet terms, ${ }^{3} F$ (ground term) and ${ }^{3} P$. In an octahedral crystal field, there are three configurations: $t_{2 \mathrm{~g}}^{2}<t_{2 \mathrm{~g}}^{1} e_{\mathrm{g}}^{1}<e_{\mathrm{g}}^{2}$, in increasing

Fig. 8.5.4.
Energy level diagram for a $\mathrm{d}^{2}$ octahedral complex, including the second-order crystal field interaction.

energy order. From Table 8.4.2, it is clear that ${ }^{3} P$ becomes ${ }^{3} T_{1 \mathrm{~g}}(P)$ in an octahedral field, with no change in energy, while the ${ }^{3} F$ term splits into ${ }^{3} T_{1 \mathrm{~g}}(F)$, ${ }^{3} T_{2 \mathrm{~g}}$, and ${ }^{3} A_{2 \mathrm{~g}}$ states. (Since there are two ${ }^{3} T_{1 \mathrm{~g}}$ states in this system, we call one ${ }^{3} T_{1 \mathrm{~g}}(P)$ and the other ${ }^{3} T_{1 \mathrm{~g}}(F)$.) Upon treating the crystal field splitting perturbationally, it is found that the ${ }^{3} T_{1 \mathrm{~g}}(F)$ state lies $6 D q$ below the energy of ${ }^{3} F$, while the ${ }^{3} T_{2 g}$ and ${ }^{3} A_{2 g}$ states are $2 D q$ and $12 D q$ above ${ }^{3} F$, respectively. (It is seen that the "center of gravity" is also preserved here.) These results are shown in Fig. 8.5.3. Note that the splittings shown in this figure are due to interactions among the components of the same term; these interactions are sometimes called first-order crystal field interactions. In addition to first-order interactions, there are also interactions among components from different terms with the same symmetry, the so-called second-order crystal field interactions. Take the energy levels in Fig. 8.5.3 as an example. Among the four states shown, only ${ }^{3} T_{1 \mathrm{~g}}(P)$ and ${ }^{3} T_{1 \mathrm{~g}}(F)$ have the same symmetry and hence they will interact with each other. In quantum mechanics, when two states of the same symmetry interact, the upper level will go still higher and the lower level further below. The results of such a second-order interaction are shown in Fig. 8.5.4. In this figure, it is seen that the (upper) ${ }^{3} T_{1 \mathrm{~g}}(P)$ level bends upward, while the (lower) ${ }^{3} T_{1 \mathrm{~g}}(F)$ bends downward.

As we have seen for the $\mathrm{d}^{1}$ and $\mathrm{d}^{6}$ systems (Fig. 8.5.2), the $\mathrm{d}^{2}$ Orgel diagram in Fig. 8.5.4 is also applicable to $\mathrm{d}^{7}$ octahedral, $\mathrm{d}^{3}$ and $\mathrm{d}^{8}$ tetrahedral complexes. Furthermore, the reverse splitting pattern applies to $d^{3}$ and $d^{8}$ octahedral, as well as to $d^{2}$ and $d^{7}$ tetrahedral complexes. These results are summarized in Fig. 8.5.5.

The two Orgel diagrams shown in Figs. 8.5.2 and 8.5.5 deal with the spin-allowed transitions for all $\mathrm{d}^{n}$ systems except $\mathrm{d}^{0}, \mathrm{~d}^{5}$, and $\mathrm{d}^{10}$. Let us confine our attention to octahedral complexes. Only one transition is expected for $\mathrm{d}^{1}\left({ }^{2} T_{2 \mathrm{~g}} \rightarrow{ }^{2} E_{\mathrm{g}}\right)$ and $\mathrm{d}^{9}\left({ }^{2} E_{\mathrm{g}} \rightarrow{ }^{2} T_{2 \mathrm{~g}}\right)$ complexes. For the $\mathrm{d}^{1}$ complex of $\left[\mathrm{Ti}\left(\mathrm{H}_{2} \mathrm{O}\right)_{6}\right]^{3+}$, this band is observed at $20,300 \mathrm{~cm}^{-1}$. This absorption shows a shoulder at $\sim 17,500 \mathrm{~cm}^{-1}$, due to the Jahn-Teller distortion of the excited state ${ }^{2} E_{\mathrm{g}}$ (arised from configuration $e_{\mathrm{g}}^{1}$ ). For a d ${ }^{2}$ complex, the ground state is ${ }^{3} T_{1 \mathrm{~g}}(F)$ and three transitions are expected: ${ }^{3} T_{1 \mathrm{~g}}(F) \rightarrow{ }^{3} T_{2 \mathrm{~g}}$, ${ }^{3} T_{1 \mathrm{~g}}(F) \rightarrow{ }^{3} T_{1 \mathrm{~g}}(P)$, and ${ }^{3} T_{1 \mathrm{~g}}(F) \rightarrow{ }^{3} A_{2 \mathrm{~g}}$. For $\left[\mathrm{V}\left(\mathrm{H}_{2} \mathrm{O}\right)_{6}\right]^{3+}$, these Transitions are observed at $17,000,25,000$, and $37,000 \mathrm{~cm}^{-1}$ (obscured somewhat by

charge transfer transitions), respectively. For a $\mathrm{d}^{3}$ system, the ground state is ${ }^{4} A_{2 \mathrm{~g}}$ and again three transitions are expected: ${ }^{4} A_{2 \mathrm{~g}} \rightarrow{ }^{4} T_{2 \mathrm{~g}},{ }^{4} A_{2 \mathrm{~g}} \rightarrow{ }^{4} T_{1 \mathrm{~g}}(F)$, ${ }^{4} A_{2 \mathrm{~g}} \rightarrow{ }^{4} T_{2 \mathrm{~g}}(P)$. For $\left[\mathrm{Cr}\left(\mathrm{H}_{2} \mathrm{O}\right)_{6}\right]^{3+}$, they are observed at $\sim 17,500,24,700$, and $37,000 \mathrm{~cm}^{-1}$, respectively.

Finally, regarding the aforementioned omissions of $\mathrm{d}^{0}, \mathrm{~d}^{5}$, and $\mathrm{d}^{10}$ systems, it is noted that $\mathrm{d}^{0}$ and $\mathrm{d}^{10}$ complexes exhibit no $\mathrm{d}-\mathrm{d}$ band, and there are no spin-allowd transitions for high-spin $\mathrm{d}^{5}$ complexes. But we shall discuss the electronic spectrum of a $\mathrm{d}^{5}$ complex, $\left[\mathrm{Mn}\left(\mathrm{H}_{2} \mathrm{O}\right)_{6}\right]^{2+}$, in the next section.

### 8.5.2 Intensities and band widths of $d$ - $d$ spectral lines

Crystal field, or d-d, transitions are defined as transitions from levels that are exclusively perturbed d orbitals to levels of the same type. In other words, the electron is originally localized at the central metal ion and remains so in the excited state. When the system has $O_{\mathrm{h}}$ symmetry, Laporte's rule says that an electric-dipole allowed transition must be between a " g " state and an " u " state, i.e., $u \leftrightarrow g$. Since all the crystal field electronic states are gerade ("g"), no electric-dipole allowed transitions are possible. In short, all d-d transitions are symmetry forbidden and hence have low intensities. The fact that the d-d transitions are observed at all is due to the interaction between the electronic motion and the molecular vibration. We will discuss this (vibronic) interaction later (Section 8.10).

In addition to the symmetry selection rule, there is also another selection rule on spin: $\Delta S=0$, i.e., only the transitions between states with the same spin are allowed. The fact that we sometimes do observe spin-forbidden d-d transitions is mainly due to spin-orbit coupling, which will be discussed later in this section.

Spin-forbidden (say, $\Delta S= \pm 1$ ) transitions, when observed, are usually about $1 \%$ as strong as the spin-allowed ones. For the octahedral complexes of the first transition series, the molar extinction coefficients $\varepsilon$ (in $\mathrm{L} \mathrm{mol}^{-1} \mathrm{~cm}^{-1}$ ) of the transitions range from $\sim 0.01$ in Mn (II) complexes (see below) to as high as $\sim 25-30$ of some non-chelate $\mathrm{Co}(\mathrm{III})$ and $\mathrm{Ni}(\mathrm{II})$ complexes. The tetrahedral

The Orgel diagram for a high-spin $\mathrm{d}^{5}$ octahedral complex.

Fig. 8.5.7.
Electronic spectrum of $\left[\mathrm{Mn}\left(\mathrm{H}_{2} \mathrm{O}\right)_{6}\right]^{2+}$.
Note that the intensities of all the transitions are very low, since they are both symmetry- and spin-forbidden.

complexes have more intense transitions (by a factor of about 50 to 200) due to their lack of center of symmetry. For examples, the $\varepsilon$ value for the ${ }^{2} T_{2 g} \rightarrow$ ${ }^{2} E_{\mathrm{g}}$ transition of $\left[\mathrm{Ti}\left(\mathrm{H}_{2} \mathrm{O}\right)_{6}\right]^{3+}$ is $\sim 5$, while those for the d-d transitions of $\left[\mathrm{V}\left(\mathrm{H}_{2} \mathrm{O}\right)_{6}\right]^{2+}$ also have similar intensity.
We now turn to the d-d transitions of the complex $\left[\mathrm{Mn}\left(\mathrm{H}_{2} \mathrm{O}\right)_{6}\right]^{2+}$. For this $\mathrm{d}^{5}$ configuration, the ground state is ${ }^{6} S$, which becomes ${ }^{6} A_{1 \mathrm{~g}}$ in an octahedral crystal field. This is the only sextet state for this configuration; the remaining states are either quartets or doublets. An Orgel diagram covering the sextet ground state and the four quartet excited states are shown in Fig 8.5.6. The electronic spectrum of $\left[\mathrm{Mn}\left(\mathrm{H}_{2} \mathrm{O}\right)_{6}\right]^{2+}$ is shown in Fig. 8.5.7.

Note that all transitions for this system are both symmetry- and spinforbidden and hence have very low $\varepsilon$ values, which are responsible for the very pale pink color of this cation. (As a comparison, tetrahedral complexes of Mn (II) are yellow-green, and the color is more intense. The molar absorbance
values for these complexes are in the range of 1.0-4.0). The assignment for the spectrum of $\left[\mathrm{Mn}\left(\mathrm{H}_{2} \mathrm{O}\right)_{6}\right]^{2+}$ shown in Fig. 8.5.7 is as follows:

\[

\]

Another feature of the $\left[\mathrm{Mn}\left(\mathrm{H}_{2} \mathrm{O}\right)_{6}\right]^{2+}$ spectrum shown in Fig. 8.5.7 is its variation of bandwidths of the spectral lines. Theoretical considerations indicate that the widths of spectral lines is dependent on the relative slopes of the two states involved in the transition. As the ligands vibrate, the value of $D q$ changes as a result [cf. eqs. (8.1.3) and (8.1.4)]. If the energy of the excited state is a sensitive function of $D q$, while that of the ground state is not, the spectral band will be broad. This argument is pictorially illustrated in Fig. 8.5.8. Referring to the Orgel diagram for $d^{5}$ complexes shown in Fig. 8.5.6, it is seen that the energies of the ground state ${ }^{6} A_{1 \mathrm{~g}}$ and the excited states ${ }^{4} A_{1 \mathrm{~g}}(G),{ }^{4} E_{1 \mathrm{~g}}(G)$, and ${ }^{4} E_{\mathrm{g}}(D)$ all happen to be independent of $D q$. Hence the spectral bands for the transitions from the ground state to these three excited states should be narrow, as are indeed found to be the case.

Before concluding this section, we briefly discuss how formally spinforbidden transitions gain their intensity. The mechanism through which this is achieved is the spin-orbit interaction. Here we use the two most stable terms, ${ }^{6} S$ and ${ }^{4} G$, of the $\mathrm{d}^{5}$ configuration for illustration. After spin-orbit $(L-S)$ coupling among the components for each term, ${ }^{6} S$ becomes ${ }^{6} S_{2^{1} / 2}$, while ${ }^{4} G$ splits into ${ }^{4} G_{5^{1 / 2}},{ }^{4} G_{4^{1 / 2}},{ }^{4} G_{3^{1 / 2}}$, and ${ }^{4} G_{2^{1} / 2}$. Such "intra-term" coupling may be considered as first-order spin-orbit interaction. Additionally, states with the same $J$ value, namely, ${ }^{6} S_{2^{1 / 2}}$ and ${ }^{4} G_{2^{1 / 2}}$ in the present example, will further interact. Such inter-term coupling is called second-order spin-orbit interaction. As a result of the interaction, the ${ }^{6} S$ term gains some quartet character; also the ${ }^{4} G$ term gains some sextet character. Mathematically, if we call the wavefunctions before and after spin-orbit interaction $\psi$ and $\psi^{\prime}$, respectively, then we have

$$
\begin{align*}
\psi^{\prime}\left({ }^{6} S\right) & =a \psi\left({ }^{6} S\right)+b \psi\left({ }^{4} G\right), & & a \gg b ;  \tag{8.5.1}\\
\psi^{\prime}\left({ }^{4} G\right) & =c \psi\left({ }^{4} G\right)+d \psi\left({ }^{6} S\right), & & c \gg d . \tag{8.5.2}
\end{align*}
$$

This minute amount of mixing of the quartet and sextet states leads to a very small intensity for the sextet-quartet transition, as, strictly speaking, the $\Delta S=0$ selection rule is no longer violated. A more detailed discussion on the spin-orbit interaction in complexes is given in Section 8.7.

Fig. 8.5.8.
Diagram showing how bandwidth varies with the ratio of the slopes of the ground and excited states. In the present example, the ground state (A) energy is independent of $D q$, while excited states B and C have energies which change as $D q$ changes. Here $\delta D q$ is the range of variation of $D q$ due to ligand vibrations, and $\delta \nu_{B}$ and $\delta v_{C}$ are the bandwidths for transitions $\mathrm{A} \rightarrow \mathrm{B}$ and $\mathrm{A} \rightarrow \mathrm{C}$, respectively.

### 8.5.3 Tanabe-Sugano diagrams

The Orgel diagrams shown in Figs. 8.5.2 and 8.5.5 have the distracting feature of decreasing ground state energy with increasing $\Delta_{0}$ or $D q$. To remedy this "deficiency," Japanese scientists Y. Tanabe and S. Sugano represented the energy of the ground state of a complex as a horizontal line. The Tanabe-Sugano diagrams for $\mathrm{d}^{2}, \mathrm{~d}^{3}$, and $\mathrm{d}^{8}$ octahedral complexes are shown in Fig. 8.5.9.

In these figures, states with spin multiplicities different from that of the ground state are also included. Thus, using these diagrams, spin-forbidden transitions may also be considered. The coordinates of the diagrams are $E / B$ and $\Delta_{\mathrm{o}} / B$, both of which are dimensionless (i.e., scalar quantities). Here $B$ is one of the Racah parameters in terms of which the energy of each (free) atomic term is expressed. Hence the diagrams shown can be used for various metal ions with the same $\mathrm{d}^{n}$ configuration and with different ligands.

The Tanabe-Sugano diagrams for $\mathrm{d}^{4}-\mathrm{d}^{7}$ octahedral complexes are shown in Fig. 8.5.10. In this figure, each diagram has two parts separated by a vertical line. The left part applies to high-spin (or weak field) complexes and the right side to low spin (or strong field) cases. Take the $\mathrm{d}^{6}$ diagram as an example. For high-spin $\mathrm{d}^{6}$ complexes, the ground state is ${ }^{5} T_{2 \mathrm{~g}}$, while that for a low-spin complex is ${ }^{1} A_{1 \mathrm{~g}}$. This is in agreement with the result shown in Fig. 8.2.1, which indicates that a high-spin $\mathrm{d}^{6}$ complex has four unpaired electrons (or a quintet spin state) and a low-spin $\mathrm{d}^{6}$ complex is diamagnetic (or a singlet state).

### 8.5.4 Electronic spectra of selected metal complexes

In this section, we present some additional spectra in order to illustrate the principles discussed in the previous sections.

## (1) $\left[\mathrm{Co}\left(\mathrm{H}_{2} \mathrm{O}\right)_{6}\right]^{2+}$ and $\left[\mathrm{CoCl}_{4}\right]^{2-}$

These are $\mathrm{d}^{7}$ complexes and their spectra are shown in Fig. 8.5.11. From the positions and the intensities of the spectral band, we can readily deduce that $\left[\mathrm{Co}\left(\mathrm{H}_{2} \mathrm{O}\right)_{6}\right]^{2+}$ is pale purple, while $\left[\mathrm{CoCl}_{4}\right]^{2-}$ is deep blue. With the help of the Orgel diagram shown in Fig. 8.5.5, and some quantitative results, the only band in each spectrum may be assigned to the following transition: ${ }^{4} A_{2} \rightarrow$ ${ }^{4} T_{1}(P)$ in $\left[\mathrm{CoCl}_{4}\right]^{2-}$ and ${ }^{4} T_{1 \mathrm{~g}}(F) \rightarrow{ }^{4} T_{1 \mathrm{~g}}(P)$ in $\left[\mathrm{Co}\left(\mathrm{H}_{2} \mathrm{O}\right)_{6}\right]^{2+}$, while the other spin-allowed transitions are not clearly seen.

For the octahedral complex, the ${ }^{4} T_{1 \mathrm{~g}}(F) \rightarrow{ }^{4} A_{2 \mathrm{~g}}$ should have comparable energy with the observed band. But ${ }^{4} T_{1 \mathrm{~g}}(F)$ arises from configuration $t_{2 \mathrm{~g}}^{5} e_{\mathrm{g}}^{2}$, while ${ }^{4} A_{2 \mathrm{~g}}$ is from $t_{2 \mathrm{~g}}^{3} e_{\mathrm{g}}^{4}$. So this is a two-electron process and hence the transition is weak. Meanwhile, the ${ }^{4} T_{1 \mathrm{~g}}(F) \rightarrow{ }^{4} T_{2 \mathrm{~g}}$ transition occurs in the near-infrared region. For the tetrahedral complex, the ${ }^{4} A_{2} \rightarrow{ }^{4} T_{1}(F)$ transition also takes place in the near infrared region, while ${ }^{4} A_{2} \rightarrow{ }^{4} T_{2}$ occurs in a region of even lower energy.

## (2) trans- $\left[\mathbf{C r}(\mathrm{en})_{2} \mathbf{F}_{2}\right]^{+}$

This is a d ${ }^{3}$ complex with a tetragonal structure with $D_{4 \mathrm{~h}}$ symmetry. (Strictly speaking, this system has $D_{2 \mathrm{~h}}$ symmetry.) Hence the Orgel diagram shown in Fig. 8.5.5 no longer applies. If we assume this cation has an elongated octahedral

Fig. 8.5.9.
Tanabe-Sugano diagrams for $\mathrm{d}^{2}, \mathrm{~d}^{3}$, and $\mathrm{d}^{8}$ octahedral complexes. Quantities $B$ and $C$ are Racah parameters, in terms of which the energy of a spectroscopic term is expressed. Hence both $E / B$ and $D q / B$ are dimensionless.

Fig. 8.5.10.
Tanabe-Sugano diagrams for $\mathrm{d}^{4}-\mathrm{d}^{7}$ octahedral complexes. Both $E / B$ and $D q / B$ are dimensionless.
geometry, the "original" triply degenerate $T$ states will split into two terms ( $E$ with $A$ or $B$ ). This splitting pattern is shown in Fig. 8.5.12. With this energy level diagram, the spectral bands of this complex, shown in Fig. 8.5.13, can be assigned in a fairly straightforward manner:

$$
\begin{array}{rll}
\text { Transition } & \mathrm{cm}^{-1} \\
{ }^{4} B_{1 \mathrm{~g}} & \rightarrow{ }^{4} E_{\mathrm{g}} & 18,500 \\
& \rightarrow{ }^{4} B_{2 \mathrm{~g}} & 21,700 \\
& \rightarrow{ }^{4} E_{\mathrm{g}} & 25,300 \\
& \rightarrow{ }^{4} A_{2 \mathrm{~g}} & 29,300 \\
& \rightarrow{ }^{4} A_{2 \mathrm{~g}} & 41,000 \text { (shoulder) } \\
& \rightarrow{ }^{4} E_{\mathrm{g}} & 43,700 \text { (calculated) }
\end{array}
$$

Fig. 8.5.11.
Visible spectra of $\left[\mathrm{Co}\left(\mathrm{H}_{2} \mathrm{O}\right)_{6}\right]^{2+}$ (curve A) and $\left[\mathrm{CoCl}_{4}\right]^{2-}$ (curve B). The $\varepsilon$ scale on the left side applies to $\left[\mathrm{Co}\left(\mathrm{H}_{2} \mathrm{O}\right)_{6}\right]^{2+}$; the one on the right applies to $\left[\mathrm{CoCl}_{4}\right]^{2-}$. As expected, the bands of the tetrahedral complex are much more intense than those of the octahedral complex.

Fig. 8.5.12.
Energy level splitting for $\mathrm{ad}^{3}$ ion as its crystal field environment changes form octahedral ( $O_{\mathrm{h}}$ symmetry) to tetragonal ( $D_{4 \mathrm{~h}}$ ).

Fig. 8.5.13.
Electronic spectrum of trans- $\left[\mathrm{Cr}(\mathrm{en})_{2} \mathrm{~F}_{2}\right]^{+}$.

Fig. 8.5.15.
Electronic spectra of $\left[\mathrm{Ni}\left(\mathrm{H}_{2} \mathrm{O}\right)_{6}\right]^{2+}(-)$ and $\left[\mathrm{Ni}(\mathrm{en})_{3}\right]^{2+}(---)$.

Fig. 8.5.14.
The visible spectrum of cis- and trans-[Co(en) $\left.2_{2} \mathrm{~F}_{2}\right]^{+}$. The broken line signifies that the most intense band actually consists of two overlapping transitions. The asymmetry of this band is caused by the slight splitting of ${ }^{1} T_{1 \mathrm{~g}}$ state in the cis isomer. For the trans isomer, the splitting is much more pronounced, and two separate bands are observed. The schematic diagram on the right shows the energy levels involved in these two electronic spectra.

## (3) cis- $\left[\mathbf{C o}(\mathbf{e n})_{2} \mathbf{F}_{2}\right]^{+}$and trans- $\left[\mathbf{C o}(\mathbf{e n})_{2} \mathbf{F}_{2}\right]^{+}$

These are low-spin $\mathrm{d}^{6}$ complexes with a ${ }^{1} A_{1 \mathrm{~g}}$ ground state. According to the Tanabe-Sugano diagram shown in Fig. 8.5.10, the two lowest energy singlet excited states for a d ${ }^{6}$ octahedral complex are ${ }^{1} T_{1 \mathrm{~g}}$ and ${ }^{1} T_{2 \mathrm{~g}}$. When the symmetry of the complex is lowered by substitution to form cis- or trans- $\left[\mathrm{CoX}_{4} \mathrm{Y}_{2}\right]^{+}$, both of the triply degenerate excited states will split. Also, the splitting of the ${ }^{1} T_{1 \mathrm{~g}}$ state will be more prominent if the ligands X and Y are far apart in the spectrochemical series; understandably this is especially so for the trans isomer. These results are summarized schematically in Fig. 8.5.14. Note that, in this figure, the splitting of the ${ }^{1} T_{2 \mathrm{~g}}$ is so small that it is completely ignored. These expected electronic transitions are observed in the respective spectra. Finally, it is noted that, since the cis isomer has no center of symmetry, its spectral bands have higher intensities.

## (4) $\left[\mathrm{Ni}\left(\mathrm{H}_{2} \mathrm{O}\right)_{6}\right]^{2+}$ and $\left[\mathrm{Ni}(\mathrm{en})_{3}\right]^{2+}$

These are $\mathrm{d}^{8}$ complexes and we may once again employ the Orgel diagram shown in Fig. 8.5.5 to interpret their spectra, which are displayed in Fig. 8.5.15. Three spin-allowed transitions are expected and observed:

$$
\begin{array}{rll}
\text { Transition } & {\left[{\left.\mathrm{Ni}\left(\mathrm{H}_{2} \mathrm{O}\right)_{6}\right]^{2+}}^{3+}\right.} & {\left[\mathrm{Ni}(\mathrm{en})_{3}\right]^{2+}} \\
{ }^{3} A_{2 \mathrm{~g}} & \rightarrow{ }^{3} T_{2 \mathrm{~g}} & 9,000 \mathrm{~cm}^{-1} \\
& \rightarrow{ }^{3} T_{1 \mathrm{~g}}(F) & 11,000 \mathrm{~cm}^{-1} \\
& \rightarrow{ }^{3} T_{1 \mathrm{~g}}(P) & 25,000 \\
18,500 \\
& 30,000
\end{array}
$$

Since ethylenediamine (en) is a stronger ligand than water, all the transitions for $\left[\mathrm{Ni}(\mathrm{en})_{3}\right]^{2+}$ have higher energies than the corresponding ones for $\left[\mathrm{Ni}\left(\mathrm{H}_{2} \mathrm{O}\right)_{6}\right]^{2+}$. Also, since $\left[\mathrm{Ni}\left(\mathrm{H}_{2} \mathrm{O}\right)_{6}\right]^{2+}$ is centrosymmetric, its spectral bands have lower intensities. From these spectra, it may be deduced that $\left[\mathrm{Ni}(\mathrm{en})_{3}\right]^{2+}$ is purple, while $\left[\mathrm{Ni}\left(\mathrm{H}_{2} \mathrm{O}\right)_{6}\right]^{2+}$ is green.

Finally, it is noted that the splitting of the middle band in the $\left[\mathrm{Ni}\left(\mathrm{H}_{2} \mathrm{O}\right)_{6}\right]^{2+}$ spectrum arises from spin-orbit interaction between the ${ }^{3} T_{1 \mathrm{~g}}(F)$ and ${ }^{1} E_{\mathrm{g}}$ states (cf. Fig. 8.5.9). These two states are close in energy at the $\Delta_{\mathrm{o}}$ value generated by six $\mathrm{H}_{2} \mathrm{O}$ molecules. But they are far apart at the stronger field of three en molecules. As a result, no splitting is observed in the spectrum of $\left[\mathrm{Ni}(\mathrm{en})_{3}\right]^{2+}$.

With the sample spectra discussed in this section, it is clear that the Orgel diagrams and/or Tanabe-Sugano diagrams are useful in making qualitative analysis for the spectra. However, there are also cases where quantitative treatments are indispensable in order to make definitive assignments and interpretations.

### 8.6 Correlation of weak and strong field approximations

In the Tanabe-Sugano diagrams for $\mathrm{d}^{2}$ complexes shown in Fig. 8.5.9, it is seen that the ${ }^{3} T_{1 \mathrm{~g}}$ ground state is identified as derived from the $t_{2 \mathrm{~g}}^{2}$ strong field configuration. Actually, such an identification can be made for all states shown. To do that, let us first give a more formal definition for weak and strong field approximations.

For the weak field case, we have the situation where the crystal field interaction is much weaker than the electronic repulsion. In this approximation, the Russell-Saunders terms ${ }^{3} F,{ }^{3} P,{ }^{1} G,{ }^{1} D$, and ${ }^{1} S$ for the $\mathrm{d}^{2}$ configuration are good basis functions. When the crystal field is "turned on," these terms split according to the results given in Table 8.4.2:

$$
\begin{aligned}
& { }^{3} F \rightarrow{ }^{3} A_{2 \mathrm{~g}}+{ }^{3} T_{1 \mathrm{~g}}+{ }^{3} T_{2 \mathrm{~g}}, \\
& { }^{3} P \rightarrow{ }^{3} T_{1 \mathrm{~g}}, \\
& { }^{1} G \rightarrow{ }^{1} A_{1 \mathrm{~g}}+{ }^{1} E_{\mathrm{g}}+{ }^{1} T_{1 \mathrm{~g}}+{ }^{1} T_{2 \mathrm{~g}}, \\
& { }^{1} D \rightarrow{ }^{1} E_{\mathrm{g}}+{ }^{1} T_{2 \mathrm{~g}}, \\
& { }^{1} S \rightarrow{ }^{1} A_{1 \mathrm{~g}} .
\end{aligned}
$$

These are the states arising from the weak field approximation.
For the strong field case, we have the reverse situation: the electronic repulsion is much smaller than the crystal field interaction. Now, for a system with two d electrons, we need to consider three crystal field configurations: $t_{2 \mathrm{~g}}^{2}, t_{2 \mathrm{~g}}^{1} e_{\mathrm{g}}^{1}$, and $e_{\mathrm{g}}^{2}$ (in the order of increasing energy). The states derived from these configurations can be obtained with the standard group theoretical methods described in Section 6.4.3. Now it is straightforward to arrive at the following results:

$$
\begin{aligned}
t_{2 \mathrm{~g}}^{2} & \rightarrow{ }^{3} T_{1 \mathrm{~g}}+{ }^{1} A_{1 \mathrm{~g}}+{ }^{1} E_{\mathrm{g}}+{ }^{1} T_{2 \mathrm{~g}}, \\
t_{2 \mathrm{~g}}^{1} e_{\mathrm{g}}^{1} & \rightarrow{ }^{3} T_{1 \mathrm{~g}}+{ }^{3} T_{2 \mathrm{~g}}+{ }^{1} T_{1 \mathrm{~g}}+{ }^{1} T_{2 \mathrm{~g}}, \\
e_{\mathrm{g}}^{2} & \rightarrow{ }^{3} A_{2 \mathrm{~g}}+{ }^{1} A_{1 \mathrm{~g}}+{ }^{1} E_{\mathrm{g}} .
\end{aligned}
$$

Fig. 8.6.1.
Correlation diagram for a $d^{2}$ octahedral complex. The g subscript is omitted in all the state or orbital designations. Note that the lines connecting the triplet states constitute the Orgel diagram shown in Fig. 8.5.4 or Fig. 8.5.5.

Of course, these are the same states obtained in the weak field approximation. The way these two sets of states is correlated is shown in Fig. 8.6.1. In drawing the connection lines, we minimize crossing, even for species with different symmetry. Note that the four lines connecting the triplet states constitute the Orgel diagram for $\mathrm{d}^{2}$ complexes (Fig. 8.5.4 or Fig. 8.5.8).

### 8.7 Spin-orbit interaction in complexes: the double group

Previously we stated that, for a state with orbital angular momentum $L$, the character for a rotation of angle $\alpha$ is given by

$$
\begin{equation*}
\chi(\alpha)=[\sin (L+1 / 2) \alpha] / \sin \alpha / 2 \tag{8.4.1.}
\end{equation*}
$$

When we use this formula to derive crystal field states of a complex, we have made the assumption that spin-orbit interaction is weak and hence is ignored.

When spin-orbit interaction is significant, the quantum number that defines a state is total angular momentum $J$, instead of $L$. Quantum number $J$ can be an integer or a half-integer. When $J$ is an integer, we can again make use of eq. (8.4.1) and replace $L$ with $J$. However, when $J$ is a half-integer, a complication arises: $\chi(\alpha+2 \pi)$ no longer equals to $\chi(\alpha)$, as it should. Mathematically

$$
\begin{align*}
\chi(\alpha+2 \pi) & =\sin [(J+1 / 2)(\alpha+2 \pi)] / \sin [1 / 2(\alpha+2 \pi)] \\
& =\sin [2 \pi+(J+1 / 2) \alpha] / \sin (\pi+\alpha / 2) \\
& =\sin [(J+1 / 2) \alpha] /(-\sin \alpha / 2)=-\chi(\alpha) \tag{8.7.1}
\end{align*}
$$

Table 8.7.1. The character table of double group $O^{\prime}$

| $O^{\prime}$ <br> $(h=48)$ | $\boldsymbol{E}$ <br> $(\alpha=4 \pi)$ | $\boldsymbol{R}$ <br> $(\alpha=2 \pi)$ | $4 \boldsymbol{C}_{3}$ <br> $4 \boldsymbol{C}_{3}^{2} \boldsymbol{R}$ | $4 \boldsymbol{C}_{3}^{2}$ <br> $4 \boldsymbol{C}_{3} \boldsymbol{R}$ | $3 \boldsymbol{C}_{2}$ <br> $3 \boldsymbol{C}_{2} \boldsymbol{R}$ | $3 \boldsymbol{C}_{4}$ <br> $3 \boldsymbol{C}_{4}^{3} \boldsymbol{R}$ | $3 \boldsymbol{C}_{4}^{3}$ <br> $3 \boldsymbol{C}_{4} \boldsymbol{R}$ | $6 \boldsymbol{C}_{2}^{\prime}$ <br> $6 \boldsymbol{C}_{2}^{\prime} \boldsymbol{R}$ |  |
| :--- | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| $\Gamma_{1}$ | $A_{1}^{\prime}$ | 1 | 1 | 1 | 1 | 1 | 1 | 1 | 1 |
| $\Gamma_{2}$ | $A_{2}^{\prime}$ | 1 | 1 | 1 | 1 | 1 | -1 | -1 | -1 |
| $\Gamma_{3}$ | $E_{1}^{\prime}$ | 2 | 2 | -1 | -1 | 2 | 0 | 0 | 0 |
| $\Gamma_{4}$ | $T_{1}^{\prime}$ | 3 | 3 | 0 | 0 | -1 | 1 | 1 | -1 |
| $\Gamma_{5}$ | $T_{2}^{\prime}$ | 3 | 3 | 0 | 0 | -1 | -1 | -1 | 1 |
| $\Gamma_{6}$ | $E_{2}^{\prime}$ | 2 | -2 | 1 | -1 | 0 | $(2)^{1 / 2}$ | $-(2)^{1 / 2}$ | 0 |
| $\Gamma_{7}$ | $E_{3}^{\prime}$ | 2 | -2 | 1 | -1 | 0 | $-(2)^{1 / 2}$ | $(2)^{1 / 2}$ | 0 |
| $\Gamma_{8}$ | $G^{\prime}$ | 4 | -4 | -1 | 1 | 0 | 0 | 0 | 0 |

To get around this difficulty, H. A. Bethe introduced a rotation by $2 \pi$, called $\boldsymbol{R}$, which is different from the identity operation $\boldsymbol{E}$. To add this operation to any rotation group such as $O$, we need to expand the group by taking the product of $\boldsymbol{R}$ with all existing rotations; these are now the operations of the new group called the double group. For example, the $O$ group has rotations $\boldsymbol{E}, 8 \boldsymbol{C}_{3}, 3 \boldsymbol{C}_{2}, 6 \boldsymbol{C}_{4}$ and $6 \boldsymbol{C}_{2}^{\prime}$ (Table 8.4.1) and its corresponding double group $O^{\prime}$ has operations $\boldsymbol{E}\left(=\boldsymbol{R}^{2}\right), \boldsymbol{R},\left(4 \boldsymbol{C}_{3}, 4 \boldsymbol{C}_{3}^{2} \boldsymbol{R}\right),\left(4 \boldsymbol{C}_{3}^{2}, 4 \boldsymbol{C}_{3} \boldsymbol{R}\right),\left(3 \boldsymbol{C}_{2}, 3 \boldsymbol{C}_{2} \boldsymbol{R}\right),\left(3 \boldsymbol{C}_{4}, 3 \boldsymbol{C}_{4}^{3} \boldsymbol{R}\right),\left(3 \boldsymbol{C}_{4}^{3}\right.$, $3 \boldsymbol{C}_{4} \boldsymbol{R}$ ), and ( $6 \boldsymbol{C}_{2}^{\prime}, 6 \boldsymbol{C}_{2}^{\prime} \boldsymbol{R}$ ), i.e., a total of 48 symmetry operations forming eight classes. The character table of the $O^{\prime}$ group is shown in Table 8.7.1. Upon examining this table, it is seen that:
(1) The $O^{\prime}$ group has eight irreducible representations, with the first five identical to those of the $O$ group (Table 8.4.1). The last three representations of the $O^{\prime}$ group are new.
(2) There are two systems of notation for the representations. The first one, $\Gamma_{1}, \Gamma_{2}, \ldots, \Gamma_{8}$, is due to Bethe. The other one, $A_{1}^{\prime}, A_{2}^{\prime}, \ldots$, etc. is due to Mulliken, who put the primes in to signify that these are the representations of the double group.

We may now use Table 8.7.1 to determine the representations, under $O$ symmetry, spanned by a state with half-integer quantum number $J$. These results are summarized in Table 8.7.2. Those for states with integral $J$ are included for convenience and completeness. In other words, this table contains all the results listed in Table 8.4.2, in addition to those for half-integer $J$ states.

To illustrate how to obtain the characters for rotation operations listed in Table 8.7.2, we take $\chi(\alpha=2 \pi)$ for $J=1 / 2$ as an example:

$$
\begin{align*}
\chi(\alpha=2 \pi) & =\lim _{\alpha \rightarrow 2 \pi}\left[\sin \left(\frac{1}{2}+\frac{1}{2}\right) \alpha\right] / \sin \frac{1}{2} \alpha \\
& =\lim _{\alpha \rightarrow 2 \pi} 2\left[\cos \alpha / \cos \frac{1}{2} \alpha\right]=-2 . \tag{8.7.2}
\end{align*}
$$

Now we consider the ${ }^{4} D$ term (an excited state) of a $d^{5}$ octahedral complex as an example. If spin-orbit interaction is ignored, this term splits into ${ }^{4} \Gamma_{3}$ and ${ }^{4} \Gamma_{5}$ states (Table 8.7.2) in a crystal field with $O_{\mathrm{h}}$ symmetry. When we "turn on"

Table 8.7.2. Representations, under $O$ or $O^{\prime}$ symmetry, spanned by a state characterized by an integral or a half-integral $J$ value

| 6 | 13 |  |  |  |  |  |  |  | $\Gamma_{1}+\Gamma_{2}+\Gamma_{3}+\Gamma_{4}+2 \Gamma_{5}$ |
| $6^{1 / 2}$ | 14 | -14 | 1 | -1 | 0 | -(2) ${ }^{1 / 2}$ | (2) ${ }^{1 / 2}$ | 0 | $\Gamma_{6}+2 \Gamma_{7}+2 \Gamma_{8}$ |

the spin-orbit interaction, these states will further split. To do this, it is seen that spin quantum number $S$ is $1 \frac{1}{2}$ for the present case; this spin state has $\Gamma_{8}$ symmetry (Table 8.7.2). When this spin state interacts with the orbitals parts ( $\Gamma_{3}$ and $\Gamma_{5}$ ), the resultant states are

$$
\begin{array}{r}
\Gamma_{3} \times \Gamma_{8}=\Gamma_{6}+\Gamma_{7}+\Gamma_{8} ; \\
\Gamma_{5} \times \Gamma_{8}=\Gamma_{6}+\Gamma_{7}+2 \Gamma_{8} .
\end{array}
$$

This means that ${ }^{4} \Gamma_{3}$ splits into three states and ${ }^{4} \Gamma_{5}$ into four. Note that now spin quantum number $S$ is no longer used to define the resultant states.

On the other hand, if spin-orbit coupling is larger than crystal field interaction, $J$ is the quantum number that defines a state before the crystal field is "turned on." For ${ }^{4} D$, we have $J$ values of $1 / 2,1^{1 / 2}, 2^{1 / 2}$, and $3^{1 / 2}$. In an octahedral crystal field, with the aid of Table 8.6.2, we can readily see that these states split into

$$
\begin{array}{ll}
J=1 / 2 & \Gamma_{6} ; \\
J=1^{1 / 2} & \Gamma_{8} ; \\
J=2^{1 / 2} & \Gamma_{7}+\Gamma_{8} ; \\
J=3^{1 / 2} & \Gamma_{6}+\Gamma_{7}+\Gamma_{8} .
\end{array}
$$

The way these two sets of states are correlated is shown in Fig. 8.7.1. It is important to note that, whenever we are dealing with spin-orbit interaction in a system with half-integral $J$ values, we should employ the double group.

### 8.8 Molecular orbital theory for octahedral complexes

In the crystal field treatment of complexes, the interaction between the central metal ion and the ligands is taken to be purely electrostatic, i.e., ionic bonding. If

## Fig. 8.7.1.

Relative effects of spin-orbit coupling and octahedral crystal field interaction on the electronic state ${ }^{4} D$.

we wish to take the overlap between the metal and ligand orbitals, i.e., covalent bonding, into account, we need to turn to molecular orbital theory. The basic concepts of this theory have already been discussed in Chapters 3 and 7.

### 8.8.1 $\sigma$ bonding in octahedral complexes

We first treat those complexes that have only $\sigma$ metal-ligand bonding. Examples of this type of complexes include $\left[\mathrm{M}\left(\mathrm{H}_{2} \mathrm{O}\right)_{6}\right]^{n+}$ and $\left[\mathrm{M}\left(\mathrm{NH}_{3}\right)_{6}\right]^{n+}$, where $\mathrm{M}^{n+}$ is a first transition series metal ion and a typical $n$ value is either 2 or 3 . A coordinate system for such a complex is shown in Fig. 8.8.1. The representation generated by the six ligand orbitals is

$$
\begin{array}{c|cccccccccc}
O_{\mathrm{h}} & \boldsymbol{E} & 8 \boldsymbol{C}_{3} & 6 \boldsymbol{C}_{2} & 6 \boldsymbol{C}_{4} & 3 \boldsymbol{C}_{2} & \boldsymbol{i} & 6 \boldsymbol{S}_{4} & 8 \boldsymbol{S}_{6} & 3 \boldsymbol{\sigma}_{\mathrm{h}} & 6 \boldsymbol{\sigma}_{\mathrm{d}} \\
\hline \Gamma_{\sigma} & 6 & 0 & 0 & 2 & 2 & 0 & 0 & 0 & 4 & 2
\end{array}
$$

## Symmetry in Chemistry

Table 8.8.1. Summary of the formation of $\sigma$ molecular orbitals (Fig. 8.8.2) in $\mathrm{ML}_{6}$

| Symmetry | Metal orbitals | Ligand $\sigma$ orbitals | Molecular orbitals |
| :---: | :---: | :---: | :---: |
| $A_{1 g}$ | $s$ | (6) ${ }^{-\frac{1}{2}}\left(\sigma_{1}+\sigma_{2}+\sigma_{3}+\sigma_{4}+\sigma_{5}+\sigma_{6}\right)$ | $1 a_{1 \mathrm{~g}}, 2 a_{1 \mathrm{~g}}$ |
| $E \mathrm{~g}$ | $\left\{\begin{array}{l}\mathrm{d}_{x^{2}-y^{2}} \\ \mathrm{~d}^{2}\end{array}\right.$ | $\left\{\begin{array}{l}\frac{1}{2}\left(\sigma_{1}-\sigma_{2}+\sigma_{3}-\sigma_{4}\right) \\ (12)^{-\frac{1}{2}}\left(2 \sigma_{5}+2 \sigma_{6}-\sigma_{1}-\sigma_{2}-\sigma_{3}-\sigma_{4}\right)\end{array}\right.$ | $1 e_{\mathrm{g}}, 2 e_{\mathrm{g}}$ |
| $T_{1 \mathrm{u}}$ | $\left\{\begin{array}{l}\mathrm{p}_{x} \\ \mathrm{p}_{y} \\ \mathrm{p}_{z}\end{array}\right.$ | $\left\{\begin{array}{l} (2)^{-\frac{1}{2}}\left(\sigma_{1}-\sigma_{3}\right) \\ (2)^{-\frac{1}{2}}\left(\sigma_{2}-\sigma_{4}\right) \\ (2)^{-\frac{1}{2}}\left(\sigma_{5}-\sigma_{6}\right) \end{array}\right.$ | $1 t_{1 \mathrm{u}}, 2 t_{1 \mathrm{u}}$ |
| $T_{2 \mathrm{~g}}$ | $\left\{\begin{array}{l}\mathrm{d}_{x y} \\ \mathrm{~d}_{y z} \\ \mathrm{~d}_{z x}\end{array}\right.$ | - | $1 t_{2 \mathrm{~g}}$ |

Fig. 8.8.2.
Linear combinations of $\sigma$ ligand orbitals matching symmetry with the atomic orbitals on the central metal ion in $\mathrm{ML}_{6}$.

which reduces as $\Gamma_{\sigma}=A_{1 \mathrm{~g}}+E_{\mathrm{g}}+T_{1 \mathrm{u}}$. The six linear combinations of ligand orbitals can be readily generated, and they match in symmetry with the suitable metal orbitals. These are summarized in Table 8.8.1 and illustrated in Fig. 8.8.2. The molecular orbital energy level diagram for an octahedral $\mathrm{ML}_{6}$ complex with only $\sigma$ bonding is shown in Fig. 8.8.3.

Examining the energy level diagram shown in Fig. 8.8.3, we see that the electron pairs from the six ligands enter into the $1 t_{1 \mathrm{u}}, 1 a_{1 \mathrm{~g}}$, and $1 e_{\mathrm{g}}$ orbitals, thus leaving $1 t_{2 \mathrm{~g}}$ and $2 e_{\mathrm{g}}$ orbitals to accommodate the d electrons from the metal ion. Also note that the $1 t_{2 \mathrm{~g}}$ orbitals are more stable than the $2 e_{\mathrm{g}}$ orbitals and the energy gap between them is once again called $\Delta_{0}$. This is in total agreement with the results of crystal field theory (Fig. 8.1.5). But the two theories arrive at their results in different ways. In crystal field theory, the $t_{2 \mathrm{~g}}$ orbitals are more stable than the $e_{\mathrm{g}}$ orbitals because the former have lobes pointing between the ligands and the latter have lobes pointing at the ligands. On the other hand, in molecular orbital theory, the $1 t_{2 \mathrm{~g}}$ orbital are more stable than the $2 e_{\mathrm{g}}$ orbitals

because the former are nonbonding orbitals, while the latter are antibonding $\sigma^{*}$ orbitals.

### 8.8.2 Octahedral complexes with $\pi$ bonding

When the ligands in complex $\mathrm{ML}_{6}$ also have $\pi$ orbitals available for interaction, the bonding picture becomes more complicated. If the ligand $\pi$ orbitals are oriented in the manner depicted in Fig. 8.8.4, it can be readily shown that the representation generated by the twelve ligand $\pi$ orbitals is

$$
\begin{array}{c|cccccccccc}
O_{\mathrm{h}} & \boldsymbol{E} & 8 \boldsymbol{C}_{3} & 6 \boldsymbol{C}_{2} & 6 \boldsymbol{C}_{4} & 3 \boldsymbol{C}_{2}\left(=\boldsymbol{C}_{4}^{2}\right) & \boldsymbol{i} & 6 \boldsymbol{S}_{4} & 8 \boldsymbol{S}_{6} & 3 \boldsymbol{\sigma}_{\mathrm{h}} & 6 \boldsymbol{\sigma}_{\mathrm{d}} \\
\hline \Gamma_{\pi} & 12 & 0 & 0 & 0 & -4 & 0 & 0 & 0 & 0 & 0
\end{array}
$$

This reduces to $\Gamma_{\pi}=T_{1 \mathrm{~g}}+T_{1 \mathrm{u}}+T_{2 \mathrm{~g}}+T_{2 \mathrm{u}}$. The twelve linear combinations with the proper symmetry are listed in Table 8.8.2. Since there are no

Fig. 8.8.4.
A coordinate system for $\mathrm{ML}_{6}$, showing the orientations of the twelve $\pi$ ligand orbitals.

Table 8.8.2. The symmetry-adapted linear combinations of ligand $\pi$ orbitals for $\mathrm{ML}_{6}$ complexes (Fig. 8.8.4) with $O_{\mathrm{h}}$ symmetry

| Symmetry | Combination | Symmetry | Combination |
| :--- | :--- | :--- | :--- |
| $T_{1 \mathrm{~g}}$ | $\frac{1}{2}\left(x_{2}+y_{4}-x_{5}-y_{6}\right)$ | $T_{1 \mathrm{u}}$ | $\frac{1}{2}\left(y_{1}-x_{3}+x_{5}-y_{6}\right)$ |
|  | $\frac{1}{2}\left(x_{1}+y_{3}-y_{5}-x_{6}\right)$ |  | $\frac{1}{2}\left(-y_{2}+x_{4}+y_{5}-x_{6}\right)$ |
|  | $\frac{1}{2}\left(-y_{1}+y_{2}-x_{3}+x_{4}\right)$ |  | $\frac{1}{2}\left(x_{1}-x_{2}-y_{3}+y_{4}\right)$ |
| $T_{2 \mathrm{~g}}$ | $\frac{1}{2}\left(x_{2}+y_{4}+x_{5}+y_{6}\right.$ | $T_{2 \mathrm{u}}$ | $\frac{1}{2}\left(y_{1}-x_{3}-x_{5}+y_{6}\right)$ |
|  | $\frac{1}{2}\left(x_{1}+y_{3}+y_{5}+x_{6}\right)$ |  | $\frac{1}{2}\left(-y_{2}+x_{4}-y_{5}+x_{6}\right)$ |
|  | $\frac{1}{2}\left(y_{1}+y_{2}+x_{3}+x_{4}\right)$ |  | $\frac{1}{2}\left(-x_{1}-x_{2}+y_{3}+y_{4}\right)$ |

Fig. 8.8.5.
Comparison of the overlaps between the $T_{1 \mathrm{u}} \sigma$ and $\pi$ ligand combinations with the same $n \mathrm{p}_{z}$ orbital on the metal. Note that the $\sigma$ type overlap will lead to more significant interaction between the ligands and the metal.

Fig. 8.8.6.
The $\pi$-type overlap with $T_{2 \mathrm{~g}}$ symmetry between the ligands and the metal.

$n \mathrm{p}_{z}$ with $1 / 2\left(x_{1}-x_{2}-x_{3}+x_{4}\right)$

$n \mathrm{p}_{z}$ with $(2)^{-1 / 2}\left(\sigma_{5}-\sigma_{6}\right)$
metal orbitals with either $T_{1 \mathrm{~g}}$ or $T_{2 \mathrm{u}}$ symmetry, the combinations of ligand orbitals with these symmetries given in Table 8.8.2 are essentially nonbonding orbitals. Also, the linear combinations of ligand $\pi$ orbitals with $T_{1 \mathrm{u}}$ symmetry will have less effective overlap with the metal $n$ p oritals than the $\sigma$ combinations (Table 8.8.1) of the same symmetry. The comparison of these two types of overlap is illustrated in Fig. 8.8.5. In other words, the molecular orbitals consisting mostly of the ligand $\pi$ orbitals with $T_{1 \mathrm{u}}$ symmetry is essentially nonbonding or at most weakly bonding. So the most important ligand orbitals participating in $\pi$ bonding are the combinations of $T_{2 \mathrm{~g}}$ symmetry. Figure 8.8.6 shows how these combinations overlap with the metal d orbitals.

When the ligands have filled $\pi$ orbitals to bond with the metal, examples of which include $\mathrm{F}^{-}, \mathrm{Cl}^{-}, \mathrm{OH}^{-}, \ldots$, etc., the schematic energy level diagram for such complexes is shown in Fig. 8.8.7. Note that the orbitals up to and including $1 t_{1 \mathrm{~g}}$ and $1 t_{2 \mathrm{u}}$ are filled by electrons from ligands, and we fill in the metal d electrons starting from $2 t_{2 \mathrm{~g}}$. Now the $2 e_{\mathrm{g}}$ orbitals remain antibonding $\sigma^{*}$ in nature, while the $2 t_{2 \mathrm{~g}}$ orbitals have become antibonding $\pi^{*}$ (recalling that these orbitals, called $1 t_{2 \mathrm{~g}}$ in Fig. 8.8.3, are nonbonding in a complex with only $\sigma$ bonding). As a result, compared to the complexes with only $\sigma$ bonding, the present system has a smaller $\Delta_{0}$. As illustrated in Fig. 8.8.8(a), such a decrease in $\Delta_{0}$ implies an electron flow from ligands to metal $(\mathrm{L} \rightarrow \mathrm{M})$.

Fig. 8.8.7.
Schematic energy level diagram for an octahedral $\mathrm{ML}_{6}$ complex in which the ligands have filled $\pi$ orbitals for bonding. Compared to complexes with only $\sigma$ bonding, the present system has a smaller $\Delta_{0}$. See also Fig. 8.8.8(a).

Fig. 8.8.8.
Comparison of the effects of $\pi$ bonding using (a) filled $\pi$ ligand orbitals for $\mathrm{L} \rightarrow \mathrm{M}$ donation and (b) empty $\pi$ ligand orbitals for $\mathrm{M} \rightarrow \mathrm{L}$ donation. Note that, compared to complexes with only $\sigma$ bonding, the former leads to a smaller $\Delta_{0}$ and the latter to a larger one

Conversely, when the ligands have low-lying empty $\pi$ orbitals for bonding, examples of which include $\mathrm{CO}, \mathrm{CN}^{-}, \mathrm{PR}_{3}, \ldots$, etc., the originally nonbonding $t_{2 \mathrm{~g}}$ orbitals now become $\pi$ bonding in nature, while the $e_{\mathrm{g}}$ orbitals remain
$\sigma^{*}$ antibonding. As a result, compared to complexes with only $\sigma$ bonding, $\Delta_{\mathrm{o}}$ becomes larger. As we feed electrons into these $\pi$ bonding $t_{2 g}$ orbitals, electrons appear to flow from metal to ligands ( $\mathrm{M} \rightarrow \mathrm{L}$ ). This is illustrated in Fig. 8.8.8(b).

To conclude this section, we once again compare and contrast the crystal field theory and molecular orbital theory for metal complexes. Both theories lead to an orbital energy ordering of $e_{\mathrm{g}}$ above $t_{2 \mathrm{~g}}$. Crystal field theory arrives at these results by arguing that the $e_{\mathrm{g}}$ orbitals point at the ligands and the $t_{2 \mathrm{~g}}$ orbitals point between the ligands. In other words, only electrostatic interaction is considered in this model. In molecular orbital theory, the overlap between the metal and ligand orbitals is taken into account. In complexes with only $\sigma$ bonding, the $e_{\mathrm{g}}$ orbitals are antibonding $\sigma^{*}$ and $t_{2 \mathrm{~g}}$ orbitals are nonbonding. In complexes with ligands having filled $\pi$ orbitals, the $e_{\mathrm{g}}$ orbitals remain antibond$\operatorname{ing} \sigma^{*}$ and $t_{2 \mathrm{~g}}$ orbitals have become antibonding $\pi^{*}$, leading to a smaller $\Delta_{0}$. In complexes with ligands having empty $\pi^{*}$ orbitals for bonding, the $e_{\mathrm{g}}$ orbitals are still antibonding $\sigma^{*}$ and $t_{2 \mathrm{~g}}$ orbitals have become $\pi$ bonding, thus yielding a larger $\Delta_{0}$.

### 8.8.3 The eighteen-electron rule

In studying the compounds of representative elements, we often speak of the octet rule, which ascribes special stability to an electronic configuration of a rare gas atom, i.e., with eight valence electrons. Since transition metals have five d orbitals in their valence shell, in addition to one s and three p orbitals, their stable electronic configuration would have eighteen valence electrons, giving rise to the eighteen-electron rule for transition metal complexes. However, while this rule is often found useful, it is by no means rigorously followed. Indeed, in reference to the eighteen-electron rule, complexes may be broadly classified into three types: (1) those with electronic configurations entirely unrelated to this rule, (2) those with eighteen or less valence electrons, and (3) those with exactly eighteen valence electrons. Employing the energy level diagram shown in Fig. 8.8.3, we will see how these three types of behavior can be accounted for.

For case (1) complexes, examples of which include many first transition series compounds (Table 8.8.3), the $1 t_{2 \mathrm{~g}}$ orbitals are essentially nonbonding and $\Delta_{0}$ is small. In other words, the $2 e_{\mathrm{g}}$ orbitals are only slightly antibonding and they may be occupied without much energy cost. Hence, there is little or no restriction on the number of $d$ electrons and the eighteen-electron rule has no influence on these complexes.

For case (2) complexes, examples of which include many second- or third-row transition metal complexes (Table 8.8.3), the $1 t_{2 \mathrm{~g}}$ orbitals are still nonbonding and $\Delta_{\mathrm{o}}$ is large. In other words, the $2 e_{\mathrm{g}}$ orbitals are strongly antibonding and there is a strong tendency not to fill them. But there is still no restriction on the number of electrons that occupy the $1 t_{2 \mathrm{~g}}$ orbitals. Hence, there are eighteen or less valence electrons for these complexes.

For case (3) complexes, examples of which include many metal carbonyls and their derivatives (Table 8.8.3), the $1 t_{2 \mathrm{~g}}$ orbitals are strongly bonding due to back donation and the $2 e_{\mathrm{g}}$ orbitals are strongly antibonding. Thus, while it is still imperative not to have electrons occupying the $2 e_{\mathrm{g}}$ orbitals, it is equally

Table 8.8.3. Three types of complexes in relation to the eighteen-electron rule

| Type (1) <br> complex | Number of <br> valence <br> electrons | Type (2) <br> complex | Number of <br> valence <br> electrons | Type (3) <br> complex | Number of <br> valence <br> electrons |
| :--- | :---: | :---: | :---: | :---: | :---: |
| $\left[\mathrm{Cr}(\mathrm{NCS})_{6}\right]^{3-}$ | 15 | $\left[\mathrm{WCl}_{6}\right]^{2-}$ | 13 | $\left[\mathrm{~V}(\mathrm{CO})_{6}\right]^{-}$ | 18 |
| $\left[\mathrm{Mn}(\mathrm{CN})_{6}\right]^{3-}$ | 16 | $\left[\mathrm{WCl}_{6}\right]^{3-}$ | 14 | $\left[\mathrm{Mo}(\mathrm{CO})_{3}\left(\mathrm{PF}_{3}\right)_{3}\right]$ | 18 |
| $\left[\mathrm{Fe}\left(\mathrm{C}_{2} \mathrm{O}_{4}\right)_{3}\right]^{3-}$ | 17 | $\left[\mathrm{TcF}_{6}\right]^{2-}$ | 15 | $\left[\mathrm{HMn}(\mathrm{CO})_{5}\right]$ | 18 |
| $\left[\mathrm{Co}\left(\mathrm{NH}_{3}\right)_{6}\right]^{3+}$ | 18 | $\left[\mathrm{OsCl}_{6}\right]^{2-}$ | 16 | $\left[\left(\mathrm{C} 5 \mathrm{H}_{5}\right) \mathrm{Mn}(\mathrm{CO})_{3}\right]$ | 18 |
| $\left[\mathrm{Co}\left(\mathrm{H}_{2} \mathrm{O}\right)_{6}\right]^{2+}$ | 19 | $\left[\mathrm{PtF}_{6}\right]$ | 16 | $\left[\mathrm{Cr}(\mathrm{CO})_{6}\right]$ | 18 |
| $\left[\mathrm{Ni}(\mathrm{en})_{3}\right]^{2+}$ | 20 | $\left[\mathrm{PtF}_{6}\right]^{-}$ | 17 | $\left[\mathrm{Mo}(\mathrm{CO})_{6}\right]$ | 18 |
| $\left[\mathrm{Cu}\left(\mathrm{NH}_{3}\right)_{6}\right]^{2+}$ | 21 | $\left[\mathrm{PtF}_{6}\right]^{2-}$ | 18 | $\left[\mathrm{~W}(\mathrm{CO})_{6}\right]$ | 18 |

important to have the $1 t_{2 \mathrm{~g}}$ orbitals fully filled. Removal of electrons from the completely occupied $1 t_{2 g}$ orbitals would destabilize the complex due to loss of bond energy. Hence these molecules tend to have exactly eighteen electrons.

### 8.9 Electronic spectra of square planar complexes

In this section, we use the square-planar complex $\mathrm{ML}_{4}$ as an example to discuss the various types of electronic transitions observed in coordination compounds.

### 8.9.1 Energy level scheme for square-planar complexes

A coordinate system for a square-planar complex $\mathrm{ML}_{4}$ ( $D_{4 \mathrm{~h}}$ symmetry) is displayed in Fig. 8.9.1. The linear combinations of ligand orbitals, matched in symmetry with the metal orbitals, and the molecular orbitals they form, are summarized in Table 8.9.1. A schematic energy level diagram for this type of complexes is given in Fig. 8.9.2.

Examining Fig. 8.9.2, we can see that the most stable molecular orbitals are bonding $\sigma$ orbitals with symmetries $B_{1 \mathrm{~g}}, A_{1 \mathrm{~g}}$, and $E_{\mathrm{u}}$; they are mainly located on the ligands. Above them are the bonding and nonbonding $\pi$ orbitals, also located on the ligands. All these orbitals are fully filled. After these two sets of levels, we come to the five orbitals (in four levels) that are essentially antibonding $\sigma^{*}$ and $\pi^{*}$ in nature and are located mainly on the metal's $d$ orbitals. The ordering of these four levels may vary from ligand to ligand, but it is well established

Fig. 8.9.1.
Coordinate system for a square-planar complex $\mathrm{ML}_{4}$, where the ligand $\sigma$ orbitals are labelled as $\sigma_{1}, \ldots, \sigma_{4}$, and the ligand $\pi$ orbitals as $v_{1}, \ldots, v_{4}$ and $h_{1}, \ldots, h_{4}$.

Table 8.9.1. Summary of the formation of molecular orbitals in squareplanar complexes $\mathrm{ML}_{4}$

| Symmetry | Metal orbital | Ligand orbitals | Molecular orbitals |
| :---: | :---: | :---: | :---: |
| $A_{1 \mathrm{~g}}$ | $\begin{aligned} & \mathrm{s} \\ & \mathrm{~d}_{z}^{2} \end{aligned}$ | $\frac{1}{2}\left(\sigma_{1}+\sigma_{2}+\sigma_{3}+\sigma_{4}\right)$ | $1 a_{1 \mathrm{~g}}, 2 a_{1 \mathrm{~g}}, 3 a_{1 \mathrm{~g}}$ |
| $A_{2 \mathrm{~g}}$ | - | $\frac{1}{2}\left(h_{1}+h_{2}+h_{3}+h_{4}\right)$ | $1 a_{2 \mathrm{~g}}$ |
| $A_{2 \mathrm{u}}$ | $\mathrm{p}_{z}$ | $\frac{1}{2}\left(v_{1}+v_{2}+v_{3}+v_{4}\right)$ | $1 a_{2 \mathrm{u}}, 2 a_{2 \mathrm{u}}$ |
| $B_{1 \mathrm{~g}}$ | $\mathrm{d}_{x^{2}-y^{2}}$ | $\frac{1}{2}\left(\sigma_{1}-\sigma_{2}+\sigma_{3}-\sigma_{4}\right)$ | $1 b_{1 \mathrm{~g}}, 1 b_{2 \mathrm{~g}}$ |
| $B_{2 g}$ | $\mathrm{d}_{x y}$ | $\frac{1}{2}\left(h_{1}-h_{2}+h_{3}-h_{4}\right)$ | $1 b_{2 \mathrm{~g}}, 2 b_{2 \mathrm{~g}}$ |
| $B_{2 \mathrm{u}}$ | - | $\frac{1}{2}\left(v_{1}-v_{2}+v_{3}-v_{4}\right)$ | $1 b_{2 \mathrm{u}}$ |
| $E_{\mathrm{g}}$ | $\left\{\begin{array}{l}\mathrm{d}_{x z} \\ \mathrm{~d}_{y z}\end{array}\right.$ | $\left\{\begin{array}{l}(2)^{-\frac{1}{2}}\left(v_{1}-v_{3}\right) \\ (2)^{-\frac{1}{2}}\left(v_{2}-v_{4}\right)\end{array}\right.$ | $1 e_{\mathrm{g}}, 2 e_{\mathrm{g}}$ |
| $E_{\mathrm{u}}$ | $\left\{\begin{array}{l}\mathrm{p}_{x} \\ \mathrm{p}_{y}\end{array}\right.$ | $\left\{\begin{array}{l}(2)^{-\frac{1}{2}}\left(\sigma_{1}-\sigma_{3}\right) \\ (2)^{-\frac{1}{2}}\left(\sigma_{2}-\sigma_{4}\right)\end{array}\right.$ | $1 e_{\mathrm{u}}, 2 e_{\mathrm{u}}, 3 e_{\mathrm{u}}$ |
|  |  | $\left\{\begin{array}{l} (2)^{-\frac{1}{2}}\left(h_{4}-h_{2}\right) \\ (2)^{-\frac{1}{2}}\left(h_{1}-h_{3}\right) \end{array}\right.$ |  |

that the $b_{1 \mathrm{~g}}\left(\mathrm{~d}_{x^{2}-y^{2}}\right)$ orbital is the most unstable one. In any event, the ordering of these four levels is consistent with the results found for square-planar halides and cyanides. Interestingly, this ordering is also identical to that obtained by crystal field theory (Fig. 8.3.4). So once again we find consistency between the results of crystal field theory and molecular orbital theory, even though these two theories arrive at their results in different manners.

As mentioned in Section 8.3, many square-planar complexes have the d ${ }^{8}$ configuration. This observation is consistent with the energy level scheme shown in Fig. 8.9.2, with eight electrons occupying the relatively more stable $e_{\mathrm{g}}, a_{1 \mathrm{~g}}$, and $b_{2 \mathrm{~g}}$ orbitals, and leaving the highly unstable $b_{1 \mathrm{~g}}$ level vacant.

Based on the energy level scheme shown in Fig. 8.9.2, we can expect three types of electronic transitions: d-d, ligand to metal ( $\mathrm{L} \rightarrow \mathrm{M}$ ), and metal to ligand $(M \rightarrow L)$ charge transfers. For $d^{8}$ square-planar complexes, there should be three spin-allowed d-d transitions: electron promoted to the $b_{1 \mathrm{~g}}$ orbital from the $b_{2 \mathrm{~g}}, a_{1 \mathrm{~g}}$, and $e_{\mathrm{g}}$ orbitals. In addition, $\mathrm{L} \rightarrow \mathrm{M}$ charge transfer bands originate from symmetry-allowed transitions promoting an electron to the $b_{1 \mathrm{~g}}$ orbital from either the $\sigma$ or $\pi$ bonding orbitals. On the other hand, for complexes with $\pi$-acceptor ligands, $\mathrm{M} \rightarrow \mathrm{L}$ charge transfer bands are due to the promotion of an electron from the three filled "metal" levels to the lowest energy "ligand" orbitals. It is useful to recall here that a charge transfer is an electronic transition from an orbital mostly localized on one atom or group to another orbital mostly localized on another atom or group. The majority of these charge transfer transitions take place in the ultraviolet region; they usually have higher energies, as well as higher intensities, than the $\mathrm{d}-\mathrm{d}$ transitions. In passing, it is noted that crystal field theory can be employed to make assignments for the d-d transitions. But we need to make use of molecular orbital theory to treat the $\mathrm{M} \rightarrow \mathrm{L}$ and $\mathrm{L} \rightarrow \mathrm{M}$ charge transfers.

### 8.9.2 Electronic spectra of square-planar halides and cyanides

With the energy level scheme shown in Fig. 8.9.2, we can easily derive two types of energy level diagrams: those for halides, as shown in Fig. 8.9.3, and those for cyanides, as shown in Fig. 8.9.4. We will make use of these results to interpret some spectral data for square-planar $\mathrm{ML}_{4}$ complexes.

Fig. 8.9.3.
Schematic energy level diagram for square-planar halides.

Fig. 8.9.4.
Schematic energy level diagram for square-planar cyanides.

Fig. 8.9.5.
Aqueous solution d-d spectrum of $\left[\mathrm{PtCl}_{4}\right]^{2-}$.

## (1) d-d bands

The d-d spectrum of $\left[\mathrm{PtCl}_{4}\right]^{2-}$ in solution is shown in Fig. 8.9.5. Note that the bands are relatively weak, signifying that they are due to symmetry-forbidden transitions. As mentioned previously, three d-d bands are expected; indeed, three are observed. Hence the assignment is relatively straightforward:

$$
\begin{aligned}
{ }^{1} A_{1 g} & \rightarrow{ }^{1} A_{2 \mathrm{~g}}\left(2 b_{2 \mathrm{~g}} \rightarrow 2 b_{1 \mathrm{~g}}\right) 21,000 \mathrm{~cm}^{-1} \\
& \rightarrow{ }^{1} B_{1 \mathrm{~g}}\left(2 a_{1 \mathrm{~g}} \rightarrow 2 b_{1 \mathrm{~g}}\right) 25,500 \\
& \rightarrow{ }^{1} E_{\mathrm{g}}\left(2 e_{\mathrm{g}} \rightarrow 2 b_{1 \mathrm{~g}}\right) \quad 30,200 .
\end{aligned}
$$

The labeling of the orbitals refers to those given in Fig. 8.9.3.

## (2) $\mathbf{L} \rightarrow \mathbf{M}$ charge transfers

Two intense bands are observed in the spectrum of $\left[\mathrm{PtCl}_{4}\right]^{2-}$, as shown in Fig 8.9.6. They are charge transfer bands, as characterized by their energies and intensities. Compared to the d-d transitions shown in Fig. 8.9.5, the charge transfer bands are seen at much higher energy and are more intense by a factor of nearly $10^{3}$. Hence these transitions must be symmetry allowed. With the aid of Fig. 8.9.3, as well as some computational treatments, the following assignments have been made:

$$
\left.\begin{array}{rl}
{ }^{1} A_{1 \mathrm{~g}} & \rightarrow{ }^{1} E_{\mathrm{u}}\left(2 e_{\mathrm{u}} \rightarrow 2 b_{1 \mathrm{~g}}\right) \\
& \rightarrow{ }^{1} A_{2 \mathrm{u}}\left(1 b_{2 \mathrm{u}} \rightarrow 2 b_{1 \mathrm{~g}}\right)
\end{array}\right\} \begin{aligned}
& 36,0000 \mathrm{~cm}^{-1} \\
&
\end{aligned} \rightarrow^{1} E_{\mathrm{u}}\left(1 e_{\mathrm{u}} \rightarrow 2 b_{1 \mathrm{~g}}\right) \quad 44,900
$$

## (3) $\mathbf{M} \rightarrow \mathbf{L}$ charge transfers

Figure 8.9 .7 shows that there are three closely spaced bands in the electronic spectrum of $\left[\mathrm{Ni}(\mathrm{CN})_{4}\right]^{2-}$. Since $\mathrm{CN}^{-}$has vacant low-lying $\pi^{*}$ orbitals, these three bands have been assigned as the transitions from three closely spaced filled metal d levels $\left(2 e_{\mathrm{g}}, 2 a_{1 \mathrm{~g}}\right.$, and $2 b_{2 \mathrm{~g}}$ in Fig. 8.9.4) to the first available ligand level, $2 a_{2 \mathrm{u}}$. Apparently, the $2 a_{2 \mathrm{u}}$ level, mostly localized on the four $\mathrm{CN}^{-}$groups, has been significantly stabilized by the $4 \mathrm{p}_{z}$ orbital on the metal. In any event, these three bands have been assigned as

$$
\begin{array}{rlrl}
{ }^{1} A_{1 \mathrm{~g}} & \rightarrow{ }^{1} B_{1 \mathrm{u}}\left(2 b_{2 \mathrm{~g}} \rightarrow 2 a_{2 \mathrm{u}}\right) & & 32,300 \mathrm{~cm}^{-1} \\
& \rightarrow{ }^{1} A_{2 \mathrm{u}}\left(2 a_{1 \mathrm{~g}} \rightarrow 2 a_{2 \mathrm{u}}\right) & 35,200 \\
& \rightarrow{ }^{1} E_{\mathrm{u}}\left(2 e_{\mathrm{g}} \rightarrow 2 a_{2 \mathrm{u}}\right) & 37,600
\end{array}
$$

It is noted that the ${ }^{1} A_{1 \mathrm{~g}} \rightarrow{ }^{1} B_{1 \mathrm{u}}$ transition is formally symmetry forbidden, even though it is Laporte allowed $(\mathrm{g} \leftrightarrow \mathrm{u})$. Hence the intensity of this transition is somewhere between a d-d band and a symmetry-allowed charge transfer band.

Fig. 8.9.6.
Charge transfer spectrum of $\left[\mathrm{PtCl}_{4}\right]^{2-}$ in aqueous solution containing excess $\mathrm{Cl}^{-}$. Note that these bands are much more intense than the d-d bands observed in $\left[\mathrm{PtCl}_{4}\right]^{2-}$ (see Fig. 8.9.5).

Fig. 8.9.7.
Charge transfer spectrum of $\left[\mathrm{Ni}(\mathrm{CN})_{4}\right]^{2-}$ in aqueous solution. Note that these bands are also much more intense than the d-d bands (Fig. 8.9.5).

### 8.10 Vibronic interaction in transition metal complexes

As mentioned earlier, in a centrosymmetric complex, d-d transitions are Laporte forbidden. The fact that they are observed at all is due to a mechanism called vibronic interaction, which is a mixing of the vibrational and electronic wavefunctions. Qualitatively, we may imagine that an electronic transition occurs at the very moment some vibrational modes of the complex distort the molecule in such a way that the center of symmetry is destroyed. When such a vibration takes place, the "g" character of the state is lost and the transition becomes (very slightly) allowed. Figure 8.10 .1 shows two vibrations, with "u" symmetry, of an octahedral complex which remove the inversion center.

When the vibrational and electronic motions are coupled, the intensity integral for the transition between $\psi^{\prime}$ (ground state) and $\psi^{\prime \prime}$ (excited state) has the form

$$
\int\left(\psi_{\mathrm{e}}^{\prime} \psi_{\mathrm{v}}^{\prime}\right) x\left(\psi_{\mathrm{e}}^{\prime \prime} \psi_{\mathrm{v}}^{\prime \prime}\right) d \tau, \quad(x \text { may also be } y \text { or } z)
$$

where $\psi_{\mathrm{e}}$ and $\psi_{\mathrm{v}}$ are the electronic and vibrational wavefunctions for a given state, respectively. To evaluate this integral by symmetry arguments, we first note that $\psi_{\mathrm{v}}^{\prime}$ is totally symmetric and can thus be ignored. (This is because all vibrational modes are in their ground state, which is totally symmetric.) Now we need to determine whether there exists a vibration (with symmetry $\Gamma_{\mathrm{v}}$ ) such that, even though the product representation of $\psi_{\mathrm{e}}^{\prime \prime} x \psi_{\mathrm{e}}^{\prime}, \Gamma\left(\psi_{\mathrm{e}}^{\prime \prime} x \psi_{\mathrm{e}}^{\prime}\right)$, does not contain the totally symmetric representation $\Gamma_{\mathrm{TS}}$, the product representation $\Gamma\left(\psi_{\mathrm{e}}^{\prime \prime} x \psi_{\mathrm{e}}^{\prime}\right) \times \Gamma_{\mathrm{v}}$ does. When $\Gamma\left(\psi_{\mathrm{e}}^{\prime \prime} x \psi_{\mathrm{e}}^{\prime}\right) \times \Gamma_{\mathrm{v}}$ contains $\Gamma_{\mathrm{TS}}$, the aforementioned intensity integral would not vanish. Also, for $\Gamma\left(\psi_{\mathrm{e}}^{\prime \prime} x \psi_{\mathrm{e}}^{\prime}\right) \times \Gamma_{\mathrm{v}}$ to contain $\Gamma_{\mathrm{TS}}$, we need $\Gamma\left(\psi_{\mathrm{e}}^{\prime \prime} x \psi_{\mathrm{e}}^{\prime}\right)$ to contain $\Gamma_{\mathrm{v}}$.
An example will illustrate the above arguments. The ground state of a $\mathrm{d}^{1}$ octahedral complex $\mathrm{ML}_{6}$ is ${ }^{2} T_{2 \mathrm{~g}}$ and the only excited state for this complex is ${ }^{2} E_{\mathrm{g}}$. In the $O_{\mathrm{h}}$ point group, $\Gamma_{x, y, z}$ is $T_{1 \mathrm{u}}$. Also, this complex has the vibrational modes

$$
\Gamma_{\mathrm{vib}}=A_{1 \mathrm{~g}}+E_{\mathrm{g}}+2 T_{1 \mathrm{u}}+T_{2 \mathrm{~g}}+T_{2 \mathrm{u}}
$$

For the transition ${ }^{2} T_{2 \mathrm{~g}} \rightarrow{ }^{2} E_{\mathrm{g}}$, we have

$$
T_{2 \mathrm{~g}} \times T_{1 \mathrm{u}} \times E_{\mathrm{g}}=A_{1 \mathrm{u}}+A_{2 \mathrm{u}}+2 E_{\mathrm{u}}+2 T_{1 \mathrm{u}}+2 T_{2 \mathrm{u}}
$$

Therefore, for this electronic transition to have any intensity, it must be accompanied by a vibration of either $T_{1 \mathrm{u}}$ or $T_{2 \mathrm{u}}$ symmetry.
We now employ one final example to conclude this discussion. The planar complex $\left[\mathrm{Cu}(3-\mathrm{Ph}-\mathrm{acac})_{2}\right]$ has $D_{2 \mathrm{~h}}$ symmetry and its structure is shown in Fig. 8.10.2. In its crystal spectrum four $y$-polarized bands are observed and they have been assigned to the transitions ${ }^{2} B_{1 \mathrm{~g}} \rightarrow{ }^{2} A_{\mathrm{g}}$ (twice), ${ }^{2} B_{1 \mathrm{~g}} \rightarrow{ }^{2} B_{2 \mathrm{~g}}$, and ${ }^{2} B_{1 \mathrm{~g}} \rightarrow{ }^{2} B_{3 \mathrm{~g}}$. Given that the " u " vibrational modes of a $\mathrm{MA}_{2} \mathrm{~B}_{2}$ complex belonging to the $D_{2 \mathrm{~h}}$ point group are of symmetries $A_{\mathrm{u}}, B_{1 \mathrm{u}}, B_{2 \mathrm{u}}$, and $B_{3 \mathrm{u}}$, we can readily determine the vibrations responsible for the forbidden transitions to gain intensity.

In the $D_{2 \mathrm{~h}}$ group, $\Gamma_{y}=B_{2 \mathrm{u}}$. So for the ${ }^{2} B_{1 \mathrm{~g}} \rightarrow{ }^{2} A_{\mathrm{g}}$ transition, we have $B_{1 \mathrm{~g}} \times B_{2 \mathrm{u}} \times A_{\mathrm{g}}=B_{3 \mathrm{u}}$; i.e., the $B_{3 \mathrm{u}}$ vibrational mode is needed. For the ${ }^{2} B_{1 \mathrm{~g}} \rightarrow$ ${ }^{2} B_{2 \mathrm{~g}}$ transition $B_{1 \mathrm{~g}} \times B_{2 \mathrm{u}} \times B_{2 \mathrm{~g}}=B_{1 \mathrm{u}}$, or the $B_{1 \mathrm{u}}$ vibrational mode is required. Finally, for ${ }^{2} B_{1 \mathrm{~g}} \rightarrow{ }^{2} B_{3 \mathrm{~g}}, B_{1 \mathrm{~g}} \times B_{2 \mathrm{u}} \times B_{3 \mathrm{~g}}=A_{\mathrm{u}}$; i.e., the $A_{\mathrm{u}}$ mode of vibration accompanies this electronic transition.

### 8.11 The $4 f$ orbitals and their crystal field splitting patterns

To conclude this chapter, we discuss the shapes of the $4 f$ orbitals as well as their splitting patterns in octahedral and tetrahedral crystal fields. The results are of use in studying the complexes of the rare-earth elements.

### 8.11.1 The shapes of the 4 f orbitals

The are seven 4 f orbitals that correspond to $m_{\ell}$ values of $0, \pm 1, \pm 2$, and $\pm 3$ in their angular parts. Of these the one with $m_{\ell}=0$ is real, but the other six are complex, and their linear combinations lead to real functions. However, there is not a unique or conventional way to express the angular functions of the sevenfold degenerate 4 f orbitals, all of which have three nodes and ungerade (u) symmetry. If simple linear combinations of the $m_{\ell}= \pm 1, \pm 2$, and $\pm 3$ functions are taken in pairs, the resulting six Cartesian functions (with abbreviated labels enclosed in square brackets) are $x\left(4 z^{2}-x^{2}-y^{2}\right)\left[x z^{2}\right] ; y\left(4 z^{2}-x^{2}-y^{2}\right)\left[y z^{2}\right]$; $x y z ; z\left(x^{2}-y^{2}\right) ; x\left(x^{2}-3 y^{2}\right)$; and $y\left(3 x^{2}-y^{2}\right)$. These six orbitals, together with $z\left(2 z^{2}-3 x^{2}-3 y^{2}\right)\left[z^{3}\right]$ arising from $m_{\ell}=0$, constitute the general set of 4 f orbitals as displayed in Table 2.1.2, and they are also listed in Table 8.11.1.

Fig. 8.10.2.

## Symmetry in Chemistry

Table 8.11.1. Angular functions of the 4 f orbitals

| Orbital $^{*}$ | The general set | The cubic set |
| :---: | :---: | :---: |
| $z^{3}$ | $\frac{1}{4}(7 / \pi)^{\frac{1}{2}}\left(5 \cos ^{3} \theta-3 \cos \theta\right)$ | $\frac{1}{4}(7 / \pi)^{\frac{1}{2}}\left(5 \cos ^{3} \theta-3 \cos \theta\right)$ |
| $z\left(x^{2}-y^{2}\right)$ | $\frac{1}{4}(105 / \pi)^{\frac{1}{2}} \sin ^{2} \theta \cos \theta \cos 2 \phi$ | $\frac{1}{4}(105 / \pi)^{\frac{1}{2}} \sin ^{2} \theta \cos \theta \cos 2 \phi$ |
| $x y z$ | $\frac{1}{4}(105 / \pi)^{\frac{1}{2}} \sin ^{2} \theta \cos \theta \sin 2 \phi$ | $\frac{1}{4}(105 / \pi)^{\frac{1}{2}} \sin ^{2} \theta \cos \theta \sin 2 \phi$ |
| $x^{3}$ | - | $\frac{1}{4}(7 / \pi)^{\frac{1}{2}} \sin \theta \cos \phi\left(5 \sin ^{2} \theta \cos ^{2} \phi-3\right)$ |
| $x\left(z^{2}-y^{2}\right)$ | - | $\frac{1}{4}(105 / \pi)^{\frac{1}{2}} \sin \theta \cos \phi\left(\cos ^{2} \theta-\sin ^{2} \theta \sin ^{2} \phi\right)$ |
| $x z^{2}$ | $\frac{1}{8}(42 / \pi)^{\frac{1}{2}} \sin \theta-\left(5 \cos ^{2} \theta-1\right) \cos \phi$ | - |
| $x\left(x^{2}-3 y^{2}\right)$ | $\frac{1}{8}(70 / \pi)^{\frac{1}{2}} \sin ^{3} \theta \cos 3 \phi$ | - |
| $y^{3}$ | $-\quad-\quad \frac{1}{4}(105 / \pi)^{\frac{1}{2}} \sin \theta \sin \phi\left(\cos ^{2} \theta-\sin ^{2} \theta \cos ^{2} \phi\right)$ |  |
| $y\left(z^{2}-x^{2}\right)$ | $\frac{1}{4}(7 / \pi)^{\frac{1}{2}} \sin \theta \sin \phi\left(5 \sin ^{2} \theta \sin ^{2} \phi-3\right)$ |  |
| $y z^{2}$ | $\frac{1}{8}(42 / \pi)^{\frac{1}{2}} \sin \theta\left(5 \cos ^{2} \theta-1\right) \sin \phi$ | - |
| $y\left(3 x^{2}-y^{2}\right)$ | $\frac{1}{8}(70 / \pi)^{\frac{1}{2}} \sin ^{3} \theta \sin 3 \phi$ | - |

$* z^{3}$ denotes the $\mathrm{f}_{z^{3}}$ orbital, etc.
The shapes of the seven 4 f orbitals in the general set are illustrated in Fig. 8.11.1, and their nodal characteristics are shown in Fig. 8.11.2. The number of vertical nodal planes varies from 0 to 3 . The $z^{3}, y z^{2}$, and $x z^{2}$ orbitals each has two nodes that are the curved surfaces of a pair of cones with a common vertex at the origin.

(

## Fig. 8.11.1.

The general set of the seven 4 f orbitals. The gray and white regions in each orbital bear positive and negative signs, respectively. Placed to the left of the $z^{3}$ orbital is a cross section of $\psi^{2}\left(z^{3}\right)$, in which dots indicate the "electron-density" maxima, and contour lines are drawn for $\psi^{2} / \psi_{\max }^{2}=0.1$.

For systems of cubic symmetry, it is convenient to choose an alternative set of combinations known as the cubic set. Their abbreviated Cartesian labels and symmetry species in point group $O_{\mathrm{h}}$ are $x y z\left(A_{2 \mathrm{u}}\right) ; x^{3}, y^{3}, z^{3}\left(T_{1 \mathrm{u}}\right) ; z\left(x^{2}-y^{2}\right)$, $x\left(z^{2}-y^{2}\right), y\left(z^{2}-x^{2}\right)\left(T_{2 \mathrm{u}}\right)$. These functions are particularly useful when octahedral and tetrahedral crystal field splitting patterns are considered. The

orbitals $x^{3}$ and $y^{3}$ have the same shape as $z^{3}$, but they lie along the $x$ and $y$ axis, respectively. The orbital $x y z$ has eight lobes pointing toward the corners of a cube. The orbitals $x\left(z^{2}-y^{2}\right), y\left(z^{2}-x^{2}\right)$, and $z\left(x^{2}-y^{2}\right)$ are shaped like $x y z$, but they are rotated by $45^{\circ}$ about the $x, y$, and $z$ axis, respectively.

The two sets of angular functions of the 4 f orbitals are compared in Table 8.11.1; it is noted that three of them, namely $z^{3}, z\left(x^{2}-y^{2}\right)$, and $x y z$, are common to both sets. The remaining four members of the two sets are related by linear transformation. Specifically,

$$
\begin{align*}
f_{x^{3}} & =-\frac{1}{4}\left[(6)^{\frac{1}{2}} f_{x z^{2}}-(10)^{\frac{1}{2}} f_{x\left(x^{2}-3 y^{2}\right)}\right],  \tag{8.11.1}\\
f_{y^{3}} & =-\frac{1}{4}\left[(6)^{\frac{1}{2}} f_{y z^{2}}+(10)^{\frac{1}{2}} f_{y\left(3 x^{2}-y^{2}\right)}\right],  \tag{8.11.2}\\
f_{x\left(z^{2}-y^{2}\right)} & =\frac{1}{4}\left[(10)^{\frac{1}{2}} f_{x z^{2}}+(6)^{\frac{1}{2}} f_{x\left(x^{2}-3 y^{2}\right)}\right],  \tag{8.11.3}\\
f_{y\left(z^{2}-x^{2}\right)} & =\frac{1}{4}\left[(10)^{\frac{1}{2}} f_{y z^{2}}-(6)^{\frac{1}{2}} f_{y\left(3 x^{2}-y^{2}\right)}\right] . \tag{8.11.4}
\end{align*}
$$

### 8.11.2 Crystal feld splitting patterns of the 4 f orbitals

In an octahedral crystal field, the seven 4 forbitals should split into two groups of triply degenerate sets and one non-degenerate orbital. This information can be readily obtained when we examine the character table of the $O_{\mathrm{h}}$ group, where it is seen that the $x^{3}, y^{3}$, and $z^{3}$ orbitals form a $T_{2 \mathrm{u}}$ set, the $z\left(x^{2}-y^{2}\right), y\left(z^{2}-x^{2}\right)$, and $x\left(z^{2}-y^{2}\right)$ functions constitute a $T_{1 \mathrm{u}}$ set, while the remaining orbital, $x y z$, has $A_{2 \mathrm{u}}$ symmetry. In the following, we discuss the energy ordering of these three sets of orbitals.

If we place six ligands at the centers of the faces of a cube, as shown in Fig. 8.11.3, it can be readily seen that the $t_{2 \mathrm{u}}$ orbitals $\left(x^{3}, y^{3}, z^{3}\right)$ have lobes pointing directly toward the ligands. Hence they have the highest energy. Also,

Fig. 8.11.2.
Nodal characteristics of the general set of $4 f$ orbitals. The positive and negative lobes in each orbital are shaded and un-shaded, respectively.

Fig. 8.11.3.

Fig. 8.11.4.
Splitting pattern of the 4 f orbitals in a tetrahedral crystal field.

the eight lobes of the $a_{2 \mathrm{u}}$ orbital ( $x y z$ ) point directly at the corners of the cube. In other words, the eight lobes of the $x y z$ orbitals are as far away from the ligands as possible. Hence, this orbital should have the lowest energy. Finally, the $t_{1 \mathrm{u}}$ orbitals have lobes pointing toward the midpoints of the edges of the cube. Hence, they have energy lower than that for the $t_{2 u}$ orbitals, but higher than that for the $a_{2 \mathrm{u}}$ orbital. When this problem is treated quantitatively by perturbation theory, we find that the $t_{2 u}$ orbitals are destabilized by $6 D q^{\prime}$, while the $t_{1 \mathrm{u}}$ and $a_{2 u}$ orbitals are stabilized by $2 D q^{\prime}$ and $12 D q^{\prime}$, respectively. These results are summarized in Fig. 8.11.3. It should be noted in the crystal field parameter $D q^{\prime}$ given in Fig. 8.11.3 is not the same as that for transition metal complexes [eqs. (8.1.3) and (8.1.4)], as f orbitals, rather than d orbitals, are involved here. Also, examining the splitting pattern shown in Fig. 8.11.3, we can see that the center of gravity is once again preserved, as the energy lost by the $t_{2 u}$ orbitals is balanced by the energy gained by the $t_{1 \mathrm{u}}$ and $a_{2 \mathrm{u}}$ orbitals.

The splitting pattern of the 4 f orbitals in a tetrahedral crystal field can be deduced in a similar manner. If we adopt the coordinate system shown in Fig. 8.11.4, we can obtain the splitting pattern shown in the same figure. As expected the 1:3:3 pattern for the tetrahedral crystal field is just the reverse of the 3:3:1 pattern of the octahedral field. Also, the symmetry classification of the orbitals in a tetrahedral complex can be readily obtained from the character table of the $T_{\mathrm{d}}$ group.

## Symmetry in Crystals

A single crystal is a homogeneous solid, which means that all parts within it have identical properties. However, it is not in general isotropic, so that physical properties such as thermal and electrical conductivity, refractive index, and non-linear optical effect generally vary in different directions.

### 9.1 The crystal as a geometrical entity

The majority of pure compounds can be obtained in crystalline form, although the individual specimens may often be very small or imperfectly formed. A well-developed crystal takes the shape of a polyhedron with planar faces, linear edges, and sharp vertices. In the simplest terms, a crystal may be defined as a homogeneous, anisotropic solid having the natural shape of a polyhedron.

### 9.1.1 Interfacial angles

In 1669 , Steno discovered that, for a given crystalline material, despite variations in size and shape (i.e., its habit), the angles between corresponding faces of individual crystals are equal. This is known as the Law of Constancy of Interfacial Angles. The geometrical properties (the form) of a crystal may be better visualized by considering an origin inside it from which perpendiculars are drawn to all faces. This radiating set of normals is independent of the size and shape of individual specimens, and is thus an invariant representation of the crystal form. In Fig. 9.1.1, a perfectly developed hexagonal plate-like crystal is shown in part (a), and a set of normals are drawn to its vertical faces from an interior point in part (b). Two other crystal specimens that look very different

Representation of vertical crystal faces of a hexagonal by a system of radiating normals from a point inside it. The broken lines indicate extensions of the planar faces.

are shown in parts (c) and (d), and they are seen to possess the same set of radiating normals.

### 9.1.2 Miller indices

For a mathematical description of crystal faces, take any three non-parallel faces (chosen to be mutually orthogonal, if possible) and take their intersections as reference axes, which are labeled $\mathrm{OA}, \mathrm{OB}$, and OC with the origin at O , as shown in Fig. 9.1.2(a). Let another face (the standard face or parametral face $\mathrm{A}^{\prime} \mathrm{B}^{\prime} \mathrm{C}^{\prime}$ ) meet these axes at $\mathrm{A}^{\prime}, \mathrm{B}^{\prime}$, and $\mathrm{C}^{\prime}$, making intercepts $\mathrm{OA}^{\prime}=a, \mathrm{OB}^{\prime}=b$ and $\mathrm{OC}^{\prime}=c$, respectively. The ratios $a: b: c$ are called the axial ratios.

If now any face on the crystal makes intercepts of $a / h, b / k$, and $c / \ell$ on the axes OA, OB, and OC, respectively, it is said to have the Miller indices ( $h k \ell$ ), which have no common divisor. The Miller indices of any face are thus calculated by dividing its intercepts on the axes by $a, b, c$, respectively, taking the reciprocals, and clearing them of fractions if necessary. If a plane is parallel to an axis, the intercept is at infinity and the corresponding Miller index is zero. The Miller indices of the standard face are (111), and the plane outlined by the dotted lines in Fig. 9.1.2(a) has intercepts $a / 3, b, c / 2$, which correspond to the Miller indices (312). In Fig. 9.1.2(b) another plane is drawn parallel to the aforesaid plane, making intercepts $a, 3 b, 3 c / 2$; it is obvious that both planes outlined by dotted lines in Fig 9.1.2 have the same orientation as described by the same Miller indices (312).

In 1784, Haüy formulated the Law of Rational Indices, which states that all faces of a crystal can be described by Miller indices ( $h k \ell$ ), and for those faces that commonly occur, $h, k$, and $\ell$ are all small integers. The eight faces of an octahedron are (111), ( $(\overline{1} 11),(1 \overline{1} 1),(11 \overline{1}),(1 \overline{1} \overline{1}),(\overline{1} 1 \overline{1}),(\overline{1} \overline{1} 1)$, and $(\overline{1} \overline{1} \overline{1})$. The form symbol that represents this set of eight faces is $\{111\}$. The form symbol for the six faces of a cube is $\{100\}$. Some examples in the cubic system are shown in Figs. 9.1.3. and 9.1.4.

### 9.1.3 Thirty-two crystal classes (crystallographic point groups)

The Hermann-Mauguin notation for the description of point group symmetry (in contrast to the Schönflies system used in Chapter 6) is widely adopted in crystallography. An $n$-fold rotation axis is simply designated as $n$. An object is said to possess an $n$-fold inversion axis $\bar{n}$ if it can be brought into an equivalent configuration by a rotation of $360^{\circ} / n$ in combination with inversion through a

(g)

(d)

(h)

point on the axis. Note that $\overline{1}$ is an inversion center, and $\overline{2}$ is the same as mirror plane $m$. The symbol $2 / m$ means a twofold axis with a mirror plane $m$ lying perpendicular to it.

A single crystal, considered as a finite object, may possess a certain combination of point symmetry elements in different directions, and the symmetry operations derived from them constitute a group in the mathematical sense. The self-consistent set of symmetry elements possessed by a crystal is known as a crystal class (or crystallographic point group). Hessel showed in 1830 that there are thirty-two self-consistent combinations of symmetry elements $n$ and $\bar{n}(n=1,2,3,4$, and 6 ), namely the thirty-two crystal classes, applicable to the description of the external forms of crystalline compounds. This important
result is a natural consequence of the Law of Rational Indices, and the deduction proceeds in the following way.

Consider a crystal having a $n$-fold rotation axis, often simply referred to as an $n$-axis. In Fig. 9.1.5, $\mathrm{OE}, \mathrm{OE}^{\prime}, \mathrm{OE}^{\prime \prime}$ represent the horizontal projections of three vertical planes generated by successive rotations of $2 \pi / n$ about the symmetry axis, which passes through point $O$. As reference axes, we adopt the $n$-axis, $\mathrm{OE}^{\prime}$, and $\mathrm{OE}^{\prime \prime}$, and the latter two are assigned unit length. Next, we consider a plane $\mathrm{E}^{\prime} \mathrm{F}$ which is drawn parallel to OE . The intercepts of $\mathrm{E}^{\prime} \mathrm{F}$ on the three axes are $\infty, 1$, and $(\sec 2 \pi / n) / 2$. The Miller indices of plane $\mathrm{E}^{\prime} \mathrm{F}$ are therefore $(0,1,2 \cos 2 \pi / n)$ which must be integers. Since $|\cos 2 \pi / n| \leq 1$, the only possible values of $2 \cos 2 \pi / n$ are $\pm 2, \pm 1$, and 0 . Hence
$\cos 2 \pi / n=1,1 / 2,0,-1 / 2,-1$, leading to $n=1,6,4,3,2$, respectively.
Therefore, in compliance with the Law of Rational Indices, only $n$-axes with $n=1,2,3,4$ and 6 are allowed in crystals. The occurrence of the inversion center means that the rotation-inversion axes $\overline{1}, \overline{2}(=m), \overline{3}, \overline{4}$ and $\overline{6}$ are also possible.

### 9.1.4 Stereographic projection

The thirty-two crystal classes are usually represented by stereographic projections of a system of equivalent points. The stereographic projection of a particular crystal class is derived in the manner illustrated in Fig. 9.1.6. Consider an idealized crystal whose planar faces exhibit the full symmetry $\overline{4}$ of its crystallographic point group. Enclose the crystal by a sphere and draw perpendiculars to all faces from a point inside the crystal. The radiating normals intersect the sphere to give a set of points A, B, C and D. From the south pole S of the sphere, draw lines to the points A and B lying in the northern hemisphere, and their intersection in the equatorial plane gives points $\mathrm{A}^{\prime}$ and $\mathrm{B}^{\prime}$ denoted by the small open circles. Similarly, lines are drawn from the north pole N to points C and D in the southern hemisphere to intersect the equatorial plane, yielding points $\mathrm{C}^{\prime}$ and $\mathrm{D}^{\prime}$ denoted by the filled dots. The set of equivalent points $\mathrm{A}^{\prime}$, $\mathrm{B}^{\prime}, \mathrm{C}^{\prime}$, and $\mathrm{D}^{\prime}$ in the equatorial circle is a faithful representation of the crystal class $\overline{4}$.

Fig. 9.1.5.
Vertical planes related by a $n$-fold rotation axis.

Fig. 9.1.6.
Stereographic projection of crystal class (point group) $\overline{4}$.

## Symmetry in Chemistry

The stereographic projection of a crystal class consists of all intersected equivalent points in the equatorial circle and associated symmetry symbols. The location of the symmetry elements and the stereographic projection of point group $\overline{4} 3 m$ is shown in Fig. 9.1.7. The graphic symbols indicate three $\overline{4}$-axes along the principal axes of the cube, four 3-axes along the body diagonals, and six mirror planes normal to the face diagonals.

All thirty-two crystal classes in stereographic projection are tabulated in Fig. 9.1.8. For each crystal class, two diagrams showing the equipoints and symmetry elements are displayed side by side. Note that the thicker lines indicate mirror planes, and the meaning of the graphic symbols of the symmetry elements are given in Table 9.3.2.

### 9.1.5 Acentric crystalline materials

Of the thirty-two crystal classes, twenty-two lack an inversion center and are therefore known as non-centrosymmetric, or acentric. Crystalline and polycrystalline bulk materials that belong to acentric crystal classes can exhibit a variety of technologically important physical properties, including optical activity, pyroelectricity, piezoelectricity, and second-harmonic generation (SHG, or frequency doubling). The relationships between acentric crystal classes and physical properties of bulk materials are summarized in Table 9.1.1.

Eleven acentric crystal classes are chiral, i.e., they exist in enantiomorphic forms, whereas ten are polar, i.e., they exhibit a dipole moment. Only five ( 1,2 , 3,4 , and 6 ) have both chiral and polar symmetry. All acentric crystal classes except 432 possess the same symmetry requirements for materials to display piezoelectric and SHG properties. Both ferroelectricity and pyroelectricity are related to polarity: a ferroelectric material crystallizes in one of ten polar crystal classes ( $1,2,3,4,6, m, m m 2,3 m, 4 m m$, and 6 mm ) and possesses a permanent dipole moment that can be reversed by an applied voltage, but the spontaneous polarization (as a function of temperature) of a pyroelectric material is not. Thus all ferroelectric materials are pyroelectric, but the converse is not true.

### 9.2 The crystal as a lattice

### 9.2.1 The lattice concept

A study of the external symmetry of crystals naturally leads to the idea that a single crystal is a three-dimensional periodic structure; i.e., it is built of a basic structural unit that is repeated with regular periodicity in three-dimensional space. Such an infinite periodic structure can be conveniently and completely described in terms of a lattice (or space lattice), which consists of a set of points (mathematical points that are dimensionless) that have identical environments.

An infinitely extended, linear, and regular system of points is called a row, and it is completely described by its repeat distance $a$. A planar regular array of points is called a net, which can be specified by two repeat distances $a$ and $b$ and the angle $\gamma$ between them. The analogous system of regularly distributed points in three dimensions constitute a lattice (or space lattice), which is described by a set of three non-coplanar vectors ( $\mathbf{a}, \mathbf{b}, \mathbf{c}$ ) or six parameters: the repeat intervals $a, b, c$ and the angles $\alpha, \beta, \gamma$ between the vectors. As far as possible, the angles are chosen to be obtuse, particularly $90^{\circ}$ or $120^{\circ}$, and lattices in one, two, and three dimensions are illustrated in Fig. 9.2.1.

### 9.2.2 Unit cell

Rather than having to visualize an infinitely extended lattice, we can focus our attention on a small portion of it, namely a unit cell, which is a parallelopiped (or box) with lattice points located at its eight corners. The entire lattice can then be re-generated by stacking identical unit cells in three dimensions. A unit

Fig. 9.2.1.
Row, net and lattice.

Fig. 9.2.2.
(a) Two-dimensional lattice showing different choices of the unit cell. (b) A primitive unit cell for a three-dimensional lattice.

cell with lattice points only at the corners is described as primitive, as it contains only one structural motif (one lattice point). Alternatively, it is also possible to choose a centered unit cell that contains more than one lattice point.

Figure 9.2.2(a) shows a net with differently chosen unit cells. The unit cells having sides $\left(a_{1}, b_{1}\right),\left(a_{2}, b_{1}\right)$, and $\left(a_{2}, b_{2}\right)$ are primitive, and the one with sides $\left(a_{1}, b_{2}\right)$ is $C$-centered. Note that the unit cell outlined by dotted lines is also a legitimate one, although it is not a good choice.

In general, the size and shape of a unit cell is specified by six parameters: the axial lengths $a, b, c$ and the interaxial angles $\alpha, \beta, \gamma$ [Fig.9.2.2(b)]. The volume of a triclinic unit cell is calculated by the formula $V=a b c\left(1-\cos ^{2} \alpha-\right.$ $\left.\cos ^{2} \beta-\cos ^{2} \gamma+2 \cos \alpha \cos \beta \cos \gamma\right)^{1 / 2}$, which reduces to simpler forms for the other crystal systems.

The choice of a unit cell depends on the best description of the symmetry elements present in the crystal structure. In practice, as far as it is possible, the unit cell is chosen such that some or all of the angles are $90^{\circ}$ or $120^{\circ}$. Repetition of the unit cell by translations in three non-coplanar directions regenerates the whole space lattice.

The unit cell is the smallest volume that contains the most essential structural information required to describe the crystal structure. For a particular crystalline compound, each lattice point is associated with a basic structural unit, which may be an atom, a number of atoms, a molecule, or a number of molecules. In other words, if the coordinates of all atoms within the unit cell are known, complete information is obtained on the atomic arrangement, molecular packing, and derived parameters such as interatomic distances and bond angles.

### 9.2.3 Fourteen Bravais lattices

Bravais showed in 1850 that all three-dimensional lattices can be classified into 14 distinct types, namely the fourteen Bravais lattices, the unit cells of which are displayed in Fig. 9.2.3. Primitive lattices are given the symbol $P$. The symbol $C$ denotes a $C$ face centered lattice which has additional lattice points at the centers of a pair of opposite faces defined by the $a$ and $b$ axes; likewise the symbol $A$ or $B$ describes a lattice centered at the corresponding A or B face. When the lattice has all faces centered, the symbol $F$ is used. The symbol $I$ is applicable when an additional lattice point is located at the center of the unit cell. The symbol $R$ is used for a rhombohedral lattice, which is based on a rhombohedral unit cell (with $a=b=c$ and $\alpha=\beta=\gamma \neq 90^{\circ}$ ) in the older literature. Nowadays the rhombohedral lattice is generally referred to as a hexagonal unit cell that has additional lattice points at $(2 / 3,1 / 3,1 / 3)$ and $(1 / 3,2 / 3,2 / 3)$ in the conventional obverse setting, or $(1 / 3,2 / 3,1 / 3)$ and $(2 / 3,1 / 3,2 / 3)$ in the alternative reverse setting. In Fig. 9.2.3 both the primitive rhombohedral $(R)$ and obverse triple hexagonal $(h R)$ unit cells are shown for the rhombohedral lattice.

### 9.2.4 Seven crystal systems

The fourteen Bravais lattices are divided into seven crystal systems. The term "system" indicates reference to a suitable set of axes that bear specific relationships, as illustrated in Table 9.2.1. For example, if the axial lengths take arbitrary values and the interaxial angles are all right angles, the crystal system

Fig. 9.2.3.
The fourteen Bravais lattices.

Table 9.2.1. Characteristics of the seven crystal systems

| System | Crystal classes | Unit cell | Standard axes |
| :---: | :---: | :---: | :---: |
| Triclinic | 1, $\overline{1}$ | $a \neq b \neq c$ | a, b, c not coplanar |
| Monoclinic | 2, m, $2 / m$ | $\begin{aligned} & \alpha \neq \beta \neq \gamma \\ & a \neq b \neq c \\ & \alpha=\gamma=90^{\circ} \end{aligned}$ | principal axis $\boldsymbol{b}$ parallel to 2-axis or perpendicular to $m$; a, $\mathbf{c}$ smallest lattice vectors perpendicular to $\mathbf{b}$ |
| Orthorhombic | 222, mm2, mmm | $\begin{aligned} & a \neq b \neq c \\ & \alpha=\beta=\gamma=90^{\circ} \end{aligned}$ | $\mathbf{a}, \mathbf{b}, \mathbf{c}$ each oriented along a 2 -axis, or perpendicular to a mirror plane |
| Tetragonal | $4, \overline{4}, 4 / m, 422$, $4 m m, \overline{4} 2 m$, 4/mmm | $\begin{aligned} & a=b \neq c \\ & \alpha=\beta=\gamma=90^{\circ} \end{aligned}$ | c oriented parallel to 4 - or $\overline{4}$-axis; $\mathbf{a}, \mathbf{b}$ smallest lattice vectors perpendicular to $\mathbf{c}$ |
| Trigonal | $3, \overline{3}, 32,3 m, \overline{3} m$ |  |  |
| Rhombohedral setting |  | $\begin{aligned} & a=b=c, \\ & \alpha=\beta=\gamma \neq 90^{\circ} \\ & \text { and }<120^{\circ} \end{aligned}$ | $\mathbf{a}, \mathbf{b}, \mathbf{c}$ selected to be the smallest non-coplanar lattice vectors related by 3 - or $\overline{3}$-axis |
| Hexagonal setting |  | $\begin{aligned} & a=b \neq c \\ & \alpha=\beta=90^{\circ} \\ & \gamma=120^{\circ} \end{aligned}$ | c parallel to 3- or $\overline{3}$-axis; $\mathbf{a}, \mathbf{b}$ smallest lattice vectors perpendicular to $\mathbf{c}$ |
| Hexagonal | $\begin{aligned} & 6, \overline{6}, 6 / m, 622, \\ & 6 m m, \overline{6} m 2, \\ & 6 / \mathrm{mmm} \end{aligned}$ | $\begin{aligned} & a=b \neq c \\ & \alpha=\beta=90^{\circ} \\ & \gamma=120^{\circ} \end{aligned}$ | c parallel to 6 - or $\overline{6}$-axis; a, $\mathbf{b}$ smallest lattice vectors perpendicular to $\mathbf{c}$ |
| Cubic | $\begin{gathered} 23, m \overline{3}, \overline{4} 32, \\ \overline{4} 3 m, m \overline{3} m \end{gathered}$ | $\begin{aligned} & a=b=c \\ & \alpha=\beta=\gamma=90^{\circ} \end{aligned}$ | $\mathbf{a}, \mathbf{b}, \mathbf{c}$ each parallel to a 2 -axis ( 23 and $m \overline{3}$ ), or to a $\overline{4}$-axis ( $\overline{4} 3 m$ ), or a 4-axis (432, $m \overline{3} m$ ) |

is orthorhombic; if only one angle is a right angle, the crystal system is monoclinic (meaning one inclined axis). The crystal system is triclinic (meaning three inclined axes) if all six parameters $a, b, c, \alpha, \beta$, and $\gamma$ take on unrestricted values. It should be emphasized that the crystal system is determined by the characteristic symmetry elements present in the crystal lattice, and not by the unit-cell parameters.

The thirty-two crystal classes (crystallographic point groups) described in Section 9.1.4 can also be classified into the same seven crystal systems, depending on the most convenient coordinate system used to indicate the location and orientation of their characteristic symmetry elements, as shown in Table 9.2.1.

### 9.2.5 Unit cell transformation

Consider two different choices of unit cells: a $F$-centered unit cell with axes $\left(a_{1}, b_{1}, c_{1}\right)$ and a primitive one with axes ( $a_{2}, b_{2}, c_{2}$ ), as shown in Fig. 9.2.4. We can write

$$
\begin{array}{lll}
\mathbf{a}_{2}=1 / 2 \mathbf{a}_{1}+1 / 2 \mathbf{c}_{1} & \mathbf{a}_{1}=\mathbf{a}_{2}+\mathbf{b}_{2}-\mathbf{c}_{2} \\
\mathbf{b}_{2}=1 / 2 \mathbf{a}_{1}+{ }^{1} / 2 \mathbf{b}_{1} & \text { and } & \mathbf{b}_{1}=-\mathbf{a}_{2}+\mathbf{b}_{2}+\mathbf{c}_{2} \\
\mathbf{c}_{2}=1 / 2 \mathbf{b}_{1}+{ }^{1 / 2} \mathbf{c}_{1} & & \mathbf{c}_{1}=\mathbf{a}_{2}-\mathbf{b}_{2}+\mathbf{c}_{2}
\end{array}
$$

These relationships may be expressed in the form of square matrices:

The $h k \ell$ indices of a reflection referred to these two unit cells are transformed in the same manner, i.e., $h_{2}=1 / 2 h_{1}+0 k_{1}+{ }^{1} / 2 \ell_{1}$, etc. The volume ratio is equal to the modulus of the determinant of the transformation matrix; if we take the left matrix, $V_{2} / V_{1}$ is equal to $1 / 4$.

As a concrete example, consider a rhombohedral lattice and the relationship between the primitive rhombohedral unit cell (in the conventional obverse setting) and the associated triple-sized hexagonal unit cell, as indicated in Fig. 9.2.5.

The triply primitive hexagonal unit cell has lattice points at (000), $(2 / 3,1 / 3,1 / 3)$, and $(1 / 3,2 / 3,2 / 3)$. From Fig. 9.2 .5 , it can be seen that the rhombohedral and hexagonal axes, labeled by subscripts " r " and " h " respectively, are related by vector addition:

$$
\begin{array}{ll}
\mathbf{a}_{\mathrm{r}}=2 / 3 \mathbf{a}_{\mathrm{h}}+1 / 3 \mathbf{b}_{\mathrm{h}}+1 / 3 \mathbf{c}_{\mathrm{h}} & \mathbf{a}_{\mathrm{h}}=\mathbf{a}_{\mathrm{r}}-\mathbf{b} \\
\mathbf{b}_{\mathrm{r}}=-1 / 3 \mathbf{a}_{\mathrm{h}}+{ }^{1 / 3} \mathbf{b}_{\mathrm{h}}+1 / 3 \mathbf{c}_{\mathrm{h}} & \text { and }
\end{array} \mathbf{b}_{\mathrm{h}}=\mathbf{b}_{\mathrm{r}}-\mathbf{c}_{\mathrm{r}} .
$$

Fig. 9.2.5.
Relationship between rhombohedral (obverse setting) and hexagonal unit cells for a rhombohedral lattice. Note that in the right figure, lattice points at $z=0,1 / 3$, and $2 / 3$ are differentiated by circles of increasingly darker circumferences, and the lattice point at $z=1$ is indicated by a filled circle, which obscures the lattice point at the origin.

## Symmetry in Chemistry

The pair of matrices can be written down easily, and the volume ratio $V_{\mathrm{r}} / V_{\mathrm{h}}$ worked out to be $1 / 3$.

In the alternative reverse setting (seldom used), the rhombohedral axes are rotated by $60^{\circ}$ in an anti-clockwise sense about the $c$ axis of the hexagonal unit cell. The equivalent lattice points are then $(000),(1 / 3,2 / 3,1 / 3)$, and $(2 / 3,1 / 3,2 / 3)$. The reader can readily deduce the vectorial and matrix relationships for the two sets of axes and verify that $V_{\mathrm{r}} / V_{\mathrm{h}}$ remains unchanged at $1 / 3$.

### 9.3 Space groups

An infinitely extended periodic structure can be brought into self-coincidence by point symmetry operations or translations $\ell \mathbf{a}+m \mathbf{b}+n \mathbf{c}$, where $\mathbf{a}, \mathbf{b}, \mathbf{c}$ are the lattice vectors and $\ell, m, n$ are arbitrary positive and negative integers, including zero. In particular, any symmetry operation that moves a lattice one translation forward (or backward) along an axis leaves it unchanged. This means that, in addition to the point symmetry operations, new types of symmetry operations are also applicable to the periodic arrangement of structural units in a crystal. Such symmetry operations, which are carried out with respect to new symmetry elements called screw axes and glide planes, are obtained by combining rotations and reflections, respectively, with translations along the lattice directions.

### 9.3.1 Screw axes and glide planes

The symmetry operation performed by a screw axis $n_{m}$ is equivalent to a combination of rotation of $2 \pi / n$ radians (or $360^{\circ} / n$ ) followed by a translation of $m / n$ in the direction of the $n$-fold axis, where $n=1,2,3,4$, or 6 is the order of the axis and the subscript $m$ is an integer less than $n$. There exist totally eleven screw axes: $2_{1}, 3_{1}, 3_{2}, 4_{1}, 4_{2}, 4_{3}, 6_{1}, 6_{2}, 6_{3}, 6_{4}$, and $6_{5}$ in the crystal lattices. Figure 9.3.1 shows the positions of the equivalent points (also called equipoints for simplicity) around the individual $4-, \overline{4}-, 4_{1^{-}}, 4_{2^{-}}$, and $4_{3}$-axes.

Fig. 9.3.1.
Equipoints related by a $4-, \overline{4}-, 4_{1^{-}}, 4_{2^{-}}$, and 43 -axis.

The small circle represents any object (an atom, a group of atoms, a molecule, a group of several molecules, etc.) and the positive sign indicates that it lies above the plane containing the reference axes ( $x$ horizontal, $y$ vertical). In the diagram showing a $\overline{4}$-axis, the comma inside the circle emphasizes that the original object has been converted to its mirror image, and the negative sign indicates that it lies below the plane.

The combination of reflection and translation gives a glide plane. If the gliding direction is parallel to the $a$ axis, the symbol for the axial glide plane is $a$ and the operation is "reflection in the plane followed by translation parallel to the $a$ axis by $a / 2^{\prime \prime}$. Similar axial glide planes $b$ and $c$ have translation components of $b / 2$ and $c / 2$, respectively.

A screw axis and a glide plane generate equivalent objects in fundamentally different ways. Consider an asymmetric object (such as a chiral molecule, which may be represented by a left hand) located at $(x, y, z)$ close to the origin of the unit cell. The $2_{1}$-axis along $b$ rotates the left hand about the line ( $x=$ $0, z=0$ ) to generate the equivalent left hand at $(\bar{x}, 1 / 2+y, \bar{z})$, as shown in Fig. 9.3.2(a). In contrast, starting with a left hand at $(x, y, z)$, reflection across the $b$ glide plane at $x=0$ generates a right hand at $(\bar{x}, 1 / 2+y, z)$, as shown in Fig. 9.3.2(b).

If the translation is parallel to a face diagonal by $1 / 2(a+b), 1 / 2(b+c)$, or $1 / 2(c+a)$, then the glide plane is called a diagonal glide and denoted by $n$. Less commonly, the $n$ glide operation may involve a translation of $1 / 2(a+b+c)$ in the tetragonal, rhombohedral, and cubic systems. A third type is the diamond glide plane $d$ which has translations of ${ }^{1 / 4}(a \pm b),{ }^{1 / 4}(b \pm c)$, or ${ }^{1 / 4}(c \pm a)$ in the orthogonal and tetragonal systems, and also ${ }^{1 / 4}(a \pm b \pm c)$ in the cubic system. The recently introduced double glide plane has two coexisting $1 / 2$ translations parallel to it; this type of $e$ glide appears in seven orthorhombic $A-, C$-, and $F$ centered space groups, five tetragonal $I$-centered space groups, and five cubic $I$ - and $F$-centered space groups.

### 9.3.2 Graphic symbols for symmetry elements

Different graphic symbols are used to label symmetry axes normal to the plane of projection, symmetry axes in the plane of the figure, symmetry axes inclined to the plane of projection, symmetry planes normal to the plane of projection, and symmetry planes parallel to the plane of projection. These symbols are illustrated in Tables 9.3.1 to 9.3.5, respectively.

Fig. 9.3.2.
Comparison of the effect of (a) a twofold screw axis and (b) a glide plane on an asymmetric object represented by a left hand. The plus and minus signs indicate that the object lies above and below the plane (001), respectively.

## Symmetry in Chemistry

Table 9.3.1. Symbols of symmetry axes normal to the plane of projection and inversion center in the plane of the figure

| Symmetry element (screw rotation is right-handed) | Graphic symbol | Translation in units of the shortest lattice vector parallel to the axis | Printed symbol |
| :---: | :---: | :---: | :---: |
| Identity | none | none | 1 |
| Twofold rotation axis | - | none | 2 |
| Twofold screw axis: "2 sub 1" |  | 1/2 | 21 |

Table 9.3.4. Symmetry planes normal to the plane of projection

| Symmetry plane or symmetry line | Graphic symbol | Glide vector in units of lattice translation vectors parallel and normal to the projection plane | Printed symbol |
| :---: | :---: | :---: | :---: |
| Reflection plane, mirror plane |  | None | $m$ |
| "Axial" glide plane |  | $1 / 2$ lattice vector along line in projection plane | $a, b$, or $c$ |
| "Axial" glide plane |  | $1 / 2$ lattice vector normal to projection plane | $a, b$, or $c$ |
| "Digonal" glide plane | ----- | One glide vector with two components: $1 / 2$ along line parallel to projection plane, and $1 / 2$ normal to projection plane | $n$ |
| "Diamond" glide plane* (pair of planes; in centred cells only) | --->------ | $1 / 4$ along line parallel to projection plane, combined with $1 / 4$ normal to projection plane (arrow indicates direction parallel to the projection plane for which the normal component is positive) | $d$ |
| "Double" glide plane (pair of planes; in centered cells only) | .. | Two coexisting glides of $1 / 2$ (related by a centering translation) parallel to and perpendicular to the projection plane | $e$ |

[^1]Table 9.3.5. Symmetry planes parallel to the plane of projection

| Symmetry plane | Graphic symbol* | Glide vector in units of lattice translation vectors parallel to the projection plane | Printed symbol |
| :---: | :---: | :---: | :---: |
| Reflection plane, mirror plane | $\Gamma^{1 / 4}$ | None | $m$ |
| "Axial" glide plane | $\nabla \quad \Gamma$ | $1 / 2$ lattice vector in the direction of the axis | $a, b$, or $c$ |
| "Diagonal" glide plane | $F$ | Latttice vector in the direction of the arrow (glide vector with two $1 / 2$ components) | $n$ |
| "Diamond" glide plane |  | $1 / 4$ lattice vector in the direction of the arrow (glide vector with two or three components) | $d$ |
| "Double" glide plane | $\downarrow$ | A pair of $1 / 2$ lattice vectors in the direction of the two arrows | $e$ |

* The symbols are given at the upper corner of the space group diagrams. A fraction $h$ attached to a symbol indicates two symmetry planes with "height" $h$ and $h+1 / 2$ above the plane of projection; e.g. $1 / 8$ stands for $h=1 / 8$ and $5 / 8$. No fraction means $h=0$ and $1 / 2$.

### 9.3.3 Hermann-Mauguin space-group symbols

The term space-group indicates a self-consistent set of symmetry operations, constituting a group in the mathematical sense, that bring an infinitely extended, three-dimensional periodic structure into self-coincidence. Between the years 1885 and 1894, Fedorow, Schönflies, and Barlow independently showed that there are 230 space groups. The Hermann-Mauguin notation for space groups includes a set of symbols sufficient to completely specify all the symmetry elements and their orientation with respect to the unit-cell axes. It consists of two parts. The first part is a symbol for the type of lattice: $P, C$ (or $A$ or $B$ ), $I$, $F$, or $R$ (formerly $H$ was also sometimes used for the hexagonal lattice). The second part is a set of symbols for symmetry elements sufficient to fully reflect the space group symmetry without listing other symmetry elements that must necessarily be present. These are written in an order that indicates the orientation of the symmetry elements, in the same manner as for the point groups. In this system a symmetry element associated with a plane has the orientation of the normal to the plane. The symbols 1 and $\overline{1}$ are usually omitted unless they are the only ones or unless they are needed as spacers. When two symmetry elements have the same orientation and both are necessary, their symbols are separated with a slash, for example, $2 / \mathrm{m}$ indicates a twofold axis with a mirror plane normal to it.

### 9.3.4 International Tables for Crystallography

The 230 space groups are described in Volume A: Space-Group Symmetry of the International Tables for Crystallography. Detailed graphic projections along the axial directions showing the symmetry elements present in the unit cell, a list of general and special equivalent positions designated by Wyckoff letters (or positions), multiciplicities, and the symmetry of each local site are given for
each space group. This volume is an expanded and updated version of Volume I: Symmetry Groups of the International Tables for X-Ray Crystallography, which contains a simplified presentation. The 230 space groups are listed in Table 9.3.6.

### 9.3.5 Coordinates of equipoints

In crystallography the coordinates of the equipoints are each expressed as a fraction of the distance along the corresponding unit-cell edge, and they are therefore actually fractional coordinates. For any space group referred to a specific choice of origin (generally at $\overline{1}$, if possible), the coordinates of all equipoints can be derived. Table 9.3.7 shows the derivation of points from those of one prototype with fractional coordinates $(x, y, z)$ by carrying out symmetry operations with respect to various symmetry elements. Note that the coordinates ( $x, y, z$ ) of a molecule composed of $n$ atoms represent the set of $3 n$ atomic coordinates $\left(x_{i}, y_{i}, z_{i} ; i=1,2, \ldots, n\right)$.

Figure 9.3.3 illustrates the derivation of coordinates for equipoints related by a 4-, 3-, and 6 -axis along $c$ through the origin. Coordinates related by a $\overline{4}$-, $\overline{3}$-, and $\overline{6}$-axis can be readily written down using this information. If a different choice of origin is made, a different set of coordinates will be obtained.

Given the fractional coordinates of all atoms in the unit cell, bond lengths $\ell_{i j}$ and bond angles $\theta_{i j k}$ can be calculated from their differences ( $\Delta x_{i j}=x_{i}-$ $\left.x_{j}, \Delta y_{i j}=y_{i}-y_{j}, \Delta z_{i j}=z_{i}-z_{j}\right)$ and the lattice parameters. In the general triclinic case, the interatomic distance between two atoms labeled 1 and 2 is given by

$$
\begin{aligned}
\ell_{12}^{2}= & \left(a \Delta x_{12}\right)^{2}+\left(b \Delta y_{12}\right)^{2}+\left(c \Delta z_{12}\right)^{2}-2 a b \Delta x \Delta y \cos \gamma \\
& -2 a c \Delta x \Delta z \cos \beta-2 b c \Delta y \Delta z \cos \alpha
\end{aligned}
$$

The $\theta_{123}$ angle at atom 2, which forms bonds with 1 and 3 , is calculated from the cosine law

$$
\cos \theta_{123}=\left(\ell_{12}^{2}+\ell_{13}^{2}-\ell_{23}^{2}\right) / 2 \ell_{12} \ell_{13}
$$

For a linear sequence of four bonded atoms $\mathrm{A}-\mathrm{B}-\mathrm{C}-\mathrm{D}$, the torsion angle $\tau$ is defined as the angle between the projections of the bond $\mathrm{B}-\mathrm{A}$ and $\mathrm{C}-\mathrm{D}$ when viewed along the direction of $\mathrm{B}-\mathrm{C}$.

The torsion angle $\tau$ an be calculated from the equation

$$
\cos \tau=(\mathbf{A B} \times \mathbf{B C}) \cdot(\mathbf{B C} \times \mathbf{C D}) / \mathrm{AB}(\mathrm{BC})^{2} \mathrm{CD} \sin \theta_{\mathrm{B}} \sin \theta_{\mathrm{C}},
$$

where $\mathbf{A B}$ is the vector from $A$ to $B, A B$ is magnitude of $\mathbf{A B}$, the symbols - and $\times$ indicate scalar and vector products, respectively, and $\theta_{\mathrm{B}}$ is the bond

| $R$-centering,* obverse setting | $x, y, z ;{ }^{2} / 3+x, 1 / 3+y, 1 / 3+z ; 1 / 3+x, 2 / 3+y, 2 / 3+z$ or $\left(0,0,0,{ }^{2} / 3,1 / 3,1 / 3 ; 1 / 3,2 / 3,2 / 3\right)+$ |
| $R$-centering, ${ }^{\text {, }}$ reverse setting | $x, y, z ;{ }^{1 / 3}+x,{ }^{2 / 3}+y,{ }^{1 / 3}+z ;{ }^{2 / 3}+x,{ }^{1 / 3}+y,{ }^{2} / 3+z$ or $\left(0,0,0 ;{ }^{1 / 3},{ }^{2 / 3}, 1 / 3 ;{ }^{2 / 3}, 1 / 3,{ }^{2 / 3}\right)+$ |

* Rhombohedral unit cell based on hexagonal lattice.
angle at atom B. Note that this formula is valid in any coordinate system, but the usual textbook expressions for the scalar and vector products in terms of vector components holds only in a Cartesian coordinate system. The torsion angle $\tau$ is not well defined when one or both of $\theta_{\mathrm{B}}$ and $\theta_{\mathrm{C}}$ is/are $0^{\circ}$ or $180^{\circ}$. A positive value of $\tau$ indicates that the $\mathrm{A}-\mathrm{B}-\mathrm{C}-\mathrm{D}$ link corresponds to the sense

## Symmetry in Chemistry

Table 9.3.8. The order of positions in the international symbols for point groups and space groups

| System | Position in international symbol |  |  |
| :---: | :---: | :---: | :---: |
|  | 1st | 2nd | 3rd |
| Triclinic | Only one symbol is used |  |  |
| Monoclinic | 1st setting: 2,21 , or $\overline{2}$ along unique $\mathbf{c}$ axis* |  |  |
| Orthorhombic | 2, $2_{1}$, or $\overline{2}$ along a | $2,2_{1}$, or $\overline{2}$ along b | $2,22_{1}$, or $\overline{2}$ along $\mathbf{c}$ |
| Tetragonal | $4,4_{1}, 4_{2}, 4_{3}$, or $\overline{4}$ along $\mathbf{c}$ | $2,2_{1}$, or $\overline{2}$ along a and $\mathbf{b}$ | 2 or $\overline{2}$ along [110] and [110] |
| Trigonal | $3,3_{1}, 3_{2}$, or $\overline{3}$ along $\mathbf{c}$ | 2 or $\overline{2}$ along $\mathbf{a}, \mathbf{b}$, and [110] | 2 or $\overline{2}$ perpendicular to $\mathbf{a}, \mathbf{b}$, and [110] |
| Hexagonal | $6,6_{1}, 6_{2}, 6_{3}, 6_{4}, 6_{5}$, or $\overline{6}$ along c | 2 or $\overline{2}$ along $\mathbf{a}, \mathbf{b}$, and [110] | 2 or $\overline{2}$ perpendicular to <br> $\mathbf{a}, \mathbf{b}$, and [110] |
| Cubic | $\begin{aligned} & 4,4_{1}, 4_{2}, 4_{3}, \overline{4}, 2,2_{1} \text {, or } \\ & \overline{2} \text { along } \mathbf{a}, \mathbf{b}, \text { and } \mathbf{c} \end{aligned}$ | $3 \text { or } \overline{3} \text { along }<111>$ | 2 or $\overline{2}$ along <110> |

* Note that a $\overline{2}$-axis is equivalent to a mirror plane $m$ normal to it; for example, $\overline{2}$ along a means $m$ perpendicular to $\mathbf{a}$.
of a right-handed screw (or helix). The sign of $\tau$ is unaffected by rotation or translation, but is reversed by reflection or inversion.

### 9.3.6 Space group diagrams

Table 9.3.8 summarizes the order of positions in the point group or space group symbols; note that a $\overline{2}$-axis is equivalent to a mirror plane $m$ perpendicular to it.

For example, in the orthorhombic system, mm 2 refers to mirror planes perpendicular to $\mathbf{a}$ and $\mathbf{b}$, and a twofold axis along $\mathbf{c}$. In the hexagonal system, $\overline{6} 2 m$ means a $\overline{6}$-axis along $\mathbf{c}$, twofold axes along $\mathbf{a}, \mathbf{b}$ and $\mathbf{a}+\mathbf{b}$ (i.e., [110]), and mirror planes perpendicular to $\mathbf{a}, \mathbf{b}$ and [110]. In some other books and tables, the equivalent alternative $\overline{6} m 2$ may be used in place of $\overline{6} 2 \mathrm{~m}$. In the cubic system, $\overline{4} 3 \mathrm{~m}$ means three $\overline{4}$-axes along the equivalent axes of a cube, four 3axes along the body diagonals $<111>$, and six mirror planes perpendicular to the face diagonals $\langle 110\rangle$. In $m \overline{3}$ the first position indicates mirror planes perpendicular to 0 the cubic axes, and the second position means $\overline{3}$-axes along the body diagonals. The third position is left blank as there is no symmetry element in the $<110>$ directions. The older symbol for $m \overline{3}$ is $m 3$, as the 3- and $\overline{3}$-axis are coincident.

The most frequently occurring space group $P 12_{1} / c 1$ (No. 14) serves as a good example to illustrate the use of the space group tables. In the HermannMauguin nomenclature, the lattice symbol is given first; here $P$ means that the lattice is primitive (i.e., there is no lattice centering). The second symbol (1) indicates that there is no symmetry with respect to $a$, the next symbol $\left(2_{1} / c\right)$ shows that both $2_{1}$ and $c$ refer to the $b$ axis (the unique symmetry axis in the conventional second setting), and the last symbol (1) indicates that there is no symmetry with respect to $c$. The symmetry elements $2_{1} / c$ mean that the

Laue symmetry is $2 / m$ (disregarding the translational components of the $2_{1-}{ }^{-}$ axis and the $c$ glide), so the space group belongs to the monoclinic system. The simplified symbol $P 2_{1} / c$ normally replaces the full symbol $P 1_{1} / c 1$, and the old Schönflies symbol $C_{2 h}^{5}$ (the fifth space group derived from the point group $C_{2 h}$ ) is seldom used.

Space group $P 2_{1} / a$ often appears in the older literature in place of $P 2_{1} / c$; in such case the unique axis is still $b$, but the glide plane is $a$. If we make a different choice of the axes normal to the $2_{1}$-axis, the glide plane might be changed to a diagonal glide $n$; and the space group symbol becomes $P 2_{1} / n$. (This choice is sometimes made to make the $\beta$ angle close to $90^{\circ}$.) Furthermore, if $c$ were chosen as the unique axis (as in the unconventional first setting), the space group symbol would become $P 2_{1} / a$ or $P 2_{1} / b$. Thus the same space group may be designated by several different symbols depending on the choice of axes and their labeling.

In the following discussion, for simplicity we make use of the pair of symmetry diagrams that constitute a representation of space group $P 2_{1} / c$ (No. 14) in International Tables for X-Ray Crystallography Volume I, as displayed in Fig. 9.3.4.

In both diagrams, the origin is located at the upper left corner of the unit cell, with $a$ pointing downward, $b$ horizontally to the right, and $c$ toward the viewer. The right diagram (b) shows the symmetry elements and their location using graphic symbols. Each colinear pair of half arrows represents a 21 -axis parallel to $b$, and the label ${ }^{1 / 4}$ indicates that it lies at a height of $z={ }^{1 / 4}$. The dotted line indicates the $c$ glide with glide component coming out of the plane of the diagram. The small open circle represents a center of symmetry (inversion center) that must be present in $P 2_{1} / c$ but is not explicitly indicated in the space group symbol. Note that all three types of symmetry elements necessarily occur at $1 / 2$ unit intervals along the lattice translations.

The left diagram (a) shows the locations and coordinates of the general equivalent positions in the space group. To see how this diagram can be derived from the symmetry diagram at the right, we insert a general point labeled $\mathbf{1}$ in the unit cell and represent it by a large open circle. This position $(x, y, z)$ has an arbitrary fractional height $z$ above the $a b$ plane, which is conventionally designated by the symbol + beside it. For the $2_{1}$ screw axis at $x=0, z=1 / 4$, rotation first carries position 1 to a point $(\bar{x}, y, 1 / 2-z)$ outside the unit cell at the top, and the

Fig. 9.3.4.
Diagrams showing (a) the general equivalent positions and (b) the symmetry elements in space group $P 2_{1} / c$ as presented in International Tables for X-Ray Crystallography Volume I. The bold numerals in the left figure are added for the purpose of discussion.

## Symmetry in Chemistry

subsequent $b / 2$ translation carries the latter to position 2 marked - (meaning a height of $-z$ ), and its coordinates are ( $\bar{x}, 1 / 2+y, 1 / 2-z$ ). For the $c$ glide at $y={ }^{1 / 4}$, reflection across the plane first brings $\mathbf{1}$ to the point $\left(x,{ }^{1 / 2}-y, z\right)$, and the subsequent $c / 2$ translation carries the latter into position 3 marked ${ }^{1 / 2+}$ (meaning a height of $1 / 2+z$ ), and its coordinates are ( $x, 1 / 2-y, 1 / 2+z$ ). The comma inside the circle means that the position, together with its environment, is a mirror image of the original position and its environment. Starting with position 2, the glide plane at $y=3 / 4$ generates the position at $(\bar{x}, 1-y, \bar{z})$, and we label it $\mathbf{4}$. The positions $\mathbf{2}^{\prime}$ and $\mathbf{4}^{\prime}$ are derived from $\mathbf{2}$ and $\mathbf{4}$, respectively, by unit translation along $a$. Note that positions 1 and $\mathbf{4}^{\prime}$ are related by the inversion center at $(1 / 2,1 / 2,1 / 2)$, positions $\mathbf{2}$ and $\mathbf{3}$ are related by the inversion center at $\left(0,{ }^{1} / 2,1 / 2\right)$, and positions $\mathbf{3}$ and $\mathbf{2}^{\prime}$ are related by the inversion center at $(1 / 2,1 / 2,1 / 2)$. The point $\mathbf{4}^{*}$ at $(\bar{x}, \bar{y}, \bar{z})$ is usually chosen instead of $\mathbf{4}$, since it is related to $\mathbf{1}$ by the inversion center at the origin. Equipoints $\mathbf{1}, \mathbf{4}^{*}, \mathbf{2}$, and $\mathbf{3}$ constitute the set of general equivalent positions in space group $P 2_{1} / c$. Further action of the symmetry operations on them produces no new position, so these four positions reflect the full symmetry of the space group. They are denoted by the Wyckoff notation $4(e)$ in the first row of Table 9.3.9.

The Wyckoff notation for a set of equivalent positions consists of two parts: (i) the multiplicity $M$, which is the number of equivalent positions per unit cell, and (ii) an italicized small letter $a$ starting at the bottom of the list and moving upward in alphabetical order. For a primitive unit cell, $M$ is equal to the order of the point group from which the space group is derived; for centered cells, $M$ is the product of the order of the point group and the number of lattice points per unit cell.

Note that in Fig. 9.3.4, diagram (b) can be derived from diagram (a), and vice versa, and either one is sufficient to represent the full symmetry of the space group.

Consider the general equivalent positions of space group $P 2_{1} / c$ as shown in Fig. 9.3.4(a). Let position $\mathbf{1}$ approach the origin of the unit cell; in other words, let the coordinates $x \rightarrow 0, y \rightarrow 0$, and $z \rightarrow 0$. As this happens, position $4^{\prime \prime}$ also approaches the origin, while both $\mathbf{2}$ and $\mathbf{3}$ simultaneously approach the center of inversion at $(0,1 / 2,1 / 2)$. When $x=0, y=0$, and $z=0, \mathbf{1}$ and $\mathbf{4}^{*}$ coalesce into one, and $\mathbf{2}$ and $\mathbf{3}$ likewise become the same position. There remain only two equivalent positions: $(0,0,0)$ and $(0,1 / 2,1 / 2)$ that occupy sites of symmetry $\overline{1}$, and they constitute the special equivalent position $2(a)$, which is designated as Wyckoff position 2(a). Other sets of special equivalent positions of site symmetry $\overline{1}$ are obtained by setting $x=1 / 2, y=0, z=0 ; x=0, y=0$,

Table 9.3.9. General and special positions of space group $P 2_{1} / c$.

| No. of positions | Wyckoff letter | Site symmetry | Coordinates of equivalent positions |
| :---: | :---: | :---: | :---: |
| 4 | $e$ | 1 | $x, y, z ; \bar{x}, \bar{y}, \bar{z} ; \bar{x},{ }^{1} / 2+y,{ }^{1} / 2-z ; x,{ }^{1 / 2}-y,{ }^{1 / 2}+z$ |
| 2 | $d$ | $\overline{1}$ | $1 / 2,0,{ }^{1 / 2}{ }^{1} / 2,{ }^{1 / 2,0}$ |
| 2 | c | $\overline{1}$ | $0,0,{ }^{1 / 2} ; 0,{ }^{1 / 2}, 0$ |
| 2 | $b$ | $\overline{1}$ | ${ }^{1 / 2,0,0} ;^{1 / 2,1 / 2,1 / 2}$ |
| 2 | $a$ | $\overline{1}$ | 0, 0, 0; 0, $1 / 2,1 / 2$ |

$z=1 / 2 ; x=1 / 2, y=0, z=1 / 2$, giving rise to Wyckoff position 2(b), 2(c), and $2(d)$, respectively (see Table 9.3.9). The multiplicity of a special position is always a divisor of that of the general position.

To describe the contents of a unit cell, it is sufficient to specify the coordinates of only one atom in each equivalent set of atoms, since the other atomic positions in the set are readily deduced from space group symmetry. The collection of symmetry-independent atoms in the unit cell is called the asymmetric unit of the crystal structure. In the International Tables, a portion of the unit cell (and hence its contents) is designated as the asymmetric unit. For instance, in space group $P 2_{1} / c$, a quarter of the unit cell within the boundaries $0 \leq x \leq 1,0 \leq y \leq 1 / 4$, and $0 \leq z \leq 1$ constitutes the asymmetric unit. Note that the asymmetric unit may be chosen in different ways; in practice, it is preferable to choose independent atoms that are connected to form a complete molecule or a molecular fragment. It is also advisable, whenever possible, to take atoms whose fractional coordinates are positive and lie within or close to the octant $0 \leq x \leq 1 / 2,0 \leq y \leq 1 / 2$, and $0 \leq z \leq 1 / 2$. Note also that if a molecule constitutes the asymmetric unit, its component atoms may be related by noncrystallographic symmetry. In other words, the symmetry of the site at which the molecule is located may be a subgroup of the idealized molecular point group.

### 9.3.7 Information on some commonly occurring space groups

Apart from $P 2_{1} / c$, other commonly occurring space groups are $C 2 / c$ (No. 15), $P 2_{1} 2_{1} 2_{1}$ (No. 19), Pbca (No. 61), and Pnma (No. 62); the symmetry diagrams and equivalent positions of these space groups are displayed in Table 9.3.10. It should be noted that each space group can be represented in three ways: a diagram showing the location of the general equivalent positions, a diagram showing the location of the symmetry elements, and a list of coordinates of the general positions. The reader should verify that, given any one of these, the other two can be readily deduced.

### 9.3.8 Using the International Tables

Detailed information on all 230 space groups are given in Volume A: SpaceGroup Symmetry of the International Tablesfor Crystallography. The tabulation for space group $C 2 / c$ is reproduced in the left column of Table 9.3.11, and explanation of various features are displayed in the right column. This may be compared with the information for $C 2 / c$ given in Table 9.3.10.

### 9.4 Determination of space groups

### 9.4.1 Friedel's law

The intensity of a reflection $(h k \ell)$ is proportional to the square of the structural factor $F(h k \ell)$, which is given by

$$
F(h k \ell)=\sum_{j} f_{j} \cos 2 \pi\left(h x_{j}+k y_{j}+\ell z_{j}\right)+\mathrm{i} \sum_{j} f_{j} \sin 2 \pi\left(h x_{j}+k y_{j}+\ell z_{j}\right)
$$

where $f_{j}$ is the atomic scattering factor of atom $j$, and the summation is over all atoms in the unit cell. For simplicity, we may write $|F(h k \ell)|^{2}=$ $A^{2}+B^{2}$.
$F(h k \ell)$ is in general a complex quantity, which can be expressed as $F(h k \ell)=$ $A+\mathrm{i} B$. The structure factor for the reflection with indices $-h,-k,-\ell$ is $F(\bar{h} \bar{\ell} \bar{\ell})$, and the observed intensity is $|F(\bar{h} \bar{k} \bar{\ell})|^{2}=A^{2}+B^{2}$.

The intensities of reflections (hk ) and ( $\bar{h} \bar{k} \bar{\ell})$ are the same, so that the diffraction pattern has an apparent center of symmetry, even if the crystal structure is not centrosymmetric. This is known as Friedel's law. Note that Friedel's law breaks down under the conditions of anomalous scattering, which happens when the wavelength is such that the X-rays are highly absorbed by the atoms in the crystal.

### 9.4.2 Lave classes

As a consequence of Friedel's law, the diffraction pattern exhibits the symmetry of a centrosymmetric crystal class. For example, a crystal in class 2 , on account of the $\overline{1}$ symmetry imposed on its diffraction pattern, will appear to be in class $2 / m$. The same result also holds for crystals in class $m$. Therefore, it is not possible to distinguish the classes $2, m$, and $2 / m$ from their diffraction patterns. The same effect occurs in other crystal systems, so that the 32 crystal classes are classified into only 11 distinct Laue groups according to the symmetry of the diffraction pattern, as shown in Table 9.4.1.

## Symmetry in Chemistry

Knowledge of the diffraction symmetry of a crystal is useful for its classification. If the Laue group is observed to be $4 / \mathrm{mmm}$, the crystal system is tetragonal, the crystal class must be chosen from $422,4 m m, \overline{4} 2 \mathrm{~m}$, and $4 / \mathrm{mmm}$, and the space group is one of those associated with these four crystallographic point groups.

### 9.4.3 Deduction of lattice centering and translational symmetry elements from systemic absences

Systematic absences (or extinctions) in the X-ray diffraction pattern of a single crystal are caused by the presence of lattice centering and translational symmetry elements, namely screw axes and glide planes. Such extinctions are extremely useful in deducing the space group of an unknown crystal.

## (1) Effect of lattice centering

In Fig. 9.4.1, the planes (100), (110), and (111) are drawn in heavy shading for pairs of adjoining primitive $(P)$, body-centered $(I)$, and face-centered $(F)$ unit cells. In the $I$-lattice, the centered points lie midway between the (100) and (111) planes, and their contribution to X-ray scattering exactly cancels out that due to points located at the corners of the unit cells. These two reflections are therefore systematically absent. However, the reflections (200), (110), and (222) are observable since each passes through all the lattice points. Similarly, in the $F$-lattice, the (100) and (110) reflections are systematically absent, but the (200), (220), and (111) reflections are observable.

For subsequent discussion of the general case, we make use of the following theorem from geometry:

A line OL from the origin O of a space lattice to a lattice point L , as represented by the vector $\mathbf{O L}=u \mathbf{a}+v \mathbf{b}+w \mathbf{c}$, is divided into $(u h+v k+w \ell)$ parts by the set of planes ( $h k \ell$ ).

Consider the $C$-centered unit cell shown in Fig. 9.4.2. Setting $\mathbf{O L}=\mathbf{a}+\mathbf{b}$, the line OL, which runs through the $C$-centered point, is divided into 5 parts by the planes (320). Thus the points located at the corners of the unit cell lie in the (320) set of planes, but the $C$-centered point does not. It is easily seen that, in general, the $C$-centered point lies in the ( $h k \ell$ ) planes when $(h+k)$ is even, and in between the planes when $(h+k)$ is odd. In the latter case, X-ray scattering by the points at the corners of the unit cell is exactly out of phase with that caused by the $C$-centered point; in other words, reflections ( $h k \ell$ ) are systematically absent with $(h+k)$ odd. Conversely, whenever this kind of systematic absences is observed, the presence of a $C$-centered lattice is indicated.

For a $F$-centered lattice, reflections ( $h k \ell$ ) are observable only when the conditions $(h+k)$ even, $(k+\ell)$ even, and $(\ell+h)$ even are simultaneously satisfied; this means that the indices $h, k, \ell$ must be either all even or all odd. This result can also be deduced analytically. In a $F$-centered lattice, the following equivalent positions are present: $(x, y, z) ;(x, y+1 / 2, z+1 / 2) ;(x+1 / 2, y, z+1 / 2)$; $(x+1 / 2, y+1 / 2, z)$. Accordingly, the structure factor expression is

$$
\begin{aligned}
F_{h k \ell}= & \sum_{j=1}^{n / 4} f_{j} \exp \left[\mathrm{i} 2 \pi\left(h x_{j}+k y_{j}+\ell z_{j}\right)\right]\{1+\exp [\mathrm{i} 2 \pi(k / 2+\ell / 2)] \\
& +\exp [\mathrm{i} 2 \pi(k / 2+\ell / 2)]+\exp [\mathrm{i} 2 \pi(k / 2+\ell / 2)]\} .
\end{aligned}
$$

For reflections of the type ( $h k \ell$ ), when the indices are all even or all odd (i.e., $h+k=2 n, h+\ell=2 n, k+\ell=2 n$ ),

$$
F_{h k \ell}=4 \sum_{j=1}^{n / 4} f_{j} \exp \left[\mathrm{i} 2 \pi\left(h x_{j}+k y_{j}+\ell z_{j}\right)\right]
$$

If the $h, k, \ell$ indices are of mixed parity (i.e., not all odd or all even), then $F_{h k \ell}=0$. For example, $F_{112}=F_{300}=0$.

For an $I$-centered lattice, we consider the vector $\mathbf{O L}=\mathbf{a}+\mathbf{b}+\mathbf{c}$ which passes through the $I$-centered point. The line OL is divided into $(h+k+\ell)$ parts, which must be even for reflections ( $h k \ell$ ) to be observable.

Consider a rhombohedral lattice referred to a hexagonal set of axes. In the obverse setting, we consider the vector $\mathbf{O L}=-\mathbf{a}+\mathbf{b}+\mathbf{c}$, which passes through the points at $(-1 / 3,1 / 3,1 / 3),(-2 / 3,2 / 3,2 / 3)$, and $(-1,1,1)$. The line OL is divided into $(-h+k+\ell)$ parts, which must be a multiple of 3 for all lattice points to lie in the planes ( $h k \ell$ ). In other words, the systematic absences for reflections ( $h k \ell$ ) are $(-h+k+\ell) \neq 3 n$ for a rhombohedral lattice in the obverse setting. In the reverse setting, the systematic absences are $(h-k+\ell) \neq 3 n$.

## (2) Effect of glide planes and screw axes

Consider the arrangement of asymmetric objects (e.g., left and right hands) generated by a $n$ glide plane normal to the $c$ axis at $z=0$, as shown in Fig. 9.4.3(a). Note that to the ( $h k 0$ ) reflections, the $z$ coordinate is immaterial, as

Fig. 9.4.2.
$C$-centered unit cell showing that the line OL is divided into five parts by the (320) planes, and the $C$-centered point lies midway between a pair of planes.

Fig. 9.4.3.
Effect of (a) $n$ glide normal to $c$ and (b) $b$ glide normal to $c$ on an asymmetric object represented by a hand. The plus and minus signs indicate that the object lies above and below the plane (001), respectively.

Fig. 9.4.4.
Effect of $2_{1}$-axis along $b$ on an asymmetric object represented by a hand. The plus and minus signs indicate that the object lies above and below the plane (001), respectively.

the structure projected onto the $a b$ plane looks exactly like a $C$-centered lattice. Hence the systematic absences $(h k 0)$ absent with $(h+k)$ odd implies the presence of a $n$ glide plane normal to the $c$ axis. Note that this condition is covered by that for $C$-centering, and therefore if the lattice is already $C$-centered, the $n$ glide may or may not be present.

In like manner, for the $b$ glide normal to $c$ shown in Fig. 9.4.3(b), the right and left hands make the same contribution to the ( $h 00$ ) reflections. Therefore, the systematic absences of ( $h k 0$ ) reflections with $k$ odd indicate the presence of a $b$ glide plane normal to the $c$ axis.

Consider now a 21 -axis parallel to the $b$ axis. As shown in Fig. 9.4.4, the coordinates $x$ and $z$ are irrelevant for the ( $0 k 0$ ) planes, and the systematic absences ( $0 k 0$ ) absent with $k$ odd implies the presence of a $22_{1}$-axis parallel to $b$. Note that this is a very weak condition as compared to those for lattice centering and glide planes, and is already covered by them. Since the ( $0 k 0$ ) reflections are few in number, some may be too weak to be observable, and hence the determination of a screw axis from systematic absences is not always reliable.

Analytical deductions can be made in the following way. Suppose the unit cell has a $c$ glide plane perpendicular to the $b$ axis. For an atom at $x, y, z$, there is an equivalent atom at $x,-y, 1 / 2+z$. The contribution of these two atoms to the structure factor is

$$
F(h k \ell)=f\{\exp [2 \pi \mathrm{i}(h x+k y+\ell z)]+\exp [2 \pi \mathrm{i}(h x-k y+\ell / 2+\ell z)]\}
$$

For the special case of $k=0$,

$$
\begin{aligned}
F(h 0 \ell) & =f \exp [2 \pi \mathrm{i}(h x+\ell z)][1+\exp (2 \pi \mathrm{i} \ell)] \\
& =f \exp [2 \pi \mathrm{i}(h x+\ell z)]\left[1+(-1)^{\ell}\right]
\end{aligned}
$$

This expression vanishes if $\ell$ is odd, and is equal to $2 f[2 \pi \mathrm{i}(h x+\ell z)$ if $\ell$ is even. Reflections of the type ( $h 0 \ell$ ) will, therefore, be missing unless $\ell$ is an even number. The characteristic absence or extinction of ( $h 0 \ell$ ) reflections with $\ell$ odd thus indicates a $c$ glide plane perpendicular to the $b$ axis.

For a twofold screw axis running parallel to $c$, the equivalent positions are $x, y, z$ and $-x,-y, z+1 / 2$.

$$
\begin{aligned}
F(h k \ell) & =\sum_{j=1}^{n} f_{j} \exp \left[\mathrm{i} 2 \pi\left(h x_{j}+k y_{j}+\ell z_{j}\right)\right] \\
& =\sum_{j=1}^{n / 2} f_{j}\left(\exp \left\{\mathrm{i} 2 \pi\left[h x_{j}+k y_{j}+\ell z_{j}\right]\right\}+\exp \left\{\mathrm{i} 2 \pi\left[-h x_{j}-k y_{j}+\ell\left(z_{j}+1 / 2\right)\right]\right\}\right)
\end{aligned}
$$

When $h$ and $k$ are both zero,

$$
F(00 \ell)=\sum_{j=1}^{n / 2} f_{j} \exp \left(\mathrm{i} 2 \pi \ell z_{j}\right)[1+\exp (\mathrm{i} 2 \pi \ell / 2)]
$$

This expression vanishes if $\ell$ is odd, and is equal to $2 \sum_{j=1}^{n / 2} f_{j} \exp \left[\mathrm{i} 2 \pi \ell_{z_{j}}\right]$ when $\ell$ is even. When reflections of the type $(00 \ell)$ are absent with $\ell$ odd, they suggest the presence of a screw axis in the $c$ direction.

The systematic absences due to the various types of lattice centering, screw axes, and glide planes are given in Table 9.4.2, which is used in the deduction of space groups.

Table 9.4.2. Determination of lattice type, screw axes, and glide planes from systematic absences of X-ray reflections

## (3) Deduction of space groups from systematic absences

Selected examples of the use of systematic absences in the deduction of space groups are illustrated in Table 9.4.3. Note that some conditions are redundant, as they are already covered by more general conditions. Some space groups can be determined uniquely, but others can only be narrowed down to a
few possibilities. In Table 9.4.4, those space groups that cannot be established unequivocally from systematic absences are listed.

### 9.5 Selected space groups and examples of crystal structures

### 9.5.1 Molecular symmetry and site symmetry

In a molecular crystal, the idealized symmetry of the molecule is often not fully expressed; in other words, the molecule occupies a site of lower point symmetry. For example, in the crystal structure of naphthalene, the $\mathrm{C}_{8} \mathrm{H}_{10}$ molecule (idealized symmetry $D_{2 h}$ ) is located at a site of symmetry $\overline{1}$. On the other hand, the hexamethylenetetramine molecule, $\left(\mathrm{CH}_{2}\right)_{6} \mathrm{~N}_{4}$, retains its $T_{\mathrm{d}}$ symmetry in the crystalline state. Biphenyl, $\mathrm{C}_{6} \mathrm{H}_{5}-\mathrm{C}_{6} \mathrm{H}_{5}$, which exists in a nonplanar conformation with a dihedral angle of $45^{\circ}$ (symmetry $D_{2}$ ) in the vapor phase, occupies a site of symmetry $\overline{1}$ in the crystalline state and is therefore completely planar.

Crystallization may in rare cases result in chemical transformation of the constituents of a chemical compound. For example, $\mathrm{PCl}_{5}$ is a trigonal bipyramidal molecule, but its crystal structure is composed of a packing of tetrahedral $\mathrm{PCl}_{4}^{+}$ and octahedral $\mathrm{PCl}_{6}^{-}$ions. In contrast, $\mathrm{PBr}_{5}$ in the crystalline state comprises $\mathrm{PBr}_{4}^{+}$and $\mathrm{Br}^{-}$ions; formation of the $\mathrm{PBr}_{6}^{-}$ion is precluded by steric repulsion between the bulky peripheral bromide ions.

### 9.5.2 Symmetry deductions: assignment of atoms and groups to equivalent positions

The presence of symmetry elements in a crystal imposes restrictions on the numbers of atoms that can be accommodated in a unit cell. If the space group does not have point symmetry elements which can generate special positions, atoms can be placed only in the general position, and their numbers in the cell are restricted to multiples of the multiplicity of that position. For example, space group $P 2_{1} 2_{1} 2_{1}$ has just one set of equivalent positions of multiplicity equal to 4; accordingly, atoms can occur only in sets of fours in the unit cell of any crystal belonging to this space group. A compound which crystallizes in this space group is codeine hydrobromide dihydrate, $\mathrm{C}_{18} \mathrm{H}_{21} \mathrm{O}_{3} \mathrm{~N} \cdot \mathrm{HBr} \cdot 2 \mathrm{H}_{2} \mathrm{O}$. The number of formula units per cell, $Z$, is equal to 4 , so that every atom must be present in multiples of 4 .

When the space group has special positions in addition to the general position, there is more latitude to the numbers of each atom type which can be present in the cell. For example, $\mathrm{FeSb}_{2}$ belongs to space group Pnnm with $Z=2$. This space group has one general eightfold, three special fourfold (site symmetry 2 or $m$ ), and four twofold (site symmetry $2 / m$ ) sets of equipoints. The Fe atoms must occupy one of the twofold sets. The Sb atoms may be assigned to two of the three remaining twofold equipoints or one of the three fourfold equipoints, but not the eightfold equipoint.

In simple inorganic crystals having only a few atoms per unit cell, equipoint considerations alone may lead to a solution of the crystal structure, or to a small number of possible solutions. For example, if a cubic crystal of composition AB has $Z=4$, its structure is fixed as either the NaCl type or the ZnS type.

## Symmetry in Chemistry

Table 9.4.4. Space groups not established uniquely from systematic absences

| Laue class | Symbol from systematic absences* | Possible space groups ${ }^{\dagger}$ |
| :---: | :---: | :---: |
| Triclinic $\overline{1}$ | $P \square$ | $P 1, P \overline{1}$ |
| Monoclinic 2/m | $P \square$ | Pm, P2, P2/m |
|  | $P \square c$ | $P c, P 2 / c$ |
|  | $P 2{ }_{1} \square$ | $P 2_{1}, P 2_{1} / m$ |
|  | $C \square$ | Cm, C2, C2/m |
|  | $C \square c$ | Cc, C2/c |
| Orthorhombic mmm | $P \square \square \square$ | Pmm2, P222, Pmmm |
|  | $P c \square \square$ | $\operatorname{Pcm}_{1}\left(=\mathrm{Pmc} 2_{1}\right), \operatorname{Pc} 2 m(=\mathrm{Pma} 2), \mathrm{Pcmm}(=\mathrm{Pmma})$ |
|  | Pn $\square \square$ | $\operatorname{Pnm2} 1_{1}\left(=P m n 2_{1}\right), \operatorname{Pnmm}(=P m m n)$ |
|  | $P c c \square$ | Pcc2, Pccm |
|  | Pca $\square$ | Pca ${ }_{1}, \operatorname{Pcam}(=\mathrm{Pbcm})$ |
|  | $P b a \square$ | Pba2, Pbam |
|  | $P n c \square$ | Pnc2, Pncm ( = Pmna) |
|  | Pna $\square$ | Pna ${ }_{1}$, Pnam ( $=$ Pnma) |
|  | Pnn $\square$ | Pnn2, Pnnm |
|  | $C \square \square \square$ | Cmm2, Cm2m (=Amm2), C222, Cmmm |
|  | $C \square c \square$ | $\mathrm{Cmc} 2{ }_{1}, \mathrm{C} 2 \mathrm{~cm}$ ( $=\mathrm{Ama} 2$ ), Cmcm |
|  | $C \square \square a$ | Cm2a (=Abm2), Cmma |
|  | $C \square c a$ | C2ca, Cmca |
|  | $C c c \square$ | Ccc $2, \mathrm{Cccm}$ |
|  | $I \square \square \square$ | Imm2, I222, I2 $1_{1} 2_{1}$, Immm |
|  | $I \square a \square$ | $\operatorname{Ima} 2, \operatorname{Imam}(=\operatorname{Imma})$ |
|  | $I b a \square$ | Iba2, Ibam |
|  | $F \square \square \square$ | Fmm2, F222, Fmmm |
| Tetragonal 4/m | $P \square$ | $P \overline{4}, P 4, P 4 / m$ |
|  | $P 4_{2} \square$ | $P 4_{2}, P 4_{2} / m$ |
|  | $I \square$ | İ $\overline{4}, I 4, I 4 / m$ |
| Tetragonal $\mathrm{P} 4 / \mathrm{mmm}$ | $P \square \square \square$ | $P \overline{4} 2 m, P \overline{4} m 2, P 4 m m, P 422, P 4 / \mathrm{mmm}$ |
|  | $P \square 2{ }_{1} \square$ | $P \overline{4} 2{ }_{1} m, P 42{ }_{1} 2$ |
|  | $P \square \square c$ | $P \overline{4} 2 c, P 4_{2} m c, P 4_{2} / m m c$ |
|  | $P \square b \square$ | $P \overline{4} b 2, P 4 b m, P 4 / \mathrm{mbm}$ |
|  | $P \square b c$ | $P 4_{2} b c, P 4_{2} / m b c$ |
|  | $P \square c \square$ | $P \overline{4} \mathrm{c} 2, \mathrm{P} 4_{2} \mathrm{~cm}, \mathrm{P} 4_{2} / \mathrm{mcm}$ |
|  | $P \square c c$ | $P 4 c c, P 4 / m c c$ |
|  | $P \square n \square$ | $P \overline{4} n 2, P 4_{2} \mathrm{~nm}, P 4_{2} / \mathrm{mnm}$ |
|  | $P \square n c$ | $P 4 n c, P 4 / m n c$ |
|  | $I \square \square \square$ | $I \overline{4} \mathrm{~m} 2, I \overline{4} 2 \mathrm{~m}, \mathrm{I} 4 \mathrm{~mm}, \mathrm{I} 422, I 4 / \mathrm{mmm}$ |
|  | $I \square c \square$ | $I \overline{4} \mathrm{c} 2, I 4 \mathrm{~cm}, I 4 / \mathrm{mcm}$ |
|  | $I \square \square d$ | $I \overline{4} 2 d, I 4_{1} m d$ |
| Trigonal $\overline{3}$ | $P \square$ | $P 3, P \overline{3}$ |
|  | $R \square$ | $R 3, R \overline{3}$ |
| Trigonal $\overline{3} m$ | $P \square \square \square$ | $P 3 m 1, P 31 m, P 312, P 321, P \overline{3} 1 m, P \overline{3} m 1$ |
|  | $P \square c \square$ | $P 3 c 1, P \overline{3} c 1$ |
|  | $P \square \square c$ | $P 31 c, P \overline{3} 1 c$ |
|  | $R \square \square$ | R3m, R32, R $\overline{3} m$ |
|  | $R \square c$ | $R 3 c, R \overline{3} c$ |
| Hexagonal 6/m | $P \square$ | $P 6, P \overline{6}, P 6 / m$ |
|  | $P 63$ | $P 6_{3}, P 66_{3} / m$ |
| Hexagonal 6/mmm | $P \square \square \square$ | $P \overline{6} \mathrm{~m} 2, P \overline{6} 2 \mathrm{~m}, ~ P 6 \mathrm{~mm}, P 622, P 6 / \mathrm{mmm}$ |
|  | $P \square c \square$ | $P \overline{6} c 2, P 6_{3} \mathrm{~cm}, P 6_{3} / \mathrm{mcm}$ |
|  | $P \square \square c$ | $P \overline{6} 2 c, P 6_{3} m c, P 6_{3} / m m c$ |
|  | $P \square c c$ | $P 6 c c, P 6 / m c c$ |
| Cubic $m \overline{3}$ | $P \square \square$ | P23, Pm $\overline{3}$ |
|  | $I \square \square$ | $I 23, I 21_{1} 3, I m \overline{3}$ |
|  | $F \square \square$ | $F 23, F m \overline{3}$ |
| Cubic $m \overline{3} m$ | $P \square \square \square$ | $P \overline{4} 3 m, P 432, P m \overline{3} m$ |
|  | $P \square \square n$ | $P \overline{4} 3 n, P m \overline{3} n{ }^{-}$ |
|  | $I \square \square \square$ | I $\overline{4} 3 \mathrm{~m}, \mathrm{I} 432, \mathrm{Im} \overline{3} m$ |
|  | $F \square \square \square$ | $F \overline{4} 3 m, F 432, F m \overline{3} m$ |
|  | $F \square \square c$ | $F \overline{4} 3 c, F m \overline{3} c$ |

[^3]The first belongs to space group $\mathrm{F} m \overline{3} m$, and the latter to $\mathrm{F} \overline{4} 3 m$, and these two possibilities can be distinguished by comparing the X-ray diffraction intensities expected from the two structure types with those actually observed. This type of deduction is based on consideration of the roles of the individual atoms in a crystal structure, which usually finds application in compounds of inorganic composition such as binary and ternary compounds, alloys, and minerals.

Symmetry considerations are most useful when applied to molecular crystals. In most organic and organometallic crystals, the building units are not the individual atoms but rather sets of atoms already organized into molecules. In such cases the whole chemical molecule must conform to the equipoint restrictions as to both number and symmetry. If the molecule occupies a general position, it need not have any imposed symmetry, because the general position has symmetry 1 . But if the molecule is located on a special position, it must have at least the symmetry of that special position. Accordingly, if the space group and the equipoint occupied by the molecule are known, the minimum symmetry which the molecule may have is determined. This information may be useful for a chemist who is trying to decide which, of several configurations that a molecule might conceivably have, is the true one.

It is commonly, but not always, true that all the molecules in a molecular crystal are equivalent. When this is the case, then all the molecules occupy the same set of equipoints; this implies that they are related to one another by the various symmetry operations of the space group. On the other hand, if the molecules occupy two or more Wyckoff positions, whether general or special, they are chemically equivalent but crystallographically distinct. A good example is the $1: 1$ adduct of hexamethylenetetramine oxide with hydroquinone, $\left(\mathrm{CH}_{2}\right)_{6} \mathrm{~N}_{4} \rightarrow \mathrm{O} \cdot p-\mathrm{C}_{6} \mathrm{H}_{4}(\mathrm{OH})_{2}$. This compound crystallizes in space group $P \overline{1}$ with $Z=2$, and the $p-\mathrm{C}_{6} \mathrm{H}_{4}(\mathrm{OH})_{2}$ molecules occupy two non-equivalent sites of $\overline{1}$ symmetry, rather than a general position. In other words, the asymmetric unit consists of a $\left(\mathrm{CH}_{2}\right)_{6} \mathrm{~N}_{4} \rightarrow \mathrm{O}$ and two "half-molecules" of $p-\mathrm{C}_{6} \mathrm{H}_{4}(\mathrm{OH})_{2}$, which are chemically equivalent but crystallographically distinguishable.

The following three compounds all crystallize in space group $P 2_{1} / c$. Useful information on molecular structure can be deduced when $Z$ is less than the space-group multiplicity of 4 .
(1) Naphthalene. Since $Z=2$, the molecule occupies a site of symmetry $\overline{1}$; in other words, there is an inversion center in the middle of the C4a-C8a bond. With reference to the atom numbering system shown below, the asymmetric unit can be taken as one of the right ( $1-4,4 a$ ), left ( $5-8,8 \mathrm{a}$ ), upper $(1,2,7,8,8 \mathrm{a})$ or lower $(3,4,4 \mathrm{a}, 5,6)$ half of the molecule. Note that the idealized molecular symmetry $D_{2 \mathrm{~h}}$ of naphthalene is not fully utilized in the solid state, and some of the chemically identical bond distances and bond angles have different measured values.

## Symmetry in Chemistry

(2) Biphenyl. Since $Z=2$, an inversion center is present in the middle of the bridging $\mathrm{C}-\mathrm{C}$ bond between the two $\mathrm{C}_{6} \mathrm{H}_{5}$ rings. This means that both phenyl rings are coplanar. The planar conformation of biphenyl in the crystalline state, which differs from its non-planar conformation in the solution and gas phases, is attributable to efficient molecular packing stabilized by intermolecular interactions between the phenyl rings.
(3) Ferrocene. With $Z=2$, the molecule must be placed in a special position of symmetry $\overline{1}$. The pair of cyclopentadienyl $(\mathrm{Cp})$ rings are thus expected to be staggered. In fact, the situation is more complicated. A thorough study of the structure of crystalline ferrocene by X-ray and neutron diffraction at temperatures of 173 and 298 K showed that the apparently staggered arrangement of the Cp rings results from the presence of molecules in different orientations randomly distributed at both 173 and 298 K. A disordered model with the two Cp ring rotated about $12^{\circ}$ from the eclipsed position is displayed in Fig. 9.5.1. (The rotation angle is $0^{\circ}$ for the precisely eclipsed $D_{5 \mathrm{~h}}$ conformation, and $36^{\circ}$ for the exactly staggered $D_{5 \mathrm{~d}}$ conformation.)

As a worked example, the assignment of atoms and groups to equivalent positions for basic beryllium acetate is illustrated in detail in the following paragraphs.

Basic beryllium acetate has the properties of a molecular solid rather than an ionic salt. X-ray analysis has shown that it consists of discrete $\mathrm{Be}_{4} \mathrm{O}\left(\mathrm{CH}_{3} \mathrm{COO}\right)_{6}$ molecules. The crystal structure is cubic, with $a=1574 \mathrm{pm}$ and $\rho_{\mathrm{x}}=1.39$ $\mathrm{g} \mathrm{cm}^{-3}$. The molecular weight of $\mathrm{Be}_{4} \mathrm{O}\left(\mathrm{CH}_{3} \mathrm{COO}\right)_{6}$ is 406 , and hence $Z=$ $\rho N_{o} V / \mathrm{M}=(1.39)\left(6.023 \times 10^{23}\right)\left(15.74 \times 10^{-8}\right)^{3} / 406 \approx 8$. The diffraction (Laue) symmetry is $m \overline{3}$. The condition for observable $h k \ell$ reflections: $h, k, \ell$ all even or all odd indicates a $F$ lattice; $0 k \ell$ present for $(k+\ell)=4 n$ indicates the presence of a $d$ glide plane. Hence the space group is uniquely established as $F d \overline{3}$ (No. 203).

Since $Z=8$, the asymmetric unit consists of one molecule located in special positions $8(a)$ or $8(b)$. The former may be taken for convenience. The molecular symmetry utilized in the space group is therefore 23 .

All atomic positional parameters, which define the crystal and molecular structure, can be assigned to the general and special equivalent positions of space group $F d \overline{3}$ (origin at 23):

Fig. 9.5.1.
A possible nearly eclipsed configuration for ferrocene in the disordered model. From P. Seiler and J. D. Dunitz, Acta Crystallogr., Sect. B 35, 1068-74 (1979).

| Wyckoff position | Site symmetry | Coordinates <br> $(0,0,0 ; 0,1 / 2,1 / 2 ; 1 / 2,0,1 / 2 ; 1 / 2,1 / 2,0)+$ |
| :--- | :---: | :---: |
| $96(g)$ | 1 | $x, y, z ;$ etc. |
| $48(f)$ | 2 | $x, 0,0 ;$ etc. |
| $32(e)$ | 3 | $x, x, x ;$ etc. |
| $16(d)$ | $\overline{3}$ | $5 / 8,5 / 8,5,8 ;$ etc. |
| $16(c)$ | 3 | $1 / 8,1 / 8,1 / 8 ;$ etc. |
| $8(b)$ | 23 | $1 / 2,1 / 2,1 / 2 ; 3,3 / 4,3 / 4$ |
| $8(a)$ | 23 | $0,0,0 ; 1 / 4,1 / 4,1 / 4$ |

The atom numbering scheme and molecular structure of $\mathrm{Be}_{4} \mathrm{O}\left(\mathrm{CH}_{3} \mathrm{COO}\right)_{6}$ is shown in Fig. 9.5.2.

The assignment of atomic positions proceeds as follows. The basic oxygen $\mathrm{O}(1)$ is placed in $8(a)$; Be in $32(e)$, not in $16(c)+16(d)$ because its coordination preference is tetrahedral rather than octahedral, and the molecule possesses symmetry element 3 but not $\overline{3}$; carboxylate carbon $\mathrm{C}(1)$ in $48(f)$ lying on twofold axis; methyl carbon $\mathrm{C}(2)$ in $48(f)$ lying on twofold axis; acetate oxygen $\mathrm{O}(2)$ in $96(\mathrm{~g})$. The crystal and molecular structure is therefore determined by six parameters: $x$ of $\mathrm{Be} ; x$ of $\mathrm{C}(1) ; x$ of $\mathrm{C}(2) ; x, y, z$ of $\mathrm{O}(2)$.

The following assignment shows that six positional parameters (neglecting the hydrogen atoms) are required for a description of the crystal structure. The hydrogen atoms are orientationally disordered, and they occupy general position $96(g)$ with half-site occupancy, as indicated in the last three rows of the table.

| Assignment | Parameters | Remarks |
| :---: | :---: | :---: |
| $\mathrm{Be}_{4} \mathrm{O}\left(\mathrm{CH}_{3} \mathrm{COO}\right)_{6}$ in $8(a)$ | none | Molecular symmetry has 23( $T$ ) |
| $\mathrm{O}(1)$ in 8(a) | none | Basic oxygen atom is at the centroid of the tetrahedron formed by Be atoms. |
| $\mathrm{Be}(1)$ in 32(e) | $x_{\text {Be }}$ | Beryllium atom lies on $C_{3}$ axis. |
| $\mathrm{O}(2)$ in $96(\mathrm{~g})$ | $x_{\mathrm{O} 2}, y_{\mathrm{O} 2}, \mathrm{z}_{\mathrm{O} 2}$ | Carboxylate oxygen atom is in general position. |
| $\mathrm{C}(1)$ in $48(f)$ | $x_{\mathrm{C} 1}$ | Carboxylate carbon atom lies on $C_{2}$ axis. |
| $\mathrm{C}(2)$ in $48(f)$ | ${ }^{\text {C2 }}$ 2 | Methyl carbon lies on the same $C_{2}$ axis. |
| $\frac{1}{2} \mathrm{H}(1)$ in $96(\mathrm{~g})$ | $x_{\mathrm{H} 1}, y_{\mathrm{H} 1}, z_{\mathrm{H} 1}$ | The methyl group is twofold disordered along |
| $\frac{1}{2} \mathrm{H}(2)$ in $96(\mathrm{~g})$ | $x_{\mathrm{H} 2}, y_{\mathrm{H} 2}, z_{\mathrm{H} 2}$ | the $\mathrm{C}-\mathrm{C}$ bond; the site occupancy factor of |
| $\frac{1}{2} \mathrm{H}(3)$ in $96(\mathrm{~g})$ | $x_{\mathrm{H} 3}, y_{\mathrm{H} 3}, z_{\mathrm{H} 3}$ | each methyl hydrogen atom is $1 / 2$. |

Fig. 9.5.2.
Molecular structure of $\mathrm{Be}_{4} \mathrm{O}\left(\mathrm{CH}_{3} \mathrm{COO}\right)_{6}$ with atom labels.

In the crystal structure, the symmetry of the $\mathrm{Be}_{4} \mathrm{O}\left(\mathrm{CH}_{3} \mathrm{COO}\right)_{6}$ molecule is 23 . The central oxygen atom is tetrahedrally surrounded by four beryllium atoms, and each beryllium atom is tetrahedrally surrounded by four oxygen atoms. The six acetate groups are attached symmetrically to the six edges of the tetrahedron. Hydrogen atoms of statistical weight $1 / 2$ are distributed over two sets of positions, corresponding to two equivalent orientations of the methyl group. Although the idealized molecular point group of $\mathrm{Be}_{4} \mathrm{O}\left(\mathrm{CH}_{3} \mathrm{COO}\right)_{6}$ is $\overline{4} 3 m\left(T_{\mathrm{d}}\right)$, the molecular symmetry in the crystal is reduced to the subgroup 23 $(T)$, and the symmetry elements 4 and $m$ are not utilized.

### 9.5.3 Racemic crystal and conglomerate

A racemic crystal contains equal numbers of both enantiomeric forms of a given compound in the unit cell of a centrosymmetric space group. A helicate consists of a linear array of metal ions along a central axis, around which there is a helical arrangement of bridging polytopic ligands. If a helicate crystallizes in a centrosymmetric space group, both right- and left-handed helices must coexist in equal numbers.
A conglomerate contains a $50: 50$ mixture of single crystals of both enantiomeric forms of a pure compound. A single crystal of either enantiomer may be picked up by chance for X-ray structure analysis. The space group is necessarily non-centrosymmetric.

Note that even for an achiral compound, there is the possibility of its building blocks being organized into chiral structures in the solid state, such as a righthanded (or left-handed) helix or three-leafed propeller. The classical inorganic example is $\alpha$-quartz; the space group is $P 3_{1} 21$ (No. 152) for the dextrorotatory form and $P 3_{2} 21$ (No. 154) for the levorotatory form. An organic example is provided by an isomorphous series of channel inclusion compounds of urea, which crystallize in the hexagonal space group $P 6_{1} 22$ (No. 178) or $P 6_{5} 22$ (No. 179). The structure of this type of compounds will be described in Section 9.6.5.

### 9.5.4 Occurrence of space groups in crystals

Nowadays the number of reported crystal structures is growing at the rate of more than 10,000 per year. There are known compounds in each of the 230 space groups. Several statistical studies have been carried out using the wealth of structural information in three major resources: Cambridge Structural Database (for organic compounds, organometallic compounds, and metal complexes containing organic ligands; abbreviated as CSD), the Inorganic Crystal Structure Database (ICSD), and the Metals Data File (MDF). The principal findings on the distribution of space groups are summarized below:
(1) Inorganic compounds are fairly evenly distributed among the seven crystal systems. Orthorhombic, monoclinic, and cubic crystals (in the order of abundance) comprise about $60 \%$ of the total number.
(2) In contrast, organic compounds are heavily concentrated in the lower-symmetry crystal systems. Monoclinic, orthorhombic, and triclinic crystals (in that order) comprise over $95 \%$ of the total number.

Table 9.5.1. Distribution of the most common space groups for crystals

| Rank | Inorganic |  | Organic |  |
| :---: | :---: | :---: | :---: | :---: |
|  | Space group | \% | Space group | \% |
| 1 | Pnma | 8.25 | $P_{2}{ }_{1} / \mathrm{c}$ | 36.57 |
| 2 | P2 $1_{1} / \mathrm{c}$ | 8.15 | $P \overline{1}$ | 16.92 |
| 3 | $\boldsymbol{F m} \overline{3} \boldsymbol{m}$ | 4.42 | $P 2_{1} 2_{1} 2_{1}$ | 11.00 |
| 4 | $P \overline{1}$ | 4.35 | C2/c | 6.95 |
| 5 | C2/c | 3.82 | $P 2_{1}$ | 6.35 |
| 6 | $\mathrm{P6}_{3} / \mathrm{mmc}$ | 3.61 | Pbca | 4.24 |
| 7 | C2/m | 3.40 | Pna2 ${ }_{1}$ | 1.63 |
| 8 | I4/mmm | 3.39 | Pnma | 1.57 |
| 9 | $F d \overline{3} m$ | 3.03 | P1 | 1.23 |
| 10 | $\boldsymbol{R} \overline{3} \boldsymbol{m}$ | 2.47 | Pben | 1.01 |
| 11 | Cmem | 1.95 | Cc | 0.97 |
| 12 | P $\overline{3} m 1$ | 1.69 | C2 | 0.90 |
| 13 | $\boldsymbol{P m} \overline{3} \boldsymbol{m}$ | 1.46 | $\mathrm{Pca}_{1}{ }_{1}$ | 0.75 |
| 14 | R $\overline{3}$ | 1.44 | $\mathrm{P}_{2} / \mathrm{m}$ | 0.64 |
| 15 | P6/mmm | 1.44 | $P 2{ }_{1}{ }_{1} 2$ | 0.53 |
| 16 | Pbca | 1.34 | C2/m | 0.49 |
| 17 | $P 2_{1} / \mathrm{m}$ | 1.33 | P2/c | 0.49 |
| 18 | $R \overline{3} \boldsymbol{c}$ | 1.10 | $R \overline{3}$ | 0.46 |

* Centrosymmetric space groups are highlighted in bold-face type. From W. H. Baur and D. Kassner, Acta Crystallogr., Sect B 48, 356-69 (1992).
(3) About $75-80 \%$ of known compounds crystallize in centrosymmetric space groups. About $80 \%$ of the non-centrosymmetric organic structures occur in space groups without an improper rotation axis $\bar{n}$ (the Sohncke groups).
(4) A 1992 survey of over 86,000 compounds in the three main crystallographic databases showed that about $57 \%$ of inorganic compounds are found in 18 most frequent space groups, which are all centrosymmetric. This is compared to about $93 \%$ for organic compounds in a different list of 18 space groups, of which eight lack an inversion center, including five possible ones for enantiomerically pure materials. Eight space groups are common to both lists. The principal findings are tabulated in Table 9.5.1.
(5) The three most common space groups for chemical compounds are $P 2_{1} / c, P \overline{1}$, and $C 2 / c$. In particular, $P 2_{1} / c$ is by far the dominant space group for organic crystals.
(6) Wrong assignment of space groups occurs most frequently for $C c$ (correct space group is $C 2 / c, F d d 2$, or $R \overline{3} c$ ). Other incorrect assignments often made are $P 1$ (correct space group $P \overline{1}$ ), Pna $2_{1}$ (correct space group Pnma), and $P c$ (correct space group $P 2_{1} / c$ ).

### 9.6 Application of space group symmetry in crystal structure determination

A precise description of the structure of a crystalline compound necessitates prior knowledge of its space group and atomic coordinates in the asymmetric unit. Illustrative examples of compounds belonging to selected space groups in the seven crystal systems are presented in the following sections.

Fig. 9.6.1.
Bond lengths and crystal structure of $\mathrm{C}_{6} \mathrm{Me}_{6}$.

### 9.6.1 Triclinic and monoclinic space groups

(1) Space group $P \overline{1}$ (no. 2), multiplicity $=2$

Hexamethylbenzene, $\mathrm{C}_{6} \mathrm{Me}_{6}$, exists as a plastic phase I above 383 K , a roomtemperature phase II, and a low-temperature phase III below 117.5 K . Both phase II and phase III crystallize in space group $P \overline{1}$ with $Z=1$. The molecule is therefore located at an inversion center, and the site symmetry $\overline{1}$ is much lower than the idealized molecular symmetry of $D_{6 h}$. The asymmetric unit consists of one-half of the molecule.

Determination of the crystal structure of phase II by Lonsdale in 1929 unequivocally settled over 70 years of debate concerning the geometry and bonding of aromatic molecular systems. The measured bond lengths and crystal structure of hexamethylbenzene are shown in Fig. 9.6.1. The hexamethylbenzene molecules lie within planes approximately perpendicular to (111). Phase III is structurally very similar to phase II, but differs from it mainly by a shearing process between molecular layers that results in a pseudo-rhombohedral, more densely packed arrangement.

Cisplatin is the commercial name of cis-diamminedichloroplatinum(II), which is widely used as an approved drug since 1978 for treating a variety of tumors. In the crystal structure, $Z=2$, and the cis- $\mathrm{PtCl}_{2}\left(\mathrm{NH}_{3}\right)_{2}$ molecule was found to occupy a general position. The measured dimensions and crystal packing are shown in Fig. 9.6.2.

## (2) $\quad$ Space group $P \mathbf{2}_{1}$ (no. 4), multiplicity $=\mathbf{2}$

This is one of the most common space groups for non-centrosymmetric molecules, particularly natural products and biological molecules. For example, sucrose is a non-reducing sugar, and X-ray analysis has revealed that its $\alpha$-D-glucopyranosyl- $\beta$-D-fructofuranoside skeleton consists of a linkage between $\alpha$-glucose and $\beta$-fructose moieties. The intramolecular hydrogen bonds and crystal structure are illustrated in Fig. 9.6.3.

Fig. 9.6.2.
Molecular and crystal structure of cis $-\mathrm{PtCl}_{2}\left(\mathrm{NH}_{3}\right)_{2}$.

## (3) Space group $\boldsymbol{P} \mathbf{2}_{1} / \boldsymbol{c}$ (no. 14), multiplicity $=4$

Naphthalene crystallizes in this space group with $Z=2$; the measured molecular dimensions and molecular packing are displayed in Fig. 9.6.4.

Also crystallizing in space group $P 2_{1} / c$, uranocene has two molecules per unit cell, so that the $\mathrm{U}\left(\mathrm{C}_{8} \mathrm{H}_{8}\right)_{2}$ molecule occupies a special position of site symmetry $\overline{1}$. In other words, the molecule has an eclipsed conformation, and it may be assigned to special position $2(a)$. Similarly, the two halves of the $\left[\mathrm{Re}_{2} \mathrm{Cl}_{8}\right]^{2-}$ dianion in $\mathrm{K}_{2}\left[\mathrm{Re}_{2} \mathrm{Cl}_{8}\right] \cdot 2 \mathrm{H}_{2} \mathrm{O}(Z=2)$ are in the eclipsed orientation with respect to each other. The measured molecular dimensions (indicating that the symmetry of the dianion is $D_{4 \mathrm{~h}}$ within experimental error) and crystal structure are shown in Fig. 9.6.5.

Fig. 9.6.3.
Molecular and crystal structure of sucrose.
With $Z=2$, the iron(II) phthalocyanine molecule occupies a $\overline{1}$ site, and its molecular and crystal structures are shown in Fig. 9.6.6.
$N^{\prime \prime}$-Cyano- $N, N$-diisopropylguanidine crystallizes in space group $P 2_{1} / c$ with $Z=40$. The asymmetric unit thus contains an exceptionally high number of ten molecules, which are labeled $\mathbf{A}$ to $\mathbf{J}$ in Fig. 9.6.7. These crystallographically independent yet structurally similar molecules constitute five

Crystallogr., Sect B, 61, 218-26 (2005).]
hydrogen-bonded dimers ( $\mathbf{A B}, \mathbf{C D}, \mathbf{E F}, \mathbf{G H}, \mathbf{I J}$ ), which are connected by additional hydrogen bonds to form a twisted ribbon. Extension of the ribbon along [101] generates an infinite helix with five dimeric units per turn.

Fig. 9.6.8.
Molecular and crystal structure of $\mathrm{Al}_{2} \mathrm{Me}_{6}$.

## (4) Space group $\boldsymbol{C 2} / \boldsymbol{c}$ (no. 15), multiplicity $=8$

Trimethylaluminum is a dimer with idealized molecular symmetry $D_{2 \mathrm{~h}}$, so that its molecular formula should be written as $\mathrm{Al}_{2} \mathrm{Me}_{6}$. There are four dimeric molecules in the unit cell. The molecule may be placed in Wyckoff position $4(a)$ of site symmetry 1 or $4(e)$ of site symmetry 2 , and the former has been found. The measured molecular dimensions and crystal structure are shown in Fig. 9.6.8.

### 9.6.2 Orthorhombic space groups

(1) Space group $P 2_{1} \mathbf{2}_{1} 2_{1}$ (no. 19), multiplicity $=4$

The iron-thiolato complex $\left(\mathrm{Me}_{4} \mathrm{~N}\right)_{2}\left[\mathrm{Fe}_{4} \mathrm{~S}_{4}\left(\mathrm{SC}_{6} \mathrm{H}_{5}\right)_{4}\right]$ crystallizes in this space group with $Z=4$, and the asymmetric unit consists of two $\mathrm{Me}_{4} \mathrm{~N}^{+}$cations and
(a)
(b)

a tetranuclear $\left[\mathrm{Fe}_{4} \mathrm{~S}_{4}\left(\mathrm{SC}_{6} \mathrm{H}_{5}\right)_{4}\right]^{2-}$ cluster dianion. The molecular and crystal structures are shown in Fig. 9.6.9.

## (2) Space group Pnma (no. 62), multiplicity $=8$

Hexachlorocyclophosphazene, $\left(\mathrm{PNCl}_{2}\right)_{3}$, has $Z=4$. Space group Pnma (no. 62) has special positions of site symmetry $\overline{1}$ and $m$; clearly $\overline{1}$ can be ruled out, and the molecule has a mirror plane passing through a $\mathrm{PCl}_{2}$ group and an opposite N atom in the ring. The molecular and crystal structure are shown in Fig. 9.6.10.

The Dewar benzene derivative $1^{\prime}, 8^{\prime}: 3,5$-naphtho[5.2.2]propella-3,8,10triene, $\mathrm{C}_{18} \mathrm{H}_{14}$, also has $Z=4$, and a crystallographic mirror plane passes through the central naphthalene $\mathrm{C}-\mathrm{C}$ bond and the midpoints of the bonds $C(8)-C\left(8^{\prime}\right), C(9)-C\left(9^{\prime}\right)$ and $C(10)-C\left(10^{\prime}\right)$. The measured bond lengths in the strained ring system and crystal structure are shown in Fig. 9.6.11.

(3) Space group Cmca (no. 64), multiplicity $=16$

If the formula of orthorhombic black phosphorus is written simply as P , then $\underline{Z}=8$. The special positions of space group Cmca are $4(a) 2 / m, 4(b) 2 / m, 8(c)$ $\overline{1}, 8(d) 2,8(e) 2,8(f) m$, and general position $16(g) 1$. The independent P atom actually is located in $8(f)$, generating a continuous double-layer structure, which is a heavily puckered hexagonal net in which each P atom is covalently bound to three others within the same layer. In Fig. 9.6.12, two puckered layers in

projection are shown on the left, and a perspective view of the crystal structure is shown on the right.

### 9.6.3 Tetragonal space groups

## (1) Space group $\mathrm{P4}_{1} \mathbf{2}_{1} \mathbf{2}$ (no. 90), multiplicity $=4$

The compound $1,1^{\prime}$-binaphthyl exists in its stable conformation as a chiral molecule. In the crystalline state, it exists in higher melting $\left(159^{\circ} \mathrm{C}\right)$ and lower melting $\left(145^{\circ} \mathrm{C}\right)$ forms. The latter form is a racemic crystal in space group $C 2 / c$.

In the crystal structure of the chiral higher melting form, a crystallographic twofold axis that bisects the central $\mathrm{C}(1)-\mathrm{C}\left(1^{\prime}\right)$ bond. The molecule has a gauche configuration about the $\mathrm{C}(1)-\mathrm{C}\left(1^{\prime}\right)$ bond with a dihedral angle of $103.1^{\circ}$. The molecular structure and packing are shown in Fig. 9.6.13.

## (2) Space group $\mathbf{P \overline { 4 }} \mathbf{2}{ }_{1} \boldsymbol{m}$ (no. 113), multiplicity $=8$

Urea was the first organic compound to be synthesized in the laboratory, a feat accomplished by Wöhler in 1828. In the crystal, urea occupies special position $2(c)$ where its $m m 2$ molecular symmetry is fully utilized. Every hydrogen atom is involved in a $\mathrm{N}-\mathrm{H} \cdots \mathrm{O}$ hydrogen bond, and this accounts for the fact that urea occurs as a solid at room temperature. A feature of chemical interest in the

Molecular and crystal structures of urea.
urea structure is that it provides the first example of a carbonyl O atom which forms four acceptor $\mathrm{N}-\mathrm{H} \cdots \mathrm{O}$ hydrogen bonds. The crystal packing of urea is shown in Fig 9.6.14.

## (3) Space group I4/mmm (no. 139), multiplicity $=32$

Xenon difluoride $\mathrm{XeF}_{2}$ and calcium carbide (form I) $\mathrm{CaC}_{2}$ are isomorphous; with $Z=2$, the linear triatomic molecule occupies Wyckoff position 2(a) of site symmetry $4 / \mathrm{mmm} . \mathrm{Hg}_{2} \mathrm{Cl}_{2}$ (calomel) has a very similar crystal structure, although it is tetraatomic. The molecular structure and crystal packing of $\mathrm{XeF}_{2}$ and $\mathrm{Hg}_{2} \mathrm{Cl}_{2}$ are compared in Fig. 9.6.15.

(4) Space group $I 4 / \mathbf{m c m}$ (no. 140), multiplicity $=32$

The newly prepared calcium nitridoberyllate $\mathrm{Ca}\left[\mathrm{Be}_{2} \mathrm{~N}_{2}\right]$ crystallizes in this space group with $a=556.15 \mathrm{pm}, c=687.96 \mathrm{pm}$, and $Z=4$. The atoms are located as shown in the following table:

(b)

| Atom | Wyckoff <br> position | Site <br> symmetry | Coordinates <br> $(0,0,0 ; 1 / 2,1 / 2,1 / 2)+$ |
| :--- | :--- | :--- | :--- |
| Be | $8(h)$ | $m m$ | $x, 1 / 2+x, 0 ; \bar{x}, 1 / 2-x, 0 ;{ }^{1 / 2}+x, \bar{x}, 0 ;{ }^{1} / 2-x, x, 0 ; x=0.372$ |
| N | $8(h)$ | $m m$ | $x, 1 / 2+x, 0 ; \bar{x},{ }^{1 / 2}-x, 0 ;{ }^{1} / 2+x, \bar{x}, 0 ; 1 / 2-x, x, 0 ; x=0.833$ |
| Ca | $4(a)$ | 42 | $0,0,1 / 4 ; 0,0,{ }^{3 / 2}$ |

The crystal structure contains planar nitridoberyllate $4.8^{2}$ nets (the notation $4.8^{2}$ indicates that each node in the net is the common vertex of one fourmembered and two eight-membered rings), which are stacked in a . . .ABAB. . . sequence but slightly rotated with respect to each other, such that the Be and N atoms aternate along the [001] direction. The slightly irregular octagonal voids between the nitridoberyllate layers are filled by $\mathrm{Ca}^{2+}$ ions, as shown in Fig. 9.6.16.

## (5) Space group $\overline{\operatorname{l}} \mathbf{2} \mathbf{2}$ (no. 122), multiplicity $=16$

meso-(Tetraphenylporphinato)iron(II), [Fe(TPP)], $\mathrm{C}_{44} \mathrm{H}_{28} \mathrm{~N}_{4} \mathrm{Fe}$, has $Z=4$. The molecule occupies Wyckoff position $4(a)$ of site symmetry $\overline{4}$; it has a ruffled structure. The dihedral angles between the porphyrin and the pyrrole planes, and between the porphyrin and the benzene planes, are $12.8^{\circ}$ and $78.9^{\circ}$, respectively. The molecular and crystal structure of Fe(TPP) are shown in Fig. 9.6.17.

### 9.6.4 Trigonal and rhombohedral space groups

(1) Space group $P \overline{\mathbf{3}}$ (no. 147), multiplicity $=6$

The crystal structure of the salt $\left[\{\mathrm{K}(2.2 .2 \text {-crypt })\}_{2}\right]\left[\mathrm{Pt} @ \mathrm{~Pb}_{12}\right]$ contains a dianion composed of a cage of 12 Pb atoms that encloses a centered Pt atom, denoted

## Symmetry in Chemistry

by the symbolic structural formula $\left[\mathrm{Pt} @ \mathrm{~Pb}_{12}\right]^{2-}$, which has near-perfect icosahedral symmetry $I_{\mathrm{h}}$. With $Z=1$, the anion occupies a $\overline{3}$ site [Wyckoff position $1(a)]$, and the $[\mathrm{K}(2 \cdot 2 \cdot 2 \text {-crypt })]^{+}$cation lies on a 3-axis [Wyckoff position 2(d)]. The molecular structure of $\left[\mathrm{Pt} @ \mathrm{~Pb}_{12}\right]^{2-}$ is shown in Fig. 9.6.18.

(2) Space group $R \overline{\mathbf{3}}$ (no. 148), multiplicity $=6$ for rhombohedral unit cell
Cubane was first synthesized by Eaton in 1964. In the crystal, with $Z=1$, the molecule has symmetry $\overline{3}$, so that there are two independent carbon atoms that occupy general position $6(f)$ and special position $2(c)$ of site symmetry 3 . The $\mathrm{C}-\mathrm{C}$ bond lengths are 155.3 (3) and 154.9 (3) pm, and the $\mathrm{C}-\mathrm{C}-\mathrm{C}$ bond angles are $89.3^{\circ}, 89.6^{\circ}$, and $90.5^{\circ}$, all being close to the values expected for a regular cube. Figure 9.6 .19 shows the molecular structure and crystal packing of cubane. Historically, the cubane structure was used in the first demonstration of the molecular graphics program ORTEP (Oak Ridge Thermal Ellipsoid Plot) written by C. K. Johnson.

## (3) Space group $\boldsymbol{R} \overline{\mathbf{3}} \boldsymbol{c}$ (no. 167), multiplicity $=36$ for hexagonal unit cell

The hexagonal unit cell of $s$-triazine has $Z=6$, and the molecule occupies Wyckoff position $2(a)$ of site symmetry 32 . The molecule is planar, but it deviates quite markedly from a regular hexagon. From a neutron study, the C-N and $\mathrm{C}-\mathrm{H}$ bond lengths are $131.5(2)$ and $93(4) \mathrm{pm}$, respectively, and the $\mathrm{N}-\mathrm{C}-\mathrm{N}$ angle is $125(1)^{\circ}$. Figure 9.6 .20 shows the molecular structure and packing of $s$-triazine molecules in the unit cell. The molecules are arranged in columns parallel to $c$ with a regular spacing of $c / 2$. Besides the pair of neighbors above and below it, each molecule is surrounded by six others at a center-to-center separation of 570 pm .

Crystalline $s$-triazine undergoes a phase transition from a rhombohedral structure (space group $R \overline{3} c$ ) at room temperature to a monoclinic structure (space group $C 2 / c$ ) below 198 K .

(4) Space group $R \overline{3} m$ (no. 166), multiplicity $=36$ for hexagonal unit cell
The hexagonal unit cell of the $\alpha$-rhombohedral form of elemental boron ( $\alpha$ R12 boron) contains 36 B atoms that form three $\mathrm{B}_{12}$ icosahedra. The $\mathrm{B}_{12}$ icosahedron occupies Wyckoff position $3(a)$ of site symmetry $\overline{3} m$, so that the asymmetric unit contains two independent B atoms in position 18(h) of site symmetry $m$.

In the crystal structure of $\alpha-\mathrm{R} 12$ boron, the $\mathrm{B}_{12}$ icosahedra are arranged in approximately cubic closest packing and are linked together in a threedimensional framework. Figure 9.6 .21 shows a layer of interlinked icosahedra perpendicular to the $\overline{3}$-axis, and a perspective view of the crystal structure approximately along the $a$ axis (note the linkage between layers of icosahedra at $z=0,1 / 3,2 / 3,1)$. Further details are given in Section 13.2.

### 9.6.5 Hexagonal space groups

## (1) Space group P61 22 (no. 178), multiplicity $=12$

Urea forms an isomorphous series of crystalline non-stoichiometric inclusion compounds with $n$-alkanes and their derivatives (including alcohols, esters, ethers, aldehydes, ketones, carboxylic acids, amines, nitriles, thioalcohols, and thioethers), provided that their main chain contains six or more carbon atoms.

The hexagonal unit cell, belonging to space group $P 6_{1} 22$ or $P 6_{5} 22$, contains six urea molecules in Wyckoff position $6(a)$ of site symmetry 2. The urea host molecules are arranged in three twined helical spirals, which are interlinked by hydrogen bonds to form the walls of each channel, within which the guest molecules are densely packed (Fig. 9.6.22, top). The host molecules are almost coplanar with the walls of the hexagonal channel, and the channels are packed in a distinctive honeycomb-like manner (Fig. 9.6.22, bottom). The host lattice is stabilized by the maximum possible number of hydrogen bonds that lie virtually within the walls of the hexagonal channels: each $\mathrm{NH}_{2}$ group forms two donor bonds, and each O atom four acceptor bonds, with their neighbors.

## (2) Space group P6/mcc (no. 192), multiplicity $=24$

Beryl has the structural formula $\mathrm{Be}_{3} \mathrm{Al}_{2}\left[\mathrm{Si}_{6} \mathrm{O}_{18}\right]$, with $a=920.88(5)$, $c=$ 918.96(7) pm and $Z=2$. The structure of beryl was determined by Bragg

A shoulder-to-shoulder urea ribbon is highlighted by showing its $\mathrm{N}-\mathrm{H} \cdots \mathrm{O}$ hydrogen bonds as open lines. (Bottom) The channel-type structure of inclusion compounds of urea viewed along the $c$ axis. For clarity the guest molecules are represented by large circles.

Fig. 9.6.23.
Crystal structure of beryl.

and West in 1926. The atoms are located in the following general and special positions.

| Atom | Wyckoff position | Site symmetry | $x$ | $y$ | $z$ |
| :--- | :---: | :---: | :---: | :---: | :---: |
| Si | $12(\ell)$ | $m$ | 0.3875 | 0.1158 | 0 |
| Be | $6(f)$ | 222 | $1 / 2$ | 0 | $1 / 4$ |
| Al | $4(c)$ | 32 | $2 / 3$ | $1 / 3$ | $1 / 4$ |
| $\mathrm{O}(1)$ | $12(\ell)$ | $m$ | 0.3100 | 0.2366 | 0 |
| $\mathrm{O}(2)$ | $24(m)$ | 1 | 0.4988 | 0.1455 | 0.1453 |

The crystal structure consists of $\left[\mathrm{SiO}_{4}\right]$ tetrahedra, which are connected by sharing oxygen atoms of the type $\mathrm{O}(1)$ so as to form a sixfold ring. The resulting $\left[\mathrm{Si}_{6} \mathrm{O}_{18}\right]^{2-}$ cyclic anions are arranged in parallel layers about the $z=0$ and $z=$ $1 / 4$ planes. They are further linked together by bonding, through oxygen atoms of the type $\mathrm{O}(2)$, to $\mathrm{Be}^{\mathrm{II}}$ and $\mathrm{Al}^{\mathrm{III}}$ ions, to give a three-dimensional framework, as shown in Fig. 9.6.23. The bond distances are $\mathrm{Si}-\mathrm{O}=159.2$ to 162.0 pm in the $\left[\mathrm{SiO}_{4}\right]$ tetrahedron, $\mathrm{Be}-\mathrm{O}=165.3 \mathrm{pm}$ in the $\left[\mathrm{BeO}_{4}\right]$ tetrahedron, and $\mathrm{Al}-\mathrm{O}=190.4 \mathrm{pm}$ in the $\left[\mathrm{AlO}_{6}\right]$ octahedron.

## (3) Space group P63/mmc (no. 194), multiplicity $=24$

The crystal structure of cesium iron fluoride, $\mathrm{Cs}_{3} \mathrm{Fe}_{2} \mathrm{~F}_{9}$, comprises a packing of binuclear face-sharing octahedral $\mathrm{Fe}_{2} \mathrm{~F}_{9}^{3-}$ units and $\mathrm{Cs}^{+}$ions. With $a=$ 634.7(1), $c=1480.5(3) \mathrm{pm}$ and $Z=2$, the locations of the atoms and the $\mathrm{Fe}_{2} \mathrm{~F}_{9}^{3-}$ anion are shown in the following table:
(a)

(b)

| Atom/Unit | Wyckoff position | Site symmetry | $x$ | $y$ | $z$ |
| :--- | :---: | :---: | :---: | :---: | :---: |
| $\mathrm{Cs}(1)$ | $2(d)$ | $\overline{6} m 2$ | $1 / 3$ | $2 / 3$ | $3 / 4$ |
| $\mathrm{Cs}(2)$ | $4(f)$ | $3 m$ | $1 / 3$ | $2 / 3$ | 0.43271 |
| Fe | $4(e)$ | $3 m$ | 0 | 0 | 0.15153 |
| $\mathrm{~F}(1)$ | $6(h)$ | $m m$ | 0.1312 | 0.2624 | $1 / 4$ |
| $\mathrm{~F}(2)$ | $12(k)$ | 1 | 0.1494 | 0.2988 | 0.5940 |
| $\mathrm{Fe}_{2} \mathrm{~F}_{9}^{3-}$ | $2(b)$ | $\overline{6} m 2$ | 0 | 0 | $1 / 4$ |

The structure of the $\mathrm{Fe}_{2} \mathrm{~F}_{9}^{3-}$ anion and the crystal packing in $\mathrm{Cs}_{3} \mathrm{Fe}_{2} \mathrm{~F}_{9}$ are shown in Fig. 9.6.24.

### 9.6.6 Cubic space groups

## (1) Space group Pā̄ (no. 205), multiplicity $=24$

The alums are a group of hydrated double salts with the general formula $\mathrm{M}^{\mathrm{I}} \mathrm{M}^{\mathrm{III}}$ $\left(\mathrm{XO}_{4}\right)_{2} \cdot 12 \mathrm{H}_{2} \mathrm{O}$ in which $\mathrm{M}^{\mathrm{I}}$ is a monovalent metal such as $\mathrm{Na}^{+}, \mathrm{K}^{+}, \mathrm{Rb}^{+}, \mathrm{Cs}^{+}$, $\mathrm{NH}_{4}^{+}$, or $\mathrm{Tl}^{+} ; \mathrm{M}^{\mathrm{III}}$ is a trivalent metal such as $\mathrm{Al}^{3+}, \mathrm{Cr}^{3+}, \mathrm{Fe}^{3+}, \mathrm{Rh}^{3+}, \mathrm{In}^{3+}$, or $\mathrm{Ga}^{3+}$ and X is S or Se. They crystallize in the space group $\operatorname{Pa} \overline{3}$ (no. 205) but occur in three distinct types, $\alpha, \beta$, and $\gamma$; the order of increasing $\mathrm{M}^{\mathrm{I}}$ size is generally $\gamma, \alpha, \beta$, but this is not always true. There are only a few known $\gamma$ alums with sodium as the monovalent $\mathrm{M}^{\mathrm{I}}$ ion. Most cesium sulfate alums adopt the $\beta$ structure, but exceptions occur when $\mathrm{M}^{\mathrm{III}}$ is cobalt, rhodium, or iridium, for which the cesium sulfate alums have the $\alpha$ structure. The best known alum is potassium aluminum alum (potash alum), $\mathrm{KAl}\left(\mathrm{SO}_{4}\right)_{2} \cdot 12 \mathrm{H}_{2} \mathrm{O}$, which belongs to the $\alpha$ type.

The crystal structure of $\mathrm{KAl}\left(\mathrm{SO}_{4}\right)_{2} \cdot 12 \mathrm{H}_{2} \mathrm{O}$ is cubic, with $a=1215.8 \mathrm{pm}$ and $Z=4$; if the formula is written as $\mathrm{K}_{2} \mathrm{SO}_{4} \cdot \mathrm{Al}_{2}\left(\mathrm{SO}_{4}\right)_{3} \cdot 24 \mathrm{H}_{2} \mathrm{O}$, then $Z=2$. The Laue symmetry of the diffraction pattern is $m \overline{3}$; the systematic absences are $0 k \ell$ reflections with $k$ odd, $h 0 \ell$ with $\ell$ odd, and $h k 0$ with $h$ odd. From these conditions, the space group can be uniquely established as $P a \overline{3}$ (no. 205). The space group symbol indicates a primitive lattice, with a glide plane normal to the $a$ axis (the glide direction is $1 / 2$ along $b$, i.e., a glide component of $b / 2$ ) and four $\overline{3}$-axes along the body diagonals of the unit cell. Since

Fig. 9.6.24.
(a) Molecular structure of the $\mathrm{Fe}_{2} \mathrm{~F}_{9}^{3-}$ anion and (b) crystal structure of its $\mathrm{Cs}^{+}$ salt.
the crystal system is cubic, the symbol $a$ also implies a glide plane normal to $b$ with glide component $c / 2$, and a glide plane normal to $c$ with glide component $a / 2$.

All atomic positional parameters of the potash alum structure can be assigned to the following general and special equivalent positions of space group $P a \overline{3}$.

| Wyckoff position | Site symmetry | Coordinates |
| :--- | :---: | :---: |
| $24(d)$ | 1 | $x, y, z ; \bar{x}, \bar{y}, \bar{z} ;$ etc. |
| $8(c)$ | 3 | $x, x, \bar{x}, \bar{x}, \bar{x} ;$ etc. |
| $4(b)$ | $\overline{3}$ | $1 / 2,1 / 2,1 / 2 ; 1 / 2,0,0 ; 0,1 / 2,0 ; 0,0,1 / 2$ |
| $4(a)$ | $\overline{3}$ | $0,0,0 ; 0,1 / 2,1 / 2 ; 1 / 2,0,1 / 2 ; 1 / 2,1 / 2,0$ |

There are four $\mathrm{K}^{+}$and four $\mathrm{Al}^{3+}$ ions in the unit cell, and they can be assigned to the $\overline{3}$ sites $4(a)$ and $4(b)$, respectively. The reverse assignment makes no real difference as it merely involves a shift of the origin of the unit cell. Once sites $4(a)$ and $4(b)$ have been filled, the eight sulfur atoms must be assigned to $8(c)$ which means that the $\mathrm{SO}_{4}^{2-}$ ion lies on a 3 -axis. The 32 sulfate oxygens can be assigned to $8(c)+24(d)$; since the sulfate ion is tetrahedral, only one of its oxygen atom can lie on the same 3 -axis; there are thus two types of independent sulfate oxygen atoms. The 48 water oxygen atoms can be assigned to $2 \times 24(d)$, and their 96 water hydrogen atoms to $4 \times 24(d)$. In summary, the positional parameters of non-hydrogen atoms can be assigned as follows:

| Assignment | Parameters | Remarks |
| :--- | :--- | :--- |
| $\mathrm{K}(1)$ in $4(a)$ | none | Arbitrarily placed |
| $\mathrm{Al}(1)$ in $4(b)$ | none | Must be placed in this position |
| $\mathrm{S}(1)$ in $8(c)$ | $x_{\mathrm{S}}$ | S atom lying on 3-axis |
| $\mathrm{O}(1)$ in $8(c)$ | $x_{\mathrm{O} 1}$ | S-O bond lying on 3-axis |
| $\mathrm{O}(2)$ in 24(d) | $x_{\mathrm{O} 2}, y_{\mathrm{O} 2}, z_{\mathrm{O} 2}$ | The other sulfate O in general position |
| $\mathrm{O}(1 \mathrm{w})$ in 24(d) | $x_{\mathrm{O} 1 w}, y_{\mathrm{O} 1 w}, z_{\mathrm{O} 1 w}$ | Water molecule coordinated to $\mathrm{K}^{+}$ |
| $\mathrm{O}(2 \mathrm{w})$ in 24(d) | $x_{\mathrm{O} 2 w}, y_{\mathrm{O} 2 w}, z_{\mathrm{O} 2 w}$ | Water molecule coordinated to $\mathrm{Al}^{3+}$ |

Therefore, eleven parameters are sufficient to define the crystal structure, and an additional $4 \times 3=12$ parameters are required if the hydrogen atoms are also included. When a water molecule is coordinated to a $\mathrm{K}^{+}$or $\mathrm{Al}^{3+}$ cation, an octahedral coordination environment is generated around the cation by the $\overline{3}$ symmetry operation. Therefore, the crystal structure of $\mathrm{KAl}\left(\mathrm{SO}_{4}\right)_{2} \cdot 12 \mathrm{H}_{2} \mathrm{O}$ can be regarded as a packing of $\left[\mathrm{K}\left(\mathrm{H}_{2} \mathrm{O}\right)_{6}\right]^{+}$and $\left[\mathrm{Al}\left(\mathrm{H}_{2} \mathrm{O}\right)_{6}\right]^{3+}$ octahedra and $\mathrm{SO}_{4}^{2-}$ tetrahedra. If the structural formula of $\mathrm{KAl}\left(\mathrm{SO}_{4}\right)_{2} \cdot 12 \mathrm{H}_{2} \mathrm{O}$ is rewritten as $\mathrm{K}\left(\mathrm{H}_{2} \mathrm{O}\right)_{6} \cdot \mathrm{Al}\left(\mathrm{H}_{2} \mathrm{O}\right)_{6} \cdot 2 \mathrm{SO}_{4}$, it is easy to see that the three kinds of moieties can be assigned to Wyckoff positions $4(a), 4(b)$, and $8(c)$, respectively. Both hydrated cations have site symmetry $\overline{3}$ (a subgroup of $m \overline{3} m$ for a regular octahedron), and the sulfate anion has site symmetry 3 (a subgroup of $\overline{4} 3 m$ for a regular tetrahedron). The crystal structure of potash alum is shown in Fig. 9.6.25.

Representative examples of the $\beta$ and $\gamma$ alums are $\mathrm{CsAl}\left(\mathrm{SO}_{4}\right)_{2} \cdot 12 \mathrm{H}_{2} \mathrm{O}$ and $\mathrm{NaAl}\left(\mathrm{SO}_{4}\right)_{2} \cdot 12 \mathrm{H}_{2} \mathrm{O}$, respectively. In the $\alpha$ and $\gamma$ alums, the six water molecules generated from $\mathrm{O}(1 \mathrm{w})$ constitute a flattened octahedron centered at $\mathrm{M}^{\mathrm{I}}$. In contrast, in a $\beta$ alum these six water molecules lie almost in a planar hexagon around the large $\mathrm{M}^{\mathrm{I}}$ atom. In both $\alpha$ and $\beta$ alums, the $\mathrm{S}-\mathrm{O}(1)$ bond points away from the nearest $\mathrm{M}^{\mathrm{I}}$ atom, but in the $\gamma$ form the $\mathrm{S}-\mathrm{O}(1)$ bond points towards it. Accordingly, the coordination number of $M^{\mathrm{I}}$ in a $\gamma$ alum is eight (six waters and two sulfate oxygens of type $\mathrm{O}(1)$ ), which is increased to twelve for the $\alpha$ and $\beta$ alums (six waters and six sulfate oxygens of type $\mathrm{O}(2)$ ). In both $\alpha$ and $\beta$ alums, the $\mathrm{M}^{\mathrm{III}}\left(\mathrm{H}_{2} \mathrm{O}\right)_{6}$ unit is a distorted octahedron whose principal axes are nearly parallel to the unit-cell axes; in contrast, the $\mathrm{M}^{\mathrm{III}}\left(\mathrm{H}_{2} \mathrm{O}\right)_{6}$ octahedron in the $\gamma$ form is very regular but rotated by approximately $40^{\circ}$ about the body diagonal of the unit cell. The crystal structures of the $\beta$ and $\gamma$ forms are compared in Fig. 9.6.26.

## (2) Space group $\overline{\mathbf{4}} \mathbf{3} m$ (no. 217), multiplicity $=48$

Hexamethylenetetramine, $\left(\mathrm{CH}_{2}\right)_{6} \mathrm{~N}_{4}$, was the first organic molecule to be subjected to crystal structure analysis. The crystals are cubic, with $a=702$ pm and measured density $\rho=1.33 \mathrm{~g} \mathrm{~cm}^{-3}$. Calculation using the formula $Z=\rho N_{o} V / \mathrm{M}=(1.33)\left(6.023 \times 10^{23}\right)\left(7.02 \times 10^{-8}\right)^{3} / 140 \sim 2$ shows that there are two molecules in the unit cell.

From the X-ray photographs, the Laue symmetry is established as cubic $m \overline{3} m$ and the systematic absences are $h k \ell$ with $(h+k+\ell)$ odd. All three point groups 432, $\overline{4} 3 m$, and $m \overline{3} m$ belong to the same Laue class $m \overline{3} m$, and three space groups I432, $I \overline{4} 3 m$, and $\operatorname{Im} \overline{3} m$ are consistent with the observed systematic absences and Laue symmetry. Furthermore, as the $\left(\mathrm{CH}_{2}\right)_{6} \mathrm{~N}_{4}$ molecule lacks either a 4 -axis or a center of symmetry, the true space group can be unequivocally established as $I \overline{4} 3 m$, which has the following general and special equivalent positions:

Fig. 9.6.25.
Crystal structure of potash alum.
(a)

(b)

Fig. 9.6.26.
Comparison of the crystal structures of (a) $\gamma$ alum $\mathrm{NaAl}\left(\mathrm{SO}_{4}\right)_{2} \cdot 12 \mathrm{H}_{2} \mathrm{O}$ and (b) $\beta$ alum $\mathrm{CsAl}\left(\mathrm{SO}_{4}\right)_{2} \cdot 12 \mathrm{H}_{2} \mathrm{O}$. For clarity the bonds between the $\mathrm{M}^{\mathrm{I}}$ atoms and the sulfate groups are represented by broken lines.

| Wyckoff position | Site symmetry | Coordinates <br> $(0,0,0 ; 1 / 2,1 / 2,1 / 2)+$ |
| :--- | :--- | :--- |
| $48(h)$ | 1 | $x, y, z ;$ etc. |
| $24(g)$ | $m$ | $x, x, z ;$ etc. |
| $24(f)$ | 2 | $x, 1 / 2,0 ;$ etc. |
| $12(e)$ | $m m$ | $x, 0,0 ;$ etc. |
| $12(d)$ | $\overline{4}$ | $1 / 4,1 / 2,0 ;$ etc. |
| $8(c)$ | $3 m$ | $x, x, x ;$ etc. |
| $6(b)$ | $\overline{4} 2 m$ | $0,1 / 2,1 / 2 ;$ etc. |
| $2(a)$ | $\overline{4} 3 m$ | $0,0,0$ |

All atomic positions, including hydrogens in the unit cell, can be assigned to the following special positions in space group $I \overline{4} 3 \mathrm{~m}$ :

| Assignment | Parameters | Remarks |
| :--- | :--- | :--- |
| $\left(\mathrm{CH}_{2}\right)_{6} \mathrm{~N}_{4}$ in 2(a) | none | molecular symmetry is $T_{\mathrm{d}}$ |
| N in 8(c) | $x_{\mathrm{N}}$ | N at the intersection of $C_{3}$ and three $\sigma_{\mathrm{d}}$ 's |
| C in 12(e) | $x_{\mathrm{C}}$ | C at the intersection of two $\sigma_{\mathrm{d}}$ 's |
| H in 24(g) | $x_{\mathrm{H}}, z_{\mathrm{H}}$ | methylene H lies in $\sigma_{\mathrm{d}}$ |

As the structure consists of a body-centered arrangement of $\left(\mathrm{CH}_{2}\right)_{6} \mathrm{~N}_{4}$ molecules, four positional parameters are required for a complete description of the crystal structure. Moreover, the fractional coordinates for carbon and nitrogen can be deduced from relevant chemical data: (a) the van der Waals
(a)

(b)

separation between carbon atoms in neighboring molecules in an axial direction $\sim 368 \mathrm{pm}$ and (b) the length of a C-N single bond $\sim 148 \mathrm{pm}$.

The carbon atoms having fractional coordinates $\left(x_{\mathrm{C}}, 0,0\right)$ and $\left(1-x_{\mathrm{C}}, 0\right.$, 0 ) are closest to each other. Therefore, $a\left[\left(1-x_{\mathrm{C}}\right)-x_{\mathrm{C}}\right]=368$, leading to $x_{\mathrm{C}}=0.238$. Now consider the bond from C at $\left(x_{\mathrm{C}}, 0,0\right)$ to N at $\left(x_{\mathrm{N}}, x_{\mathrm{N}}, x_{\mathrm{N}}\right)$, which gives $\left.a\left[\left(0.238-x_{\mathrm{N}}\right)^{2}+x_{\mathrm{N}}^{2}+x_{\mathrm{N}}^{2}\right)\right]^{1 / 2}=148$. Solution of this equation yields $x_{\mathrm{N}}=0.127$ or 0.032 . Consideration of the molecular dimensions of $\left(\mathrm{CH}_{2}\right)_{6} \mathrm{~N}_{4}$ shows that the first answer is the correct one. The molecular and crystal structures of $\left(\mathrm{CH}_{2}\right)_{6} \mathrm{~N}_{4}$ are illustrated in Fig. 9.6.27.

Methyllithium, $\left(\mathrm{CH}_{3} \mathrm{Li}\right)_{4}$, also crystallizes in space group $I \overline{4} 3 m$ with $a=724$ pm and $Z=2$. The tetrameric unit may be described as a tetrahedral array of Li atoms with a methyl C atom located above the center of each face of the $\mathrm{Li}_{4}$ tetrahedron or, alternately, as a distorted cubic arrangement of Li atoms and $\mathrm{CH}_{3}$ groups. The locations of the $\left(\mathrm{CH}_{3} \mathrm{Li}\right)_{4}$ unit and its constituent atoms are listed in the following table.

| Atom/unit | Wyckoff position | Site symmetry | $x$ | $y$ | $z$ |
| :--- | :---: | :---: | :--- | :--- | :--- |
| Li | $8(c)$ | $3 m$ | 0.131 | 0.131 | 0.131 |
| C | $8(c)$ | $3 m$ | 0.320 | 0.320 | 0.320 |
| H | $24(g)$ | $m$ | 0.351 | 0.351 | 0.192 |
| $\left(\mathrm{CH}_{3} \mathrm{Li}\right)_{4}$ | $2(a)$ | $\overline{4} 3 m$ | 0 | 0 | 0 |

The crystal structure of methyllithium is not built of discrete $\left(\mathrm{CH}_{3} \mathrm{Li}\right)_{4}$ molecules. Such tetrameric units are connected together to give a threedimensional polymeric network, as illustrated in Fig. 9.6.28. The $\mathrm{Li}-\mathrm{C}$ bond length within a tetrameric unit is 231 pm , which is comparable to the intertetramer Li-C bond distance of 236 pm .

## (3) Space group $\boldsymbol{F m} \overline{\mathbf{3}} \boldsymbol{m}$ (no. 225), multiplicity $=192$

Adamantane, a structural analog of hexamethylenetetramine, crystallizes at room temperature in the cubic space group $F m \overline{3} m$ with $a_{\mathrm{C}}=944.5 \mathrm{pm}$ and $Z=4$. The structure is disordered, not ordered in space group $F \overline{4} 3 m$ (no. 216, multiplicity $=96$ ) as described in a previous report. The cubic close-packed arrangement of $\left(\mathrm{CH}_{2}\right)_{6}(\mathrm{CH})_{4}$ is favored over the body-centered cubic structure

Fig. 9.6.27.
(a) Molecular structure of $\left(\mathrm{CH}_{2}\right)_{6} \mathrm{~N}_{4}$, with H atoms represented by small open circles. There are three 2 -axes, each passing through a pair of carbon atoms, four 3-axes, each through a nitrogen atom, and six $\sigma_{\mathrm{d}}$ 's, each containing a methylene group. (b) Crystal structure of $\left(\mathrm{CH}_{2}\right)_{6} \mathrm{~N}_{4}$; the H atoms are not shown.

(b)

## Fig. 9.6.28.

(a) Polymeric crystal structure of methyllithium. (b) Space-filling model of the tetrameric $\left(\mathrm{CH}_{3} \mathrm{Li}\right)_{4}$ unit.

Fig. 9.6.29.
Stereoview of the tetragonal structure of adamantane at $-110^{\circ} \mathrm{C}$.
of $\left(\mathrm{CH}_{2}\right)_{6} \mathrm{~N}_{4}$ because the $\left(\mathrm{CH}_{2}\right)_{6}(\mathrm{CH})_{4}$ molecule is approximately spherical. The model which gives the best fit with the intensity data consists of hindered reorientations of a rigid molecular skeleton with the CH groups aligned in the [111] directions.

Below $-65^{\circ} \mathrm{C}$, disordered cubic adamantane transforms to an ordered tetragonal form [space group $P \overline{4} 2_{1} c$ (no. 114), multiplicity $=8, a_{\mathrm{T}}=660, c_{\mathrm{T}}=881$ pm at $-110^{\circ} \mathrm{C}, Z=2$, molecule occupying site of symmetry $\left.\overline{4}\right]$. The measured $\mathrm{C}-\mathrm{C}$ bond lengths have a mean value of $153.6(11) \mathrm{pm}$. The structure of this low-temperature phase, as illustrated in Fig. 9.6.29, is related to that at room temperature in that $a_{\mathrm{T}}$ lies along the $a b$ face diagonal of the cubic cell $\left[\left|a_{\mathrm{T}}\right| \sim|a| /(2)^{1 / 2}\right]$ and $c_{\mathrm{T}}$ corresponds to $c_{\mathrm{C}}=a_{\mathrm{C}}$ in the cubic form.

Many compounds exhibiting the adamantane skeleton can be formally derived by the exchange of "equivalent" atoms or groups. For instance, replacing all four CH groups of $\left(\mathrm{CH}_{2}\right)_{6}(\mathrm{CH})_{4}$ by nitrogen atoms gives rise to hexamethylenetetramine, $\left(\mathrm{CH}_{2}\right)_{6} \mathrm{~N}_{4}$. Some examples of adamantane-like cage compounds containing equivalent constituents include $\mathrm{O}_{6} \mathrm{E}_{4}(\mathrm{E}=\mathrm{P}, \mathrm{As}, \mathrm{Sb})$, $(\mathrm{AlMe})_{6}(\mathrm{CMe})_{4},(\mathrm{BMe})_{6}(\mathrm{CH})_{4},\left(\mathrm{SnR}_{2}\right)_{6} \mathrm{P}_{4}(\mathrm{R}=\mathrm{Me}, \mathrm{Bu}, \mathrm{Ph}), \mathrm{E}_{6}(\mathrm{SiH})_{4}(\mathrm{E}=$ $\mathrm{S}, \mathrm{Se}), \mathrm{S}_{6}(\mathrm{EMe})_{4}(\mathrm{E}=\mathrm{Si}, \mathrm{Sn}, \mathrm{Ge}), \mathrm{S}_{6}(\mathrm{PE})_{4}(\mathrm{E}=\mathrm{O}, \mathrm{S}),(\mathrm{NMe})_{6}(\mathrm{PE})_{4}(\mathrm{E}=\mathrm{O}$, $\mathrm{S}, \mathrm{Se})$ and $\left[\mathrm{O}_{6}\left(\mathrm{TaF}_{3}\right)_{4}\right]^{4-}$.

A stereoview of the crystal structure of hexamethylenetetramine $N$-oxide, $\left(\mathrm{CH}_{2}\right)_{6} \mathrm{~N}_{4} \mathrm{O}$, which crystallizes in space group $R 3 m$ (no. 160 , multiplicity $=$ 6 with $Z=1$ in the rhombohedral unit cell), is shown in Fig. 9.6.30. The molecular packing is related to that of $\left(\mathrm{CH}_{2}\right)_{6} \mathrm{~N}_{4}$ in a simple way. Starting with a body-centered cubic unit cell of $\left(\mathrm{CH}_{2}\right)_{6} \mathrm{~N}_{4}$ (space group $I \overline{4} 3 \mathrm{~m}, \mathrm{Z}=2$ ), one can arrive at the $\left(\mathrm{CH}_{2}\right) \mathrm{N}_{4} \mathrm{O}$ structure in three steps: (i) remove the $\left(\mathrm{CH}_{2}\right)_{6} \mathrm{~N}_{4}$ molecule at the body-center, then (ii) introduce the $\mathrm{N} \rightarrow \mathrm{O}$ function in the [111] direction to each remaining molecule, and finally (iii) compress the resulting primitive lattice along [111] until the oxygen atom of each $\left(\mathrm{CH}_{2}\right)_{6} \mathrm{~N}_{4} \mathrm{O}$ molecule nests snugly in a recess formed by three hydrogen atoms of a neighboring molecule.

The borine adduct $\left(\mathrm{CH}_{2}\right)_{6} \mathrm{~N}_{4} \cdot \mathrm{BH}_{3}$ and the hydrohalides $\left[\left(\mathrm{CH}_{2}\right)_{6} \mathrm{~N}_{4} \mathrm{H}\right]^{+} \mathrm{X}^{-}$ $(\mathrm{X}=\mathrm{Cl}, \mathrm{Br})$ are isomorphous with $\left(\mathrm{CH}_{2}\right)_{6} \mathrm{~N}_{4} \mathrm{O}$. Table 9.6.1 shows the relationship of hexamethylenetetramine with its quaternized derivatives and the effect of the different "substituents."

Table 9.6.1. Structural relationship of $\left(\mathrm{CH}_{2}\right)_{6} \mathrm{~N}_{4}$ and some quaternized derivatives

| Compound | Space group | $Z$ | $a_{\mathrm{R}}(\mathrm{pm})$ | $\alpha_{\mathrm{R}}\left(^{\circ}\right)$ | $V_{\mathrm{R}}\left(\mathrm{pm}^{3}\right) / Z^{*}$ |

* $V_{\mathrm{R}}$ is the volume of the rhombohedral unit cell.

## (4) Space group $\boldsymbol{F d} \overline{3} \boldsymbol{m}$ (No. 227), multiplicity $=192$

The structure of spinel, $\mathrm{MgAl}_{2} \mathrm{O}_{4}$, was first analyzed independently by W. H. Bragg and S. Nishikawa in 1915. It has an essentially cubic close-packed array of oxide ions with $\mathrm{Mg}^{2+}$ and $\mathrm{Al}^{3+}$ ions occupying tetrahedral and octahedral interstices, respectively. With $a=808.00$ (4) pm and $Z=8$, the atoms are located in special positions as shown below.

| Atom | Wyckoff position | Site symmetry | $x$ | $y$ | $z$ |
| :--- | :---: | :---: | :---: | :---: | :---: |
| Mg | $8(a)$ | $\overline{4} 3 m$ | 0 | 0 | 0 |
| Al | $16(d)$ | $\overline{3} m$ | $5 / 8$ | $5 / 8$ | $5 / 8$ |
| O | $32(\mathrm{e})$ | $3 m$ | 0.387 | 0.387 | 0.387 |

Origin at $\overline{4} 3 m$, at $(-1 / 8,-1 / 8,-1 / 8)$ from center $(\overline{3} m)$.

Fig. 9.6.30.
Stereoview of the packing of $\left(\mathrm{CH}_{2}\right)_{6} \mathrm{~N}_{4} \mathrm{O}$ molecules in a rhombohedral unit cell.

Fig. 9.6.31.
Crystal structure of spinel.

Figure 9.6.31 shows the crystal structure of spinel, the unit cell being divided into octants. The $\mathrm{MgO}_{4}$ tetrahedra and $\mathrm{AlO}_{6}$ octahedra are arranged alternately, so that every oxide ion is the common vertex of one tetrahedron and three octahedra.

The type II clathrate hydrates of the general formula $8 \mathrm{G}_{\mathrm{L}} \cdot 16 \mathrm{G}_{\mathrm{S}} \cdot 136 \mathrm{H}_{2} \mathrm{O}$ also crystallize in space group $F d \overline{3} m$ with $a \sim 1.7 \mathrm{~nm}$ and $Z=1$. The water molecules are connected by $\mathrm{O}-\mathrm{H} \cdot \mathrm{O}$ hydrogen bonds to form a host network composed of a close-packed arrangement of $\left(\mathrm{H}_{2} \mathrm{O}\right)_{20}$ pentagonal dodecahedra (12-hedra bounded by 12 pentagonal faces, idealized symmetry $I_{\mathrm{h}}$ ) and $\left(\mathrm{H}_{2} \mathrm{O}\right)_{24}$ hexakaidecahedra (16-hedra composed of 12 pentagons and 4 hexagons, idealized symmetry $T_{\mathrm{d}}$ ) in the ratio of 2 to 1 . In the crystal structure, both kinds of polyhedra have slightly nonplanar faces with unequal edges and angles. The large guest molecules $\mathrm{G}_{\mathrm{L}}$ are accommodated in the 16hedra, whereas the small guest species $\mathrm{G}_{\mathrm{S}}$ occupy the 12-hedra, as illustrated in Fig. 9.6.32(a). Note that here the choice of origin of the space group differs from that used in the structural description of spinel.

Formation of type II clathrate hydrates is facilitated by passing in $\mathrm{H}_{2} \mathrm{~S}$ or $\mathrm{H}_{2} \mathrm{Se}$ as a "help gas" during the preparation. Crystal structure analyses have been reported for the tetrahydrofuran- $\mathrm{H}_{2} \mathrm{~S}$ hydrate $\left(8 \mathrm{C}_{4} \mathrm{H}_{8} \mathrm{O} \cdot 16 \mathrm{H}_{2} \mathrm{~S} \cdot 136 \mathrm{H}_{2} \mathrm{O}\right)$ at 250 K , the carbon disulphide $-\mathrm{H}_{2} \mathrm{~S}$ hydrate $\left(8 \mathrm{CS}_{2} \cdot 16 \mathrm{H}_{2} \mathrm{~S} \cdot 136 \mathrm{H}_{2} \mathrm{O}\right)$ at 140 K , and the carbon tetrachloride-Xe hydrate $8 \mathrm{CCl}_{4} \cdot n \mathrm{Xe} \cdot 136 \mathrm{D}_{2} \mathrm{O}(n=3.5)$ at 13 K and 100 K . For the last compound, the host and guest molecules are assigned to the special positions in the following table. The $\mathrm{CCl}_{4}$ molecule exhibits orientational disorder, and the Xe atom has a statistical site occupancy of 0.22 .

Fig. 9.6.32.
(a) Stereogram illustrating the type II clathrate hydrate host framework, with two 16 -hedra centered at $(3 / 8,3 / 8,3 / 8)$ and $(5 / 8,5 / 8,5 / 8)$, and two cluster units (each consisting of four 12 -hedra) centered at ( $1 / 8,1 / 8,1 / 8$ ) and ( $7 / 8,7 / 8,7 / 8$ ). Each line represents a $\mathrm{O}-\mathrm{H} \cdots \mathrm{O}$ hydrogen bond between two host water molecules. The open circles of decreasing sizes represent guest species $G_{L}$ and $G_{S}$, respectively, located inside the corresponding 16-and 12 -hedra. (b) The host framework of a type I clathrate hydrate. The 12 -hedra occupy the center and corners of the cubic unit cell, and two fused 14-hedra are highlighted by darkened edges.

| Atom | Wyckoff position | Site symmetry | $x$ | $y$ | $z$ |
| :--- | :---: | :---: | :---: | :---: | :---: |
| $\mathrm{H}_{2} \mathrm{O}(1)$ | $8(a)$ | $\overline{4} 3 m$ | $1 / 8$ | $1 / 8$ | $1 / 8$ |
| $\mathrm{H}_{2} \mathrm{O}(2)$ | $32(e)$ | $3 m$ | 0.21658 | 0.21658 | 0.21658 |
| $\mathrm{H}_{2} \mathrm{O}(3)$ | $96(g)$ | $m$ | 0.18215 | 0.18215 | 0.36943 |
| $\mathrm{G}_{\mathrm{L}}=\mathrm{CCl}_{4}$ | $8(b)$ | $\overline{4} 3 m$ | $3 / 8$ | $3 / 8$ | $3 / 8$ |
| $\mathrm{G}_{\mathrm{S}}=\mathrm{Xe}$ | $16(c)$ | $\overline{3} m$ | 0 | 0 | 0 |

Origin at center $\overline{3} m$, at $(1 / 8,1 / 8,1 / 8)$ from $\overline{4} 3 m$. At $100 \mathrm{~K}, a=1.7240 \mathrm{~nm}$.
Since small gas species such as $\mathrm{O}_{2}, \mathrm{~N}_{2}, \mathrm{O}_{3}$, and Kr may be trapped inside the 12-hedra, all type II clathrate hydrates usually contain non-stoichiometric amounts of air unless special precautions are taken to avoid its inclusion as guest species.

## (5) Space group $\operatorname{Pm} \overline{\mathbf{3}} \boldsymbol{n}$ (no. 223), multiplicity $=48$

The type I clathrate hydrates of the general formula $6 \mathrm{G}_{L} \cdot 2 \mathrm{G}_{S} \cdot 46 \mathrm{H}_{2} \mathrm{O}$ crystallize in this space group with $a \sim 1.2 \mathrm{~nm}$ and $Z=1$. The hydrogen-bonded host framework is composed of fused $\left(\mathrm{H}_{2} \mathrm{O}\right)_{20}$ pentagonal dodecahedra and $\left(\mathrm{H}_{2} \mathrm{O}\right)_{22}$ tetrakaidecahedra (14-hedra composed of 12 pentagons and 2 hexagons, idealized symmetry $D_{6 \mathrm{~d}}$ ) in the ratio of 1 to 3, as illustrated in Fig. 9.6.32(b). The 12 -hedra are generally empty or partially filled by air as guest species $\mathrm{G}_{S}$, and the 14 -hedra can accommodate a variety of guest species $\mathrm{G}_{\mathrm{L}}$ such as Xe , $\mathrm{Cl}_{2}, \mathrm{SO}_{2}, \mathrm{CH}_{4}, \mathrm{CF}_{4}, \mathrm{CH}_{3} \mathrm{Br}$, and ethylene oxide. The type I clathrates of COS, $\mathrm{CH}_{3} \mathrm{SH}$, and $\mathrm{CH}_{3} \mathrm{CHF}_{2}$ are reported to change to type II in the presence of $\mathrm{H}_{2} \mathrm{~S}$ as a help gas.

In a neutron diffraction study of the ethylene oxide clathrate deuterohydrate $6\left(\mathrm{CH}_{2}\right)_{2} \mathrm{O} \cdot 46 \mathrm{D}_{2} \mathrm{O}$, the hydrogen-bonded host framework is defined by three independent deuterated water oxygen atoms occupying special positions, as shown in the table below. The deuterium atoms are located precisely as

## Symmetry in Chemistry

disordered half-atoms. The ethylene oxide guest molecule $\left(\mathrm{CH}_{2}\right)_{2} \mathrm{O}$ is disordered about $G_{L}$, and a small amount of entrapped air (site occupancy 0.067) is disordered about $\mathrm{G}_{\mathrm{S}}$.

| Atom | Wyckoff position | Site symmetry | $x$ | $y$ | $z$ |
| :--- | :---: | :---: | :---: | :---: | :---: |
| $\mathrm{O}(i)$ | $16(i)$ | 3 | 0.18375 | 0.18375 | 0.18375 |
| $\mathrm{O}(k)$ | $24(k)$ | $m$ | 0 | 0.3082 | 0.1173 |
| $\mathrm{O}(c)$ | $6(c)$ | $\overline{4} 2 m$ | 0 | $1 / 2$ | $1 / 4$ |
| $\mathrm{D}(i i)$ | $16(i)$ | 3 | 0.2323 | 0.2323 | 0.2323 |
| $\mathrm{D}(c k)$ | $24(k)$ | $m$ | 0 | 0.4340 | 0.2015 |
| $\mathrm{D}(k c)$ | $24(k)$ | $m$ | 0 | 0.3787 | 0.1588 |
| $\mathrm{D}(k k)$ | $24(k)$ | $m$ | 0 | 0.3161 | 0.2015 |
| $\mathrm{D}(k i)$ | $48(l)$ | 1 | 0.0676 | 0.2648 | 0.1397 |
| $\mathrm{D}(i k)$ | $48(l)$ | 1 | 0.1170 | 0.2276 | 0.1588 |
| $\mathrm{G}_{\mathrm{L}}$ | $6(d)$ | $\overline{4} 2 m$ | 0 | $1 / 4$ | $1 / 2$ |
| $\mathrm{G}_{\mathrm{S}}$ | $2(a)$ | $m \overline{3}$ | 0 | 0 | 0 |

Origin at center $m \overline{3}$. All D atoms have a site occupancy factor of $1 / 2 ; \mathrm{D}(c k)$ is a deuterium atom that is covalently bound to $\mathrm{O}(c)$ and hydrogen-bonded to $\mathrm{O}(k)$. At $80 \mathrm{~K}, a=1.187 \mathrm{~nm}$.

## References

The principles and practice of the determination of crystal and molecular structures by X-ray crystallography (single-crystal X-ray analysis) are not covered in this book. The interested reader may consult references [15] to [24], which are arranged in increasing levels of sophistication.

## 10

## Basic Inorganic Crystal Structures and Materials

Over 25 million compounds are known, but only about one percent of them have their crystal structures elucidated by X-ray and neutron diffraction methods. Many inorganic structures are closely related to each other. Sometimes one basic structural type can incorporate several hundred compounds, and new crystalline compounds may arise from the replacement of atoms, deformation of the unit cell, variation of the stacking order, and the presence of additional atoms in interstitial sites.

This chapter describes some basic inorganic crystal structures and their relationship to the new structural types, which often exhibit different symmetry and characteristic properties that make them useful in materials research and industrial applications.

### 10.1 Cubic closest packing and related structures

### 10.1.1 Cubic closest packing (ccp)

Many pure metals and noble gases adopt the cubic closest packing (ccp) structure of identical spheres, which is based on a face-centered cubic (fcc) lattice in space group $O_{\mathrm{h}}^{5}-F m \overline{3} m$. The atomic coordinates and equivalent points of this space group are listed in Table 10.1.1. These data are taken from International Tables for Crystallography, Vol. A.

Table 10.1.1. Atomic coordinates* of space group $O_{\mathrm{h}}^{5}-F m \overline{3} m$

| Multiplicity | Wyckoff <br> position | Site <br> symmety | Coordinates <br> $\left(0,0,0 ; 0, \frac{1}{2}, \frac{1}{2} ; \frac{1}{2}, 0, \frac{1}{2} ; \frac{1}{2}, \frac{1}{2}, 0\right)+$ |
| :---: | :---: | ---: | :---: |
| 32 | $f$ | $3 m$ | $x, x, x ; x, \bar{x}, \bar{x} ; \bar{x}, x, \bar{x} ; \bar{x}, \bar{x}, x ;$ |
| 24 | $e$ | $4 m m$ | $x, 0,0 ; 0, x, 0 ; 0,0, x ; \bar{x}, 0,0 ; 0, \bar{x}, 0 ; 0,0, \bar{x}$. |
| 24 | $d$ | $m m m$ | $0, \frac{1}{4}, \frac{1}{4} ; \frac{1}{4}, 0, \frac{1}{4} ; \frac{1}{4}, \frac{1}{4}, 0 ; 0, \frac{1}{4}, \frac{3}{4} ; \frac{3}{4}, 0, \frac{1}{4} ; \frac{1}{4}, \frac{3}{4}, 0$. |
| 8 | $c$ | $\overline{4} 3 m$ | $\frac{1}{4}, \frac{1}{4}, \frac{1}{4} ; \frac{3}{4}, \frac{3}{4}, \frac{3}{4}$. |

| 4 | $a$ | $m \overline{3} m$ | $0,0,0$ |

[^4]In three-dimensional closest packing, the spherical atoms are located in position $4(a)$. There are two types of interstices: octahedral and tetrahedral holes which occupy positions $4(b)$ and $8(c)$, respectively. The number of tetrahedral holes is twice that of the spheres, while the number of octahedral holes is equal to that of the spheres. The positions of the holes are shown in Fig.10.1.1.
The elements with the ccp structure and their unit-cell parameters are listed in Table 10.1.2.

Some alloys in high-temperature disordered phases adopt the ccp structure. For example, Au and Cu have the same valence electronic configuration. When these two metals are fused and then cooled, the mixture solidifies into a completely disordered solid solution phase, in which the gold atom randomly and statistically replaces the copper atom. Figure 10.1.2(a) shows the structure of $\mathrm{Cu}_{1-x} \mathrm{Au}_{x}$ with $x=0.25$, and the space group is still $O_{\mathrm{h}}^{5}-F m \overline{3} m$. If the $\mathrm{Cu}_{0.75} \mathrm{Au}_{0.25}$ alloy ( or $\mathrm{Cu}_{3} \mathrm{Au}$ ) is annealed at a temperature lower than $395^{\circ} \mathrm{C}$ through isothermal ordering, the gold atoms occupy the corners of the

* This table is not complete; equivalent positions with multiplicities greater than 8 are not listed.
cube while the copper atoms occupy the centers of the faces, as shown in Fig. 10.1.2(b). This disordered-to-ordered phase transition gives rise to a simple cubic $\alpha$-phase in space group $O_{\mathrm{h}}^{1}-\operatorname{Pm} \overline{3} m$. The equivalent positions of space group $O_{\mathrm{h}}^{1}-P m \overline{3} m$ are listed in Table 10.1.3. In the structure of $\mathrm{Cu}_{3} \mathrm{Au}$ in this low-temperature ordered phase, the Au atom is located in position $1(a)$, and the Cu atoms occupy position 3(c).

### 10.1.2 Structure of NaCl and related compounds

## (1) Structure type of sodium chloride (rock salt, halite), and its common occurrence

The structure of NaCl can be regarded as being formed from a ccp arrangement of $\mathrm{Cl}^{-}$anions with the smaller $\mathrm{Na}^{+}$cations located in the octahedral interstices. Since spherical $\mathrm{Na}^{+}$and $\mathrm{Cl}^{-}$conform to the $m \overline{3} m$ symmetry of the sites $4(a)$ and $4(b)$, respectively (listed in Table 10.1.1), the space group of NaCl is also $O_{\mathrm{h}}^{5}-F m \overline{3} m$. Either the $\mathrm{Na}^{+}$or $\mathrm{Cl}^{-}$ion can be placed at the origin (site $4 a$ ), and each has coordination number six. There are more than 400 binary compounds that belong to the NaCl structural type, such as alkali metal halides and hydrides, alkaline-earth oxides and chalcogenides, the oxides of divalent early first-row transition metals, the chalcogenides of divalent lanthanides and actinides, the

nitrides, phosphides, arsenides and bismuthides of the lanthanide and actinide elements, silver halides (except the iodide), tin and lead chalcogenides, and many interstitial alloys. Some examples and the parameters of their cubic unit cells are listed in Table 10.1.4.

The data listed in Table 10.1.4 are useful in understanding the structure and properties of many compounds. Two examples are presented below.

## (a) Deduction of ionic radii

The effective ionic radii listed in Table 4.2.2 can be calculated from the experimentally determined values of the ionic distances or the parameters of the unit cells. For example, NaH has the structure of NaCl type with $a=488 \mathrm{pm}$, so the $\mathrm{Na}^{+} \cdots \mathrm{H}^{-}$distance is 244 pm . Taking the radius of $\mathrm{Na}^{+}$as 102 pm , the radius of $\mathrm{H}^{-}$in the NaH crystal is 142 pm .
(b) The strength of ionic bonding and the melting point of compounds

The alkaline-earth oxides MO are composed of $\mathrm{M}^{2+}$ and $\mathrm{O}^{2-}$ stabilized by electrostatic forces. The electrostatic Coulombic energies are directly proportional to the product of the two ionic charges and inversely proportional to the interionic distance. The alkaline-earth oxides MO are 2:2 valence compounds and have the same electronic charge for $\mathrm{M}^{2+}$, but the radii of $\mathrm{M}^{2+}$ and the
distances of $\mathrm{M}^{2+} \ldots \mathrm{O}^{2-}$ are successively increased with atomic number in the order $\mathrm{Mg}^{2+}<\mathrm{Ca}^{2+}<\mathrm{Sr}^{2+}<\mathrm{Ba}^{2+}$. The strength of ionic bonding decreases successively, so the melting points and the hardness also decrease in the same sequence. The experimental melting points and hardness data listed below are consistent with expectation.

|  | MgO | CaO | SrO | BaO |
| :---: | ---: | ---: | ---: | ---: |
| $\mathrm{M}^{2+} \ldots \mathrm{O}^{2-}$ distance $(\mathrm{pm})$ | 211 | 241 | 258 | 276 |
| $\mathrm{mp}(\mathrm{K})$ | 3125 | 2887 | 2693 | 2191 |
| Mohs hardness | 6.5 | 4.5 | 3.5 | 3.3 |

## (2) Defects in the structure type of $\mathbf{N a C l}$

Various kinds of packing defects exist in the ionic crystals of NaCl type. A pair of cation and anion may be shifted from their stable positions toward the surface of the crystal, thus leaving behind a pair of vacancies. This is called the Schottky defect. The cation may leave its stable position and enter into an interstitial site. The formation of an interstitial cation and a vacancy is called the Frenkel defect. In addition to these two common kinds of defects, the presence of impurity atoms, atoms of varied valence, vacancies, and/or interstitial atoms is also possible. Some other important defects are discussed below.

## (a) Color center

A color center or F-center is formed from diffusion of a small quantity of $\mathrm{M}^{+}$ ion into an ionic crystal MX. Since the crystal must keep its charge neutrality, additional electrons readily move to fill the vacancies normally occupied by anions. Thus the composition of the crystal becomes $\left(\mathrm{M}^{+}\right)_{1+\delta}\left(\mathrm{X}^{-} e_{\delta}^{-}\right)$. The origin of the color is due to electronic motion, and a simple picture of an electron in a vacancy is illustrated by the particle in a three-dimensional box problem, which is discussed in Section 1.5.2.
(b) Koch cluster of $\mathrm{Fe}_{1-\delta} \mathrm{O}$

The structure of crystalline FeO belongs to the NaCl type. When iron(II) oxide is prepared under normal conditions, the composition of the product (wustite) is always $\mathrm{Fe}_{1-\delta} \mathrm{O}$. In order to retain overall electric neutrality, part of the $\mathrm{Fe}^{2+}$ is oxidized to $\mathrm{Fe}^{3+}$, and the chemical formula becomes $\mathrm{Fe}_{2 \delta}^{3+} \mathrm{Fe}_{1-3 \delta}^{2+} \mathrm{O}$. Since the radius of $\mathrm{Fe}^{3+}$ is small, the $\mathrm{Fe}^{3+}$ cations tend to occupy the tetrahedral holes to form a short-range ordered $\mathrm{Fe}_{4} \mathrm{O}_{10}$ cluster, which is called the Koch cluster of $\mathrm{Fe}_{1-\delta} \mathrm{O}$, as shown in Fig. 10.1.3. The Koch clusters are distributed randomly in the crystal structure. To satisfy charge neutrality, the formation of a Koch cluster must be accompanied by the presence of six $\mathrm{Fe}^{2+}$ vacancies, one of which is located at the center of the cluster, and the remaining five are distributed randomly at the centers of the edges of the cubic unit cell.
(c) Vacancies in the NbO crystal

The unit cell of niobium monoxide NbO can be derived from the cubic unit cell of NaCl , by deleting the body-central $\mathrm{Na}^{+}$(coordinate: $\frac{1}{2}, \frac{1}{2}, \frac{1}{2}$ ) and the vertex

$\mathrm{Cl}^{-}$(coordinate: $0,0,0$ ), and then replacing $\mathrm{Na}^{+}$by $\mathrm{Nb}^{2+}$ and $\mathrm{Cl}^{-}$by $\mathrm{O}^{2-}$. The crystal structure of NbO can be regarded as arising from ordered vacancy defects of the NaCl structural type, as shown in Fig. 10.1.4(a). The NbO crystal has a primitive cubic lattice in space group $O_{\mathrm{h}}^{1}-\operatorname{Pm} \overline{3} m$, in which the $\mathrm{Nb}^{2+}$ and $\mathrm{O}^{2-}$ ions occupy sites $3(d)$ and $3(c)$, respectively, as listed in Table 10.1.3. In the NbO crystal, the Nb atoms form octahedral clusters held by $\mathrm{Nb}-\mathrm{Nb}$ metallic bonds, which result from the overlap of the 5 s and 4 d orbitals. The $\mathrm{Nb}_{6}$ octahedral clusters constitute a three-dimensional framework by sharing vertices, and each Nb atom is in square-planar coordination with four O neighbors. Although the geometrical arrangement and coordination environment of the Nb and O atoms are equivalent to each other, an analogously drawn $\mathrm{O}_{6}$ octahedral cluster has no physical meaning as the O atom lacks d orbitals for bonding.

Some lower oxidation state oxoniobates contain the $\mathrm{Nb}_{6} \mathrm{O}_{12}$ cluster shown in Fig. 10.1.4(b) as a basic structural unit. An O atom located above an edge of the $\mathrm{Nb}_{6}$ octahedron may belong to the cluster or connect with another cluster. Up to six O atoms can be attached to the apices of the $\mathrm{Nb}_{6}$ octahedron to constitute an outer coordination sphere; such additional atoms may be exclusive to the cluster or shared between clusters.

(b)

## (3) Structure of $\mathrm{CaC}_{2}$ and $\mathrm{BaO}_{2}$

Calcium carbide $\mathrm{CaC}_{2}$ exists in at least four crystalline modifications whose occurrence depends on the temperature of formation and the presence of impurities. The tetragonal phase $\mathrm{CaC}_{2}(\mathrm{I})$, which is stable between 298 and 720 K , is

Fig. 10.1.3.
Structure of Koch cluster of $\mathrm{Fe}_{1-\delta} \mathrm{O}$ (black circle, $\mathrm{Fe}^{3+}$; large white circle, $\mathrm{O}^{2-}$; small white circle represents an octahedral vacancy).

Fig. 10.1.4.
(a) Unit cell of NbO . (b) $\mathrm{Nb}_{6} \mathrm{O}_{12}$ cluster with capacity for attachment of six ligands to its metal centers.

the common form found in the commercial product. Its structure can be derived from the NaCl structure by replacing the $\mathrm{Na}^{+}$cations by $\mathrm{Ca}^{2+}$ and the $\mathrm{Cl}^{-}$ anions by $\mathrm{C}_{2}^{2-}$, thereby reducing the crystal symmetry from cubic $F m \overline{3} m$ to tetragonal $I 4 / \mathrm{mmm}$, with the $\mathrm{C}_{2}^{2-}$ group lying on the unique 4 -axis. The measured $\mathrm{C} \equiv \mathrm{C}$ bond length of 120 pm is in agreement with its triple-bond character. Figure 10.1.5 shows the crystal structure of $\mathrm{CaC}_{2}(\mathrm{I})$, in which solid lines represent the body-centered tetragonal unit cell with $a=389 \mathrm{pm}$ and $c=638$ pm , and the broken lines represent a non-primitive face-centered tetragonal unit cell, with $a^{\prime}=550 \mathrm{pm}$ and $c=638 \mathrm{pm}$, which clearly traces its lineage to the NaCl structure.

There are many compounds that are isomorphous with tetragonal $\mathrm{CaC}_{2}(\mathrm{I})$, such as the acetylides of the alkaline- and rare-earth elements $\left(\mathrm{BaC}_{2}, \mathrm{SrC}_{2}\right.$, $\mathrm{LaC}_{2}, \mathrm{CeC}_{2}, \mathrm{PrC}_{2}, \mathrm{NdC}_{2}, \mathrm{SmC}_{2}$ ), the silicides of molybdenum and tungsten $\left(\mathrm{MoSi}_{2}, \mathrm{WSi}_{2}\right)$, the superoxides of alkali metals $\left(\mathrm{KO}_{2}, \mathrm{RbO}_{2}, \mathrm{CsO}_{2}\right)$, and the peroxides of alkaline-earth metals $\left(\mathrm{CaO}_{2}, \mathrm{BaO}_{2}\right)$. In $\mathrm{O}_{2}^{-}$, the $\mathrm{O}-\mathrm{O}$ distance is 128 pm ; in $\mathrm{O}_{2}^{2-}$, the $\mathrm{O}-\mathrm{O}$ distance is 149 pm ; in $\mathrm{Si}_{2}^{2-}$, the $\mathrm{Si}-\mathrm{Si}$ distance is 260 pm .

### 10.1.3 Structure of $\mathrm{CaF}_{2}$ and related compounds

The structure of fluorite, $\mathrm{CaF}_{2}$, may be regarded as being composed of cubic closest packed $\mathrm{Ca}^{2+}$ cations with all the tetrahedral interstices occupied by $\mathrm{F}^{-}$ anions, as shown in Fig. 10.1.6. The stoichiometric formula is consistent with the fact that the number of tetrahedral holes is twice that of the number of closest packed atoms.

Some compounds, such as $\mathrm{Na}_{2} \mathrm{O}$ and $\mathrm{K}_{2} \mathrm{~S}$, have the inverse fluorite (or antifluorite) structure, which is a ccp structure of anions with all the tetrahedral interstices occupied by cations.

Many inorganic compounds have the fluorite and inverse fluorite structures: (a) all halides of the larger divalent cations except two fluorides in this class; (b) oxides and sulfides of univalent ions; (c) oxides of large quadrivalent cations; and (d) some intermetallic compounds. Table 10.1.5 lists some compounds of the fluorite and inverse fluorite types and their $a$ parameters.

The fluorite structure may also be regarded as being composed of a simple cubic packing of anions, and the number of cubic holes is the same as the

Table 10.1.5. Some compounds with fluorite and anti-fluorite structures and $a$ values

*The last two elements either occupy $1 / 4,1 / 1,1 / 4, ; 3 / 4,3 / 4,3 / 4 ;$ F.C. separately or are statistically distributed over these positions. ${ }^{\dagger}$ The metal atoms are statistically distributed over the calcium positions of $\mathrm{CaF}_{2} .{ }^{\ddagger}$ The nitrogen atom takes the place of the calcium atom in $\mathrm{CaF}_{2}$, and the two kinds of metal atoms are statistically distributed over the fluorine positions.
number of anions. Half of the holes are occupied by cations, and the other half are unoccupied. The center of the unit cell shown in Fig. 10.1.6 is an unoccupied cubic hole.

The structure of zircon, $\mathrm{ZrO}_{2}$, is of the fluorite type. $\mathrm{The}_{\mathrm{Zr}}{ }^{4+}$ cations occupy half of the cubic holes, and the $\mathrm{O}^{2-}$ anions can easily migrate through the empty cubic holes. Doping of $\mathrm{ZrO}_{2}$ with $\mathrm{Y}_{2} \mathrm{O}_{3}$ or CaO stabilizes the fluorite structure and introduces vacant $\mathrm{O}^{2-}$ sites. The resulting doped crystalline material shows higher electrical conductivity when the temperature is increased. Hence $\mathrm{ZrO}_{2}\left(\mathrm{Y}_{2} \mathrm{O}_{3}\right)$ is a good solid electrolyte of the anionic ( $\mathrm{O}^{2-}$ ) type which can be utilized in devices for measuring the amount of dissolved oxygen in molten steel, and as an electrolyte in fuel cells.

The structure of $\mathrm{Li}_{3} \mathrm{Bi}$ is formed by a ccp of Bi atoms with the Li atoms occupying all the tetrahedral and octahedral holes.

### 10.1.4 Structure of cubic zinc sulfide

The structure of cubic zinc sulfide (zinc blende, sphalerite) may be described as a ccp of S atoms, in which half of the tetrahedral sites are filled with Zn atoms; the arrangement of the filled sites is such that the coordination numbers of $S$ and Zn are both four, as shown in Fig. 10.1.7. The crystal belongs to space group $T_{\mathrm{d}}^{2}-F \overline{4} 3 \mathrm{~m}$. Note that the roles of the Zn and S atoms can be interchanged by a simple translation of the origin.

Fig. 10.1.7.
Structure of cubic zinc sulfide.

## Symmetry in Chemistry

Many binary compounds adopt the cubic zinc sulfide structure. Some of these compounds and their unit-cell parameter $a$ values are listed in Table 10.1.6.

The ternary iodide $\mathrm{Ag}_{2} \mathrm{HgI}_{4}$ exists in two forms: the low-temperature form $(\beta)$ is a yellow tetragonal crystal, whereas the high-temperature form $(\alpha)$ is an orange-red cubic crystal, the transition temperature being $50.7^{\circ} \mathrm{C}$. The structure of $\mathrm{Ag}_{2} \mathrm{HgI}_{4}$ is shown in Fig. 10.1.8. In the $\beta$-form, two Ag atoms occupy the sites $(0,0,0)$ and $\left(\frac{1}{2}, \frac{1}{2}, 0\right)$, and one Hg atom is disordered over the sites $\left(0, \frac{1}{2}, \frac{1}{2}\right)$ and $\left(\frac{1}{2}, 0, \frac{1}{2}\right)$ with occupancy $\frac{1}{2}$. When the $\beta$-form undergoes transformation to the $\alpha$-form, the Ag and Hg atoms are almost randomly distributed over all four sites, so that the average composition at each site is $\left(\operatorname{Ag} \frac{1}{2} \mathrm{Hg}_{\frac{1}{4}}^{\frac{1}{4}} \frac{1}{4}\right)$. The $\alpha$-form has the structure type of cubic zinc sulfide and is a good superionic conductor. Therefore, the structure of $\mathrm{Ag}_{2} \mathrm{HgI}_{4}$ can be considered as a closest packed arrangement of $\mathrm{I}^{-}$anions, with the $\mathrm{Ag}^{+}$and $\mathrm{Hg}^{2+}$ cations occupying the tetrahedral holes in either an ordered or disordered fashion.

The ternary iodide $\mathrm{Cu}_{2} \mathrm{HgI}_{4}$, a structural analog of $\mathrm{Ag}_{2} \mathrm{HgI}_{4}$ with very similar properties, exists as brown tetragonal crystals at room temperature. Its hightemperature crystalline form (transition temperature is $80^{\circ} \mathrm{C}$ ) belongs to the cubic system and exhibits the red color.

Many ternary, quaternary, and multicomponent metal sulfides also exhibit tetrahedral coordination of atoms and possess structures similar to that of cubic

zinc sulfide. In these compounds, the Zn atoms are orderly replaced by other atoms or by vacancies. Figure 10.1.9 shows the structures of (a) $\mathrm{CuFeS}_{2}$, (b) $\mathrm{CdAl}_{2} \mathrm{~S}_{4}$, and (c) $\mathrm{Cu}_{2} \mathrm{FeSnS}_{4}$. In these structures, the c axis of the unit cell is twice as long as $a$ and $b$.

### 10.1.5 Structure of spinel and related compounds

The mixed-metal oxide spinel, $\mathrm{MgAl}_{2} \mathrm{O}_{4}$, is one of the most important inorganic materials. The structure of spinel can be regarded as a ccp structure of $\mathrm{O}^{2-}$ anions with $\mathrm{Mg}^{2+}$ ions orderly occupying $1 / 8$ of the tetrahedral interstices, and $\mathrm{Al}^{3+}$ ions orderly occupying half of the octahedral interstices; the remainder $7 / 8$ tetrahedral interstices and half octahedral interstices are unoccupied. The sites of the three kinds of ions in the face-centered cubic unit cell are displayed in Fig. 9.6.29.

Figure 10.1 .10 shows the crystal structure of spinel. The unit cell (represented by solid lines) is divided into eight small cubic octants (represented by broken lines) of two different types, as shown in (a); the structure of type I and type II octants and the connections of atoms are shown in (b). There are four $\mathrm{O}^{2-}$ in each octant. The number of $\mathrm{O}^{2-}$ in the unit cell is $32(=8 \times 4)$. The $\mathrm{Mg}^{2+}$ ions are located at the centers of type I octants and half of the vertices of type I and type II

Fig. 10.1.9.
Structure of some multimetal sulfides: (a) $\mathrm{CuFeS}_{2}$, (b) $\mathrm{CdAl}_{2} \mathrm{~S}_{4}$, (c) $\mathrm{Cu}_{2} \mathrm{FeSnS}_{4}$.

Fig. 10.1.10.
Crystal structure of spinel.

## Symmetry in Chemistry

octants. The number of $\mathrm{Mg}^{2+}$ in the unit cell is $8\left[=4(1+4 \times 1 / 8)+4 \times 4 \times \frac{1}{1 / 8}\right]$. The $\mathrm{Mg}^{2+}$ ions have tetrahedral coordination. There are four $\mathrm{Al}^{3+}$ ions in the type II octant. The number of $\mathrm{Al}^{3+}$ in the unit cell is $16(=4 \times 4)$. The $\mathrm{Al}^{3+}$ ions have octahedral coordination.

According to the cation distribution over the $8(a)$ and $16(d)$ sites, the spinels of formula $\mathrm{AB}_{2} \mathrm{O}_{4}$ can be divided into normal and inverse classes. Examples of normal spinels are $\mathrm{MgAl}_{2} \mathrm{O}_{4}$ and $\mathrm{MgTi}_{2} \mathrm{O}_{4}$, in which the oxidation states of Al and Ti are both +3 ; their respective structural formulas are $\left[\mathrm{Mg}^{2+}\right]_{\mathrm{t}}\left[\mathrm{Al}_{2}^{3+}\right]_{o} \mathrm{O}_{4}$ and $\left[\mathrm{Mg}^{2+}\right]_{\mathrm{t}}\left[\mathrm{Ti}_{2}^{3+}\right]_{\mathrm{o}} \mathrm{O}_{4}$, in which the subscripts t and o indicate tetrahedral and octahedral sites, respectively.

In inverse spinels, half of the B ions are in tetrahedral 8(a) sites, leaving the remaining B ions and the A ions to fill the $16(d)$ sites. Usually, the occupancy of these $16(d)$ sites is disordered. Examples of inverse spinels are $\mathrm{MgFe}_{2} \mathrm{O}_{4}$ and $\mathrm{Fe}_{3} \mathrm{O}_{4}$; their structural formulas are $\left[\mathrm{Fe}^{3+}\right]_{\mathrm{t}}\left[\mathrm{Mg}^{2+} \mathrm{Fe}^{3+}\right]_{o} \mathrm{O}_{4}$ and $\left[\mathrm{Fe}^{3+}\right]_{\mathrm{t}}\left[\mathrm{Fe}^{2+} \mathrm{Fe}^{3+}\right]_{o} \mathrm{O}_{4}$, respectively.

In intermediate spinels any combination of cation arrangement between the extremes of normal and inverse spinels is possible. Table 10.1.7 lists some normal spinels and inverse spinels and the values of their unit-cell parameter $a$.

Table 10.1.7. Some normal spinels and inverse spinels and their a parameters

### 10.2 Hexagonal closest packing and related structures

### 10.2.1 Hexagonal closest packing (hcp)

The crystal structure of many pure metals adopts the hcp of identical spheres, which has a primitive hexagonal lattice in space group $D_{6 \mathrm{~h}}^{4}-P 6_{3} / \mathrm{mmc}$. There are two atoms in the hexagonal unit cell with coordinates $(0,0,0)$ and $\left(\frac{2}{3}, \frac{1}{3}, \frac{1}{2}\right)$.
(a)

(b)

There are two types of interstices in the hcp structure: octahedral and tetrahedral holes, as in the ccp structure. However, the hcp and ccp structures differ in the linkage of interstices. In ccp, neighboring octahedral interstices share edges, and the tetrahedral interstices behave likewise. In hcp, neighboring octahedral interstices share faces, and a pair of tetrahedral interstices share a common face to form a trigonal bipyramid, so these two tetrahedral interstices cannot be filled by small atoms simultaneously. Figure 10.2 .1 shows the positions of the octahedral interstices (a) and tetrahedral interstices (b). Table 10.2.1 lists the pure metals with hcp structure and the parameters of the unit cell.

Table 10.2.1. Metals with hcp structure and the parameters of the hexagonal unit cell

Fig. 10.2.2.
Structure of hexagonal zinc sulfide.

## Symmetry in Chemistry

### 10.2.2 Structure of hexagonal zinc sulfide

In the crystal structure of hexagonal zinc sulfide (wurtzite), the S atoms are arranged in hcp, in which half of the tetrahedral interstices are filled with Zn atoms, and the space group is $C_{6 v}^{4}-P 6_{3} m c$. The positions of atoms in the hexagonal unit cell are

$$
\begin{array}{ll}
\mathrm{S} & 0,0,0 ; 2 / 3,1 / 3,1 / 2 \\
\mathrm{Zn} & 0,0,3 / 8 ; 2 / 3,1 / 3,7 / 8
\end{array}
$$

The Zn atoms are each tetrahedrally coordinated by four S atoms, and likewise the S atoms are each connected to four Zn atoms, as shown in Fig. 10.2.2. The bonding has both covalent and ionic character.

Note that an equivalent structure is obtained when the positions of the Zn and S atoms are interchanged, but in this case the polar direction of the crystal is reversed. This arises because $P 6_{3} m c$ is a polar space group, and historically the polar sense of a single crystal of ZnS has been used to demonstrate the breakdown of Friedel's law under conditions of anomalous dispersion.

Many binary compounds adopt the structure type of hexagonal zinc sulfide. Table 10.2.2 lists some of these compounds and their unit-cell parameters.

### 10.2.3 Structure of NiAs and related compounds

In the crystal structure of nickel asenide, NiAs, the As atoms are in hcp with all octahedral interstices occupied by the Ni atoms, as shown in Fig. 10.2.3(a). An important feature of this structure is that the Ni and As atoms are in different coordination environments. Each As atom is surrounded by six equidistant Ni atoms situated at the corners of a regular trigonal prism. Each Ni atom, on the other hand, has eight close neighbors, six of which are As atoms arranged octahedrally about it, while the other two are Ni atoms immediately above and below it at $z= \pm c / 2$. The $\mathrm{Ni}-\mathrm{Ni}$ distance is $c / 2=503.4 / 2=251.7 \mathrm{pm}$, which corresponds to the interatomic distance in metallic nickel. Compound NiAs is semi-metallic, and its metallic property results from the bonding between Ni atoms. In the NiAs structure, the axial ratio $c / a=503.4 / 361.9=1.39$ is much

Table 10.2.2 Some compounds with hexagonal zinc sulfide structure and their unit-cell parameters

| Compound | $a(\mathrm{pm})$ | $c(\mathrm{pm})$ | Compound | $a(\mathrm{pm})$ | $c(\mathrm{pm})$ |
| :--- | :--- | :--- | :--- | :--- | :--- |
| AgI | 458.0 | 749.4 | MgTe | 454 | 739 |
| AlN | 311.1 | 497.8 | MnS | 397.6 | 643.2 |
| BeO | 269.8 | 437.9 | MnSe | 412 | 672 |
| CdS | 413.48 | 674.90 | MnTe | 408.7 | 670.1 |
| CdSe | 430.9 | 702.1 | SiC | 307.6 | 504.8 |
| CuCl | 391 | 642 | ZnO | 324.95 | 520.69 |
| CuH | 289.3 | 461.4 | ZnS | 381.1 | 623.4 |
| GaN | 318.0 | 516.6 | ZnSe | 398 | 653 |
| InN | 353.3 | 569.3 | ZnTe | 427 | 699 |

(a)

(b)

Fig. 10.2.3.
Structure of NiAs: (a) origin at As atom (white circle); (b) origin at Ni atom (black circle).
smaller than the calculated value for hcp of identical spheres (1.633). This fact suggests that, with a decrease in ionic character, metal atoms are less likely to repel each other, and more likely to form metal-metal bonds.

The space group of NiAs is $D_{6 \mathrm{~h}}^{4}-P 6_{3} / m m c$. The atomic coordinates are

$$
\begin{array}{lllll}
\text { As } & 2(\text { a }) & \overline{3} m & 0,0,0 ; & 1 / 3,1 / 3,1 / 2 \\
\mathrm{Ni} & 2(\text { c }) & \overline{6} m 2 & 1 / 3,2 / 3,3 / 4, & 1 / 3,2 / 3,1 / 4
\end{array}
$$

When a translation is applied so that the origin of the unit cell now resides on the Ni atom, as shown in Fig. 10.2.3(b), the atomic coordinates become

$$
\begin{array}{lllll}
\text { As } & 2(a) & \overline{3} m & 1 / 3,2 / 3,1 / 4 ; & 2 / 3,1 / 3,3 / 4 \\
\mathrm{Ni} & 2(c) & \overline{6} m 2 & 0,0,0 ; & 0,0,1 / 2
\end{array}
$$

Figure 10.2.3(b) shows clearly that the Ni atoms are arranged in hexagonal layers which exactly eclipse one another, and only half of the large trigonal pyramidal interstices are filled by the As atoms. The large vacant interstices can be occupied easily by other atoms of an additional component. The structure of $\mathrm{Ni}_{2} \mathrm{In}$ can be regarded as two Ni atoms forming hexagonal layers that lead to four trigonal pyramidal interstices per unit cell, which are occupied by two In atoms and two Ni atoms.

Some compounds with the NiAs structure and their unit-cell parameters are listed in Table 10.2.3.

### 10.2.4 Structure of $\mathrm{Cdl}_{2}$ and related compounds

The hcp structure consists of a stacking of atomic layers in the sequence ABABAB . . . The octahedral holes are located between adjacent layers, as shown in Fig. 10.2.3(a). In the crystal structure of nickel asenide, the As atoms constitute a hcp lattice, and the Ni atoms occupy all the octahedral holes. In contrast, cadmium iodide, $\mathrm{CdI}_{2}$, may be described as a hcp of $\mathrm{I}^{-}$ anions, in which only half the octahedral holes are occupied by $\mathrm{Cd}^{2+}$ ions. The manner of occupancy of the octahedral interstices is such that entire layers of octahedral interstices are filled, and these alternate with layers of empty

interstices. The layer stacking sequence along the $c$ axis of the unit cell in $\mathrm{CdI}_{2}$ is shown schematically in Fig. 10.2.4(a), and the unit cell is shown in Fig. 10.2.4(b).

A layer structure can be conveniently designated by the following scheme: the capital letters A, B, C indicate the relative positions of anions, lower-case letters $\mathrm{a}, \mathrm{b}, \mathrm{c}$ indicate the positions of cations, and vacant octahedral interstices are represented by $\square$. The structure of $\mathrm{CdI}_{2}$ can thus be written asAc B $\qquad$ A.....

Table 10.2.4. Some compounds with the $\mathrm{CdI}_{2}$ structure and their unit-cell parameters

| $\mathrm{VI}_{2}$ | 400.0 | 667.0 |  |  |  |

Many binary compounds which consist of $\mathrm{I}^{-}, \mathrm{Br}^{-}, \mathrm{OH}^{-}$and $\mathrm{M}^{2+}$ cations, or $\mathrm{S}^{2-}, \mathrm{Se}^{2-}, \mathrm{Te}^{2-}$, and $\mathrm{M}^{4+}$ cations, usually adopt the $\mathrm{CdI}_{2}$ structure. Table 10.2.4 lists some compounds with the $\mathrm{CdI}_{2}$ structure and their unit-cell parameters.

The crystal structure of $\mathrm{CdCl}_{2}$ is closely related to that of $\mathrm{CdI}_{2}$. Both originate from the same type of MXM sandwiches, differing only in the way of stacking. The $\mathrm{CdI}_{2}$ structure is based on the hcp type, whereas the $\mathrm{CdCl}_{2}$ structure is based on the ccp type. The structure of $\mathrm{CdCl}_{2}$ is represented by the layer sequence:

$$
\mathrm{Ac} \mathrm{~B} \square \mathrm{Cb} \mathrm{~A} \square \mathrm{~B} \mathrm{a} \mathrm{C} \square \mathrm{Ac} \mathrm{~B} \square \mathrm{C} \ldots .
$$

### 10.2.5 Structure of $\alpha-\mathrm{Al}_{2} \mathrm{O}_{3}$

$\alpha-\mathrm{Al}_{2} \mathrm{O}_{3}$ occurs as the mineral corundum. Because of its great hardness (9 on the Mohs scale), high melting point $\left(2045^{\circ} \mathrm{C}\right)$, involatility ( 0.1 Pa at $1950^{\circ} \mathrm{C}$ ), chemical inertness, and good electrical insulating properties, it is an important inorganic material that finds many applications in abrasives, refractories, and ceramics. Larger crystals of $\alpha-\mathrm{Al}_{2} \mathrm{O}_{3}$, when colored with metal-ion impurities, are prized as gemstones with names such as ruby $\left(\mathrm{Cr}^{3+}\right.$, red), sapphire $\left(\mathrm{Fe}^{2+/ 3+}\right.$ and $\mathrm{Ti}^{4+}$, blue), and oriental amethyst $\left(\mathrm{Cr}^{3+} / \mathrm{Ti}^{4+}\right.$, violet). Many of these crystals are synthesized on an industrial scale and used as laser materials, gems, and jewels.
$\alpha-\mathrm{Al}_{2} \mathrm{O}_{3}$ belongs to the trigonal system in space group $D_{3 \mathrm{~d}}^{6}-R \overline{3} c$. The parameters of the hexagonal unit cell are $a=476.280 \mathrm{pm}, c=1300.320 \mathrm{pm}$ $\left(31^{\circ} \mathrm{C}\right)$. The atomic coordinates ( $R$-centered) are

$$
\begin{aligned}
& \mathrm{Al}(12 c)\left(0,0,0 ; 1 / 3,2 / 3,2 / 3 ; 2_{3}^{2}, 1 / 3,1 / 3\right) \pm(0,0, z ; 0,0,1 / 2+z), \mathrm{z}=0.352 \\
& \mathrm{O}(18 e)(0,0,0 ; 1 / 3,2 / 3,2 / 3 ; 2 / 3,1 / 3,1 / 3) \pm(x, 0,1 / 4 ; 0, x, 1 / 4 ; \bar{x}, \bar{x}, 1 / 4), x=0.306
\end{aligned}
$$

## Symmetry in Chemistry

In the crystal structure of $\alpha-\mathrm{Al}_{2} \mathrm{O}_{3}$, the O atoms are arranged in hcp, while the Al atoms are orderly located in the octahedral interstices. As the number of Al atoms is $2 / 3$ of the number of O atoms, there are $1 / 3$ vacant octahedral interstices. The distribution of the interstices can be described in terms of the arrangement of the Al atoms. Between each pair of adjacent closest packed O layers, the Al atoms form a planar hexagonal layer, and the center of each hexagon is an interstice (which is analogous to the arrangement of C atoms in hexagonal graphite). The interstices are evenly distributed in the unit cell at three different sites, as indicated by $\mathrm{C}^{\prime}, \mathrm{C}^{\prime \prime}$, and $\mathrm{C}^{\prime \prime \prime}$ in Fig. 10.2.5. The Al atoms of two neighboring layers overlap, so that the two $\mathrm{AlO}_{6}$ octahedral coordination polyhedra are connected by face sharing, as represented by the vertical lines in Fig. 10.2.5(a).

Some trivalent metal oxides adopt the corundum structure. Table 10.2.5 lists these compounds and the parameters of their hexagonal unit cells.

### 10.2.6 Structure of rutile

Rutile, $\mathrm{TiO}_{2}$, belongs to the tetragonal space group $D_{4 \mathrm{~h}}^{14}-P 4_{2} / m n m$. The parameters of the unit cell are $a=459.366 \mathrm{pm}, c=295.868 \mathrm{pm}(298 \mathrm{~K})$. The atomic coordinates are

$$
\begin{aligned}
& \mathrm{Ti}(2 a) 0,0,0 ; 1 / 2,1 / 2,1 / 2 \\
& \mathrm{O}(4 f) \pm(x, x, 0,1 / 2+x, 1 / 2-x, 1 / 2), x=0.30479
\end{aligned}
$$

Table 10.2.5. Compounds with the corundum structure and their lattice parameters

| Compound | $a(\mathrm{pm})$ | $c(\mathrm{pm})$ | Compound | $a(\mathrm{pm})$ | $c(\mathrm{pm})$ |

Fig. 10.2.6.
Structure of rutile: (a) connection of $\mathrm{TiO}_{6}$ octahedra and the unit cell, (b) chains share vertices, viewed along the caxis.

In the structure of rutile, the Ti atoms constitute deformed $\mathrm{TiO}_{6}$ octahedra, in which the Ti-O distance are 194.85 pm (four) and 198.00 pm (two). The $\mathrm{TiO}_{6}$ octahedra share edges to form chains, which further share vertices to yield a three-dimensional network, as shown in Fig. 10.2.6.
The structure of rutile may also be described as a nearly hcp of O atoms, with Ti atoms located in half of the octahedral interstices.

Many tetravalent metal oxides and divalent metal fluorides adopt the rutile structure. Table 10.2.6 lists some compounds with the rutile structure and the parameters of their tetragonal unit cells.

### 10.3 Body-centered cubic packing and related structures

### 10.3.1 Body-centered cubic packing (bcp)

Body-centered cubic packing (bcp) is a common structure type among metals. The space group is $O_{\mathrm{h}}^{9}-\operatorname{Im} \overline{3} m$, and the atomic coordinates of equivalent positions are listed in Table 10.3.1.

In the bcp structure, the cubic unit cell has two atoms in site $2(a)$ : $(0,0,0 ; 1 / 2,1 / 2,1 / 2)$. Figure 10.3 .1(a) shows that at the center of every face and the edge of the unit cell there are octahedral interstices, each surrounded by

* This table is not complete and only lists eight sets.
six spheres. Each sphere of radius $R$ corresponds to three such octahedral interstices. These octahedra are not regular but are compressed along one axis. The shortest dimension of an interstice dictates the radius $r$ of a small sphere that can be accommodated in it, and the ratio $r / R$ is 0.154 .

Distorted tetrahedral interstices also occur on the faces of the unit cell. Each face has four such distorted tetrahedral interstices with a radius ratio $r / R=$ 0.291 , as shown in Fig. 10.3.1(b). Each sphere corresponds to six of these tetrahedral interstices.

> (a)

(b)

These two types of interstitial polyhedra are not mutually exclusive; i.e., a particular part of volume in the unit cell does not belong to one particular polyhedron. In addition, distorted trigonal-bipyramidal interstitial polyhedra are each formed from two face-sharing tetrahedra. The number of such interstices that corresponds to one sphere is 12 . Therefore, each sphere in the bcp structure is associated with three octahedral, six tetrahedral, and twelve trigonalbipyramidal interstices, i.e., a total of 21 interstices. The size and distribution

Table 10.3.2 Some metals with the bcp structure and their $a$ values

| Metal | $a(\mathrm{pm})$ | Metal | $a(\mathrm{pm})$ | Metal | $a(\mathrm{pm})$ |

of these interstices directly affect the properties of the structure. Table 10.3.2 lists some metals with the bcp structure and their $a$ values.

### 10.3.2 Structure and properties of $\alpha$-Agl

Silver iodide, AgI , exists in several polymorphic forms. In the $\alpha-\mathrm{AgI}$ crystal, the $\mathrm{I}^{-}$ions adopt the bcp structure, and the $\mathrm{Ag}^{+}$cations are distributed statistically among the $6(b), 12(d)$, and $24(h)$ sites of space group $O_{\mathrm{h}}^{9}-\operatorname{Im} \overline{3} m$, as listed in Table 10.3.1, and also partially populate the passageways between these positions. The cubic unit cell, with $a=504 \mathrm{pm}$, provides 42 possible positions for two $\mathrm{Ag}^{+}$cations, and the $\mathrm{Ag}^{+} \ldots \mathrm{I}^{-}$distances are listed below:

6(b) positions having $2 \mathrm{I}^{-}$neighbors at 252 pm ,
12(d) positions having $4 \mathrm{I}^{-}$neighbors at 282 pm , and
$24(h)$ positions having $3 \mathrm{I}^{-}$neighbors at 267 pm .
Figure 10.3 .2 shows the crystal structure of $\alpha-\mathrm{AgI}$ and the possible positions of the $\mathrm{Ag}^{+}$ions, the mobility of which accounts for the prominent ionic transport properties of $\alpha-\mathrm{AgI}$ as a solid electrolyte.

The structure of AgI varies at different temperatures and pressures. The stable form of AgI below $409 \mathrm{~K}, \gamma-\mathrm{AgI}$, has the zinc blende (cubic ZnS ) structure. On the other hand, $\beta$ - AgI , with the wurtzite (hexagonal ZnS ) structure, is the stable form between 409 and 419 K . Above $419 \mathrm{~K}, \beta$-AgI undergoes a phase change to cubic $\alpha$-AgI. Under high pressure, AgI adopts the NaCl structure. Below room temperature, $\gamma$-AgI obtained from precipitation from an aqueous solution exhibits prominent covalent bond character, with a low electrical conductivity of about $3.4 \times 10^{-4} \mathrm{ohm}^{-1} \mathrm{~cm}^{-1}$. When the temperature is raised, it undergoes a phase change to $\alpha-\mathrm{AgI}$, and the electrical conductivity increases ten-thousandfold to $1.3 \mathrm{ohm}^{-1} \mathrm{~cm}^{-1}$. Compound $\alpha-\mathrm{AgI}$ is the prototype of an important class of ionic conductors with $\mathrm{Ag}^{+}$functioning as the carrier.

The transformation of $\beta$ - AgI to $\alpha$ - AgI is accompanied by a dramatic increase in the ionic electrical conductivity of the solid, which leaps by a factor of nearly 4000 from $3.4 \times 10^{-4}$ to $1.3 \mathrm{ohm}^{-1} \mathrm{~cm}^{-1}$. This arises because in $\beta-\mathrm{AgI}$ the Ag

Fig. 10.3.2.
Structure of $\alpha$-AgI.

atoms have tetrahedral coordination, in which covalent bonding is the dominant factor, but ionic bonding becomes important in $\alpha$-AgI.

The reaction of AgI with RbI forms $\mathrm{RbAg}_{4} \mathrm{I}_{5}$, which has been found to have the highest specific electrolytic conductivity at room temperature ( $0.27 \mathrm{ohm}^{-1} \mathrm{~cm}^{-1}$ ) among known solids, and this property is retained at low temperature.

The AgI-type superionic solids are important inorganic materials. Several generalizations on the relationship between the conductivity of solid electrolytes and their structures can be made:
(a) Almost all solid electrolytes of any kind have a network of passageways formed from the face-sharing of anionic polyhedra.
(b) In structures in which the sites available to the current carriers are not crystallographically equivalent, the distribution of carriers over different sites is markedly non-uniform.
(c) The conductivity is associated with the nature of the passageways: more open channels lead to higher conductivity. In general, three-dimensional networks exhibit higher average conductivities than two-dimensional networks. A larger number of available sites and/or a larger crystal volume available to the conduction passageways tends to give higher conductivities.
(d) The stability of the $\mathrm{Ag}^{+}$ions in both four- and three-coordination and their univalent character account for the fact that they constitute the mobile phase in most good solid electrolytes.

### 10.3.3 Structure of CsCl and related compounds

The cesium chloride structure may be regarded as derived from the two equivalent atoms of the cubic bcp unit cell by changing one to $\mathrm{Cs}^{+}$and the other to

## (a)

(b)

Fig. 10.3.3.
Unit cell of (a) CsCl and (b) $\mathrm{Cr}_{2} \mathrm{Al}$.
$\mathrm{Cl}^{-}$. The lattice type is reduced from face-centered cubic to primitive cubic, and the space group of CsCl is $O_{\mathrm{h}}^{1}-\operatorname{Pm} \overline{3} m$. Figure 10.3.3(a) shows a unit cell in the crystal structure of CsCl .

In the CsCl structure, the coordination number of either kind of ion is eight, and the interionic distance is $\left[\frac{1}{2}(3)^{1 / 2}\right] a$. Two principal kinds of compounds crystallize with the CsCl structure. In one group are the halides of the largest univalent ions, and in the other are intermetallic compounds. Some examples are listed in Table 10.3.3.

Table 10.3.3. Compounds of CsCl structure type and their unit-cell parameters

| Compound | $a(\mathrm{pm})$ | Compound | $a(\mathrm{pm})$ | Compound | $a(\mathrm{pm})$ |
| :--- | :--- | :--- | :--- | :--- | :--- |
| AgCd | 333 | CsBr | 428.6 | MgTl | 362.8 |
| AgCe | 373.1 | CsCl | 412.3 | $\mathrm{NH}_{4} \mathrm{Cl}$ | 386 |
| AgLa | 376.0 | CsI | 456.67 | $\mathrm{NH}_{4} \mathrm{Br}$ | 405.94 |
| AgMg | 328 | CuPd | 298.8 | $\mathrm{NH}_{4} \mathrm{I}$ | 437 |
| AgZn | 315.6 | CuZn | 294.5 | NiAl | 288.1 |
| AuMg | 325.9 | FeTi | 297.6 | NiIn | 309.9 |
| AuZn | 319 | LiAg | 316.8 | NiTi | 301 |
| BeCo | 260.6 | LiHg | 328.7 | SrTl | 402.4 |
| BeCu | 269.8 | LiTl | 342.4 | TlBi | 398 |
| BePd | 281.3 | MgCe | 389.8 | TlBr | 397 |
| CaTl | 384.7 | MgHg | 344 | TlCl | 383.40 |
| CoAl | 286.2 | MgLa | 396.5 | TII | 419.8 |
| CoTi | 298.6 | MgSr | 390.0 | TlSb | 384 |

The structures of some intermetallic compounds are formed from the stacking of blocks, each resembling a unit cell of the CsCl type. For example, the unit cell of $\mathrm{Cr}_{2} \mathrm{Al}$ may be regarded as a stack of three blocks, as shown in Fig. 10.3.3(b).

### 10.4 Perovskite and related compounds

### 10.4.1 Structure of perovskite

The mineral $\mathrm{CaTiO}_{3}$ is named perovskite, the structure of which is related to a vast number of inorganic crystals, and it plays a central role in the development of the inorganic functional materials.
(a)

(b)

Perovskite crystallizes in the cubic space group $O_{\mathrm{h}}^{1}-P m \overline{3} m$. The $\mathrm{Ti}^{4+}$ ions are located at the corners of the unit cell, $\mathrm{a}_{\mathrm{Ca}}{ }^{2+}$ ion at the body center, and $\mathrm{O}^{2-}$ ions at the mid-points of the edges; this so-called A-type cell is shown in Fig. 10.4.1(a). When the origin of the cubic unit cell is taken at the $\mathrm{Ca}^{2+}$ ion, the $\mathrm{Ti}^{4+}$ ion occupies the body center and the $\mathrm{O}^{2-}$ ions are located at the face centers; this B-type unit cell is shown in Fig. 10.4.1(b).

Each $\mathrm{Ca}^{2+}$ is thus twelve-coordinated and each $\mathrm{Ti}^{4+}$ six-coordinated by oxygen neighbors, while each $\mathrm{O}^{2-}$ is linked to four $\mathrm{Ca}^{2+}$ and two $\mathrm{Ti}^{4+}$ ions. As expected, it is the larger metal ion that occupies the site of higher coordination. Geometrically the structure can be regarded as a ccp of $\left(\mathrm{O}^{2-}\right.$ and $\left.\mathrm{Ca}^{2+}\right)$ ions, with the $\mathrm{Ti}^{4+}$ ions orderly occupying $1 / 4$ of the octahedral interstices.

The basic perovskite structure $\mathrm{ABX}_{3}$ forms the prototype for a wide range of other structures related to it by combinations of topological distortions, substitution of the $\mathrm{A}, \mathrm{B}$ and X ions, and intergrowth with other structure types. These compounds exhibit a range of magnetic, electrical, optical, and catalytic properties of potential application in solid state physics, chemistry, and materials science.

Many $\mathrm{ABX}_{3}$ compounds have true cubic symmetry, whereas some owing to strain or to small departures from perfect cubic symmetry have appreciably distorted atomic arrangements. In the idealized structure, a simple relationship exists between the radii of the component ions,

$$
r_{\mathrm{A}}+r_{\mathrm{X}}=(2)^{1 / 2}\left(r_{\mathrm{B}}+r_{\mathrm{X}}\right)
$$

where A is the larger cation. It is found that, in practice, the real structure conforms to the condition

$$
r_{\mathrm{A}}+r_{\mathrm{X}}=t(2)^{1 / 2}\left(r_{\mathrm{B}}+r_{\mathrm{X}}\right)
$$

where $t$ is a "factor of tolerance" which lies within the approximate limiting range of $0.7-1.0$. If $t$ lies outside this range, other structures are obtained. Table 10.4.1 lists some compounds with the perovskite structure.

Only a small fraction of the enormous number of perovskite-type compounds is listed in Table 10.4.1. For instance, substitution of the lanthanide element

Table 10.4.1. Some compounds with the perovskite structure

La for Sm will generate another isostructural series. In view of the common occurrence of perovskite-type compounds, it is worthwhile to elaborate their structural characteristics and important trends.

## (1) Relative sizes of ion $A$ and ion $B$ in $A B X_{3}$

In all the perovskite compounds, the A ions are large and comparable in size to the oxygen or fluoride ion. The B ions must have a radius for six-coordination by oxygen (or fluorine). Thus, the radii of A and B ions must lie within the ranges 100 to 140 pm and 45 to 75 pm , respectively.

## (2) Valences of A and B cations

Oxides with the perovskite structure must have a pair of cations of valences +1 and +5 (e.g. $\mathrm{KNbO}_{3}$ ), +2 and +4 (e.g. $\mathrm{CaTiO}_{3}$ ), or +3 and +3 (e.g. $\mathrm{LaCrO}_{3}$ ). Sometimes, the A and/or B sites are not all occupied by atoms of the same kind, as in $\left(\mathrm{K}_{0.5} \mathrm{La}_{0.5}\right) \mathrm{TiO}_{3}, \mathrm{Sr}\left(\mathrm{Ga}_{0.5} \mathrm{Nb}_{0.5}\right) \mathrm{O}_{3},\left(\mathrm{Ba}_{0.5} \mathrm{~K}_{0.5}\right)\left(\mathrm{Ti}_{0.5} \mathrm{Nb}_{0.5}\right) \mathrm{O}_{3}$. The components of these compounds need to satisfy overall charge neutrality.

## (3) Perovskite as a complex oxide

Despite the resemblance between the empirical formulas $\mathrm{CaCO}_{3}$ and $\mathrm{CaTiO}_{3}$, these two compounds are structurally entirely distinct. While $\mathrm{CaCO}_{3}$ is a salt that contains the anion $\mathrm{CO}_{3}^{2-}, \mathrm{CaTiO}_{3}$ has no discrete $\mathrm{TiO}_{3}^{2-}$ species in its crystal structure, in which each $\mathrm{Ti}^{4+}$ ion is coordinated symmetrically by six $\mathrm{O}^{2-}$. Thus $\mathrm{CaTiO}_{3}$ should more properly be regarded as a complex oxide.

## (4) Perovskite compounds are not limited to oxides and fluorides

The compound $\mathrm{MgCNi}_{3}$ has the perovskite structure, as determined by neutron diffraction, and is a superconducting material with $T_{\mathrm{C}}=8 \mathrm{~K}$.

Table 10.4.2. Structure and properties of $\mathrm{BaTiO}_{3}$ in different temperature ranges

### 10.4.2 Crystal structure of $\mathrm{BaTiO}_{3}$

Mixed solid solutions of the general formula $(\mathrm{Ba}, \mathrm{Sr}, \mathrm{Pb}, \mathrm{Ca})(\mathrm{Ti}, \mathrm{Zr}, \mathrm{Sn}) \mathrm{O}_{3}$ are the most commonly used ferroelectric materials.

In different temperature ranges, barium titanate $\mathrm{BaTiO}_{3}$ exists in several stable phases. Table 10.4.2 lists the crystal data and properties of the polymorphic forms of $\mathrm{BaTiO}_{3}$, and Fig. 10.4.2 shows their structures.

Above $393 \mathrm{~K}, \mathrm{BaTiO}_{3}$ has the perovskite structure, as shown in Fig. 10.4.2(a). This cubic crystal has a center of symmetry and does not exhibit ferroelectric properties.

In the temperature range $278-393 \mathrm{~K}$, the $\mathrm{BaTiO}_{3}$ lattice is transformed to the tetragonal system with local $C_{4 \mathrm{v}}$ symmetry. The tetragonal unit cell has axial ratio $c / a=1.01$. The $\mathrm{Ti}^{4+}$ ion departs from the center and moves toward the upper face; the $\mathrm{O}^{2-}$ ions are divided into two sets, one moving downward and other moving upward, as shown in Fig. 10.4.2(b). The arrows in the figure indicate the direction of the movement. $\mathrm{The}^{\mathrm{TiO}} 66$ octahedra are no longer regular, which is the result of spontaneous polarization, the strength of which depends on temperature (thermoelectric effect) and pressure (piezoelectric effect).

In the temperature range $193-278 \mathrm{~K}$, the atoms in the $\mathrm{BaTiO}_{3}$ crystal undergo further shifts, and the lattice symmetry is reduced to the orthorhombic system and $C_{2 \mathrm{v}}$ point group, as shown in Fig. 10.4.2(c). This crystalline modification has spontaneous polarization with ferroelectric properties.
(a)

(b)

(d)

Fig. 10.4.2.
Structure of $\mathrm{BaTiO}_{3}$ : (a) cubic, (b) tetragonal, (c) orthorhombic, (d) hexagonal (white circles, $\mathrm{O}^{2-}$; large black circles, $\mathrm{Ba}^{2+}$; small black circles, $\mathrm{Ti}^{4+}$ ).

When the temperature is below 193 K , the orthorhomic form further transforms to the hexagonal system in space group $D_{6 \mathrm{~h}}^{4}-P 6_{3} / m m c$. The $\mathrm{O}^{2-}$ and $\mathrm{Ba}^{2+}$ ions together form close packed layers and stack in the sequence ABCACB and the $\mathrm{Ti}^{4+}$ ions occupy the octahedral interstices composed only of $\mathrm{O}^{2-}$ anions. In this layer stacked structure, the A layers have horizontal mirror symmetry as shown in Fig. 10.4.2(d). Two-thirds of the $\mathrm{TiO}_{6}$ octahedra share faces to form the $\mathrm{Ti}_{2} \mathrm{O}_{9}$ group, in which the $\mathrm{Ti}-\mathrm{Ti}$ distance is 267 pm , as represented by a line. This centrosymmetrical crystal is non-ferroelectric.

### 10.4.3 Superconductors of perovskite structure type

The crystal structure of many oxide superconductors can be regarded as based on the perovskite structure, which can be modified by atomic replacements, displacements, vacancies, and changes in the order of stacking layers.
(a) Structure of $\mathrm{La}_{2} \mathrm{CuO}_{4}$

The first-discovered oxide superconductor is $\mathrm{La}_{2} \mathrm{CuO}_{4}$ and it has the $\mathrm{K}_{2} \mathrm{NiF}_{4}$ structure type, as shown in Fig. 10.4.3(a). This structure can be derived from one B-type unit cell of the perovskite structure in combination with two Atype unit cells, each with one layer removed. In this manner, a tetragonal unit cell with $c \sim 3 a$ is generated. The resulting structure belongs to space group $D_{4 \mathrm{~h}}^{17}-I 4 / \mathrm{mmm}$, in which the Cu atom has octahedral coordination and the La atom has nine-coordination. $\mathrm{The} \mathrm{CuO}_{6}$ octahedra share vertices and form infinite layers.

(b) Structure of $\mathrm{YBa}_{2} \mathrm{Cu}_{3} \mathrm{O}_{6}$ and $\mathrm{YBa}_{2} \mathrm{Cu}_{3} \mathrm{O}_{7}$

These two compounds are both high-temperature superconductors with similar structures, as shown in Figs. 10.4.3(b) and (c). $\mathrm{YBa}_{2} \mathrm{Cu}_{3} \mathrm{O}_{6}$ belongs to the tetragonal system in space group $D_{4 \mathrm{~h}}^{1}-P 4 / \mathrm{mmm}$, with $a=385.70 \mathrm{pm}$ and $c=1181.94 \mathrm{pm}$. The crystals of $\mathrm{YBa}_{2} \mathrm{Cu}_{3} \mathrm{O}_{7}$ are orthorhombic, space group $D_{2 \mathrm{~h}}^{1}-P m m m$, with $a=381.98 \mathrm{pm}, b=388.49 \mathrm{pm}$, and $c=1167.62 \mathrm{pm}$. These two structures are conveniently described as oxygen-deficient perovskites with triple A-type unit cells owing to $\mathrm{Ba}-\mathrm{Y}$ ordering along the $c$ axis. In $\mathrm{YBa}_{2} \mathrm{Cu}_{3} \mathrm{O}_{7}$, one set of Cu atoms from linear chains of corner-linked squares orientated along the $b$ axis, and the other set of Cu atoms form layers of corner-shared square pyramids. The structure of $\mathrm{YBa}_{2} \mathrm{Cu}_{3} \mathrm{O}_{6}$ is derived from that of $\mathrm{YBa}_{2} \mathrm{Cu}_{3} \mathrm{O}_{7}$ by removal of the oxygen atoms at the base. The coordination geometry of the Cu atom at the origin then becomes linear two-coordinate, but the square-pyramidal environment of the other Cu atoms remains unchanged. In these two crystals, the Cu and O atoms that constitute the basal components of a square-pyramidal $\mathrm{Cu}-\mathrm{O}$ layer are not coplanar.

### 10.4.4 $\mathrm{ReO}_{3}$ and related compounds

## (1) Structure of $\mathrm{ReO}_{3}$

The rhenium trioxide $\mathrm{ReO}_{3}$ structure consists of regular octahedra sharing vertices to form a large unoccupied interstice surrounded by 12 O atoms, as shown in Fig. 10.4.4(a). The structure of $\mathrm{ReO}_{3}$ can also be regarded as derived from the perovskite structure by deleting all $\mathrm{Ca}^{2+}$ ions and keeping the $\mathrm{TiO}_{3}$ framework. It belongs to space group $O_{\mathrm{h}}^{1}-\operatorname{Pm} \overline{3} m$, the same one for perovskite.

Some trivalent metal fluorides, hexavalent metal oxides, and copper(I) nitride adopt the $\mathrm{ReO}_{3}$ structure:

$$
\begin{array}{lll}
\mathrm{MoF}_{3}, a=389.85 \mathrm{pm} ; & \mathrm{TaF}_{3}, a=390.12 \mathrm{pm} ; & \mathrm{NbF}_{3}, a=390.3 \mathrm{pm} \\
\mathrm{UO}_{3}, a=415.6 \mathrm{pm} ; & \mathrm{ReO}_{3}, a=373.4 \mathrm{pm} ; & \mathrm{Cu}_{3} \mathrm{~N}, a=380.7 \mathrm{pm}
\end{array}
$$

Fig. 10.4.4.
Crystal structure of (a) $\mathrm{ReO}_{3}$, and (b) $\mathrm{Na}_{x} \mathrm{WO}_{3}$ (central large circle, $\mathrm{Na}^{+}$of fractional site occupancy).

## (2) Structure of $\mathrm{Na}_{x} \mathrm{WO}_{3}$

The structure of $\mathrm{WO}_{3}$ is of the $\mathrm{ReO}_{3}$ type, as shown in Fig. 10.4.4(a). The tungsten bronzes of the formula $\mathrm{M}_{x} \mathrm{WO}_{3}(0<x<1)$ are derived from the threedimensional network of $\mathrm{WO}_{3}$, in which the W atoms adopt variable valence states, and the large unoccupied interstices conveniently accommodate other cationic species. When a portion of the $\mathrm{W}^{6+}$ cations is converted to $\mathrm{W}^{5+}$, the requisite cations M (normally Na or K ; but also $\mathrm{Ca}, \mathrm{Sr}, \mathrm{Ba}, \mathrm{Al}, \mathrm{In}, \mathrm{Tl}, \mathrm{Sn}, \mathrm{Pb}$, $\mathrm{Cu}, \mathrm{Ag}, \mathrm{Cd}$, lanthanides, $\mathrm{H}^{+}$, and $\mathrm{NH}_{4}^{+}$) are incorporated into the structure to maintain electrical neutrality. The additional cations M are partially located at the centers of the unit cells to give the perovskite structure type, as shown in Fig. 10.4.4(b).

The name "tungsten bronzes" originates from their characteristic properties: intense color, metallic luster, metallic conductivity or semiconductivity, a range of variable composition, and resistance to attack by non-oxidizing acids. The bronzes $\mathrm{Na}_{x} \mathrm{WO}_{3}$ exhibit colors that change with the occupancy factor $x$ as follows:

### 10.5 Hard magnetic materials

### 10.5.1 Survey of magnetic materials

There are four different classes of hard magnetic materials:
(a) Steel and iron-based alloys, such as carbon steel and the alnicos;
(b) Transition metal oxides, such as $\mathrm{Fe}_{3} \mathrm{O}_{4}, \gamma-\mathrm{Fe}_{2} \mathrm{O}_{3}$, and M-type ferrites $\left[\mathrm{MO} \cdot 6 \mathrm{Fe}_{2} \mathrm{O}_{3}(\mathrm{M}=\mathrm{Ba}, \mathrm{Sr}, \mathrm{Pb})\right]$;
(c) Rare-earth intermetallics, such as $\mathrm{SmCo}_{5}, \mathrm{Sm}_{2} \mathrm{Co}_{17}$, and $\mathrm{Nd}_{2} \mathrm{Fe}_{14} \mathrm{~B}$; and
(d) Metal complexes containing organic ligands, such as $\mathrm{V}(\mathrm{TCNE})_{x}$. $y\left(\mathrm{CH}_{2} \mathrm{Cl}_{2}\right)$.

Table 10.5.1. Trends in $[\mathrm{BH}]_{\max }$ at 300 K of hard magnetic materials

| Years | Materials | $[\mathrm{BH}]_{\text {max }}\left(\mathrm{kJ} \mathrm{m}^{-3}\right)$ |
| :---: | :---: | :---: |
| 1960s | Magnetic materials of transition metals oxides: |  |
|  | Ba-ferrite (anis.) | 70 |
|  | Sr-ferrite (anis.) | 80 |
|  | Iron-based alloys: alnico 8, 9 | 100 |
| 1970s | Rare-earth intermetallics: |  |
|  | First generation: $\mathrm{SmCo}_{5}$ | 150 |
|  | Second generation: $\mathrm{Sm}(\mathrm{Co}, \mathrm{Cu}, \mathrm{Fe}, \mathrm{Zr})_{7.4}$ | 250 |
| 1980s | Third generation: $\mathrm{Nd}_{2} \mathrm{Fe}_{14} \mathrm{~B}$ | 300 |
| 1990s | Improved third generations: $\mathrm{Nd}_{2} \mathrm{Fe}_{14} \mathrm{~B}$ | 400 |
|  | Organic ferromagnets: $\mathrm{V}(\mathrm{TCNE})_{x} \cdot \mathrm{y}\left(\mathrm{CH}_{2} \mathrm{Cl}_{2}\right)$ | $\sim 5$ |

For many centuries, carbon steels were the only synthetic permanent magnetic materials superior to loadstone. Starting in about 1890, improved understanding of the metallurgy of alloy steels, and later, control of solid state precipitation in iron-based alloys via heat treatment led to substantial advances. Today the alnicos ( $\mathrm{Fe}-\mathrm{Co}-\mathrm{Ni}-\mathrm{Al}-\mathrm{Cu}$ alloys) corner a large fraction of the market on magnets. However, increasing availability of rare-earth metals has led to a new development path based on compounds containing 3d (transition) and $4 f$ (rare-earth) metals. The trend in the maximum energy product $[\mathrm{BH}]_{\max }$ at 300 K for different classes of hard magnetic materials that have been studied over the past four decades is displayed in Table 10.5.1.

Transition metal oxides having the spinel structure are typical magnetic materials. In a magnetic solid, the spin interaction between neighboring cations through oxygen as a bridging element plays a major role in determining the magnitude of the magnetic moment. This spin interaction is most effective when the adjacent cations and bridging oxygens are in a straight line. In spinel $\mathrm{AB}_{2} \mathrm{O}_{4}$, the A (tetrahedral cation)- $\mathrm{O}-\mathrm{B}$ (octahedral cation) angle is $125^{\circ}$, while the angles for $\mathrm{A}-\mathrm{O}-\mathrm{A}$ and $\mathrm{B}-\mathrm{O}-\mathrm{B}$ are $79^{\circ}$ and $90^{\circ}$, respectively. Since the $\mathrm{A}-\mathrm{B}$ interaction is the most effective, the magnetic properties of spinel structures can be fine-tuned by controlling the normal and inverse structures through composition changes and heat treatment.

The alnicos are a very important group of permanent magnetic alloys, which are used in a wide range of applications. They are essentially heat-treated alloys of variable $\mathrm{Fe}-\mathrm{Co}-\mathrm{Ni}-\mathrm{Al}-\mathrm{Cu}$ composition:

## Alnico-5 (wt \%): Ni 12-15, Al 7.8-8.5, Co 23-25, Cu 2-4, Ti 4-8, Nb 0-1, Fe as remainder

Alnico-9 (wt \%): Ni 14-16, Al 7-8, Co 32-36, $\mathrm{Cu} 3-4, \mathrm{Nb} 0-1, \mathrm{~S} 0.3, \mathrm{Fe}$ as remainder

The alnicos are polycrystalline solids, in which very complex structural disorder generally occurs, due to the wide variety of deviations from periodicity that may be present. Physical disorder corresponds to the displacement of atoms, and/or the presence of amorphous regions and non-uniform crystallite sizes, while chemical disorder corresponds to site occupation by impurity atoms, and/or the presence of vacancies accompanied by variable valence states of
metal ions. The compositions and heat treatment history have dominating effects on the properties of magnetic materials.

### 10.5.2 Structure of $\mathrm{SmCo}_{5}$ and $\mathrm{Sm}_{2} \mathrm{Co}_{17}$

Most of the permanent magnets based on cobalt-rare-earth alloys exhibit several times higher magnetic energy than conventional magnets such as alnicos and hard ferrites. They also exhibit very high stability of magnetic flux density even at elevated temperatures, a property unattainable with any other existing permanent-magnet materials.

Among the rare-earths, samarium is the most commonly used because it provides the best permanent-magnet property. Other rare-earth elements are sometimes employed in combination with samarium to meet special requirements. The compounds $\mathrm{SmCo}_{5}$ and $\mathrm{Sm}_{2} \mathrm{Co}_{17}$ are the most important magnetic materials among the cobalt-lanthanide alloys.

Compound $\mathrm{SmCo}_{5}$ belongs to the hexagonal system, space group $\mathrm{P} 6 / \mathrm{mmm}$, with $a=498.9 \mathrm{pm}$ and $c=398.1 \mathrm{pm}$. Its crystal structure, as shown in Fig. 10.5.1, consists of two different layers of atoms. One layer is composed of two kinds of atoms in the ratio of 1:2 for samarium to cobalt, with the Sm atoms arranged in a closed packed layer and the Co atoms at the center of each triangular interstice. This layer alternates with another layer consisting of only cobalt atoms.

The crystal structure of $\mathrm{Sm}_{2} \mathrm{Co}_{17}$ is closely related to the $\mathrm{SmCo}_{5}$ structure. One Sm atom is substituted by a pair of Co atoms at one-third of the Sm sites in the $\mathrm{SmCo}_{5}$ structure. This pair of Co atoms lie along the $c$ axis. The positions of the substitution in the neighboring (but similar) layer are different. The order of the substitution can be either (a) $\operatorname{ABABAB} \ldots$ or (b) $\operatorname{ABCABC} \ldots$ along the $c$-axis, as shown in Fig. 10.5.2.

In the substitution order $\mathrm{ABABAB} \ldots, \mathrm{Sm}_{2} \mathrm{Co}_{17}$ forms a hexagonal structure, with $a=836.0 \mathrm{pm}$ and $c=851.5 \mathrm{pm}$ [Fig. 10.5.2(a)]. The substitution order ABCABC $\ldots$ yields a rhombohedral form of $\mathrm{Sm}_{2} \mathrm{Co}_{17}$ with $a=837.9 \mathrm{pm}$ and $c=1221.2 \mathrm{pm}$ [Fig. 10.5.2(b)].

### 10.5.3 Structure of $\mathrm{Nd}_{2} \mathrm{Fe}_{14} \mathrm{~B}$

Permanent magnets based on the $\mathrm{Nd}_{2} \mathrm{Fe}_{14} \mathrm{~B}$ phase were introduced in 1983 and are currently the strongest magnets available.

Fig. 10.5.1.
Crystal structure of $\mathrm{SmCo}_{5}$.
(a)

Crystal structure of $\mathrm{Sm}_{2} \mathrm{Co}_{17}$ : (a) hexagonal form and (b) rhombohedral form.

Fig. 10.5.3.
Crystal structure of $\mathrm{Nd}_{2} \mathrm{Fe}_{14} \mathrm{~B}$ (large black circles, Nd; small black circles, B; open circles, Fe ). of $\mathrm{Nd}_{2} \mathrm{Fe}_{14} \mathrm{~B}$.

The $\mathrm{Nd}_{2} \mathrm{Fe}_{14} \mathrm{~B}$ crystal is tetragonal, with space group $P 4_{2} / m n m$, unit cell $a=880 \mathrm{pm}, c=1220 \mathrm{pm}$, and $Z=4$. There is a six-layer stacking sequence along the $c$ axis. The first and fourth layers are mirror planes that contain $\mathrm{Fe}, \mathrm{Nd}$, and B atoms, and the other layers are puckered nets containing only Fe atoms. Each B atom is at the center of a trigonal prism formed by six Fe atoms, three above and three below the $\mathrm{Fe}-\mathrm{Nd}-\mathrm{B}$ planes. Figure 10.5.3 shows the structure

An effective strategy of modifying the magnetic properties of iron-rich rareearth intermetallics is to incorporate small interstitial atoms into the crystal lattice. Besides hydrogen, only boron, carbon, and nitrogen atoms are small enough to enter the structure in this way, and they preferentially occupy interstitial sites surrounded by the largest number of rare-earth atoms. For example, in
$\mathrm{Sm}_{2} \mathrm{Fe}_{17}$ (iso-structural to $\mathrm{Sm}_{2} \mathrm{Co}_{17}$ ) there are three octahedral interstitial sites which may be filled by nitrogen atoms to form $\mathrm{Sm}_{2} \mathrm{Fe}_{17} \mathrm{~N}_{3}$. The effect of interstitial atoms on the intrinsic magnetic properties of iron-based intermetallics can be further exploited in materials design.

## Structural Chemistry of Selected Elements

Part III comprises a succinct account of the structural chemistry of the elements in the Periodic Table.

In general, each chemical element or group has its own characteristic structural chemistry. In Part III, seven chapters are devoted to discussing the structural chemistry of hydrogen, alkali, and alkaline-earth metals, and the elements in Group 13 to Group 18. These chapters are followed by one chapter each on the rare-earth elements, transition metal clusters, and supramolecular structural chemistry. The compounds described include organometallics, metal-metal bonded systems, coordination polymers, host-guest compounds, and supramolecular assemblies. Basic organic crystal structures are discussed in Chapter 14 under the chemistry of carbon. The structural chemistry of bioinorganic compounds is not covered here as, in the writers' opinion, the subject would be better taught in a separate course on "Bioinorganic Chemistry," for which several excellent texts are available.

The presentation in Part III attempts to convey the message that inorganic synthesis is inherently less organized than organic synthesis, and serendipitous discoveries are being made from time to time. Selected examples illustrating interesting aspects of structure and bonding, generalizations of structural patterns, and highlights from the current literature are discussed in the light of the theoretical principles presented in Parts I and II. The most up-to-date resources and references are used in the compilation of tables of structural data. It is hoped that the immense impact of chemical crystallography in the development of modern chemistry comes through naturally to the reader.

## Structural Chemistry of Hydrogen

### 11.1 The bonding types of hydrogen

Hydrogen is the third most abundant element (after oxygen and silicon in terms of the number of atoms) in the earth's crust and oceans. Hydrogen atom exists as three isotopes: ${ }^{1} \mathrm{H}$ (ordinary hydrogen, protium, H ), ${ }^{2} \mathrm{H}$ (deuterium, D ) and ${ }^{3} \mathrm{H}$ (tritium, T). Some of the important physical properties of the isotopes of hydrogen are listed in Table 11.1.1. Hydrogen forms more compounds than any other element, including carbon. This fact is a consequence of the electronic structure of the hydrogen atom.

Hydrogen is the smallest atom with only one electron and one valence orbital, and its ground configuration is $1 \mathrm{~s}^{1}$. Removal of the lone electron from the neutral atom produces the $\mathrm{H}^{+}$ion, which bears some similarity with an alkali metal cation, while adding one electron produces the $\mathrm{H}^{-}$ion, which is analogous to a halide anion. Hydrogen may thus be placed logically at the top of either Group 1 or Group 17 in the Periodic Table. The hydrogen atom forms many bonding types in a wide variety of compounds, as described below.

## (1) Covalent bond

The hydrogen atom can use its 1s orbital to overlap with a valence orbital of another atom to form a covalent bond, as in the molecules listed in Table 11.1.2. The covalent radius of hydrogen is 37 pm .

Table 11.1.1. Properties of hydrogen, deuterium, and tritium

| Property | H | D | T |
| :--- | :--- | :--- | :--- |
| Abundance (\%) | 99.985 | 0.015 | $\sim 10^{-16}$ |
| Relative atomic mass | 1.007825 | 2.014102 | 3.016049 |
| Nuclear spin | $1 / 2$ | 1 | $1 / 2$ |
| Nuclear magnetic moment $\left(\mu_{\mathrm{N}}\right)$ | 2.79270 | 0.85738 | 2.9788 |
| NMR frequency (at 2.35 T) (MHz) | 100.56 | 15.360 | 104.68 |
| Properties of diatomic molecules | $\mathrm{H}_{2}$ | $\mathrm{D}_{2}$ | $\mathrm{~T}_{2}$ |
| mp (K) | 13.957 | 18.73 | 20.62 |
| bp (K) | 20.30 | 23.67 | 25.04 |
| $T_{c}(\mathrm{~K})$ | 33.19 | 38.35 | 40.6 (calc.) |
| Enthalpy of dissociation $\left(\mathrm{kJ} \mathrm{mol}^{-1}\right)$ | 435.88 | 443.35 | 446.9 |
| Zero point energy $\left(\mathrm{kJ} \mathrm{mol}^{-1}\right)$ | 25.9 | 18.5 | 15.1 |

Table 11.1.2. Molecules containing covalently bonded hydrogen

| Molecules | $\mathrm{H}_{2}$ | HCl | $\mathrm{H}_{2} \mathrm{O}$ | $\mathrm{NH}_{3}$ | $\mathrm{CH}_{4}$ |
| :--- | :--- | :--- | :--- | :--- | :--- |
| Bond | $\mathrm{H}-\mathrm{H}$ | $\mathrm{H}-\mathrm{Cl}$ | $\mathrm{H}-\mathrm{O}$ | $\mathrm{H}-\mathrm{N}$ | $\mathrm{H}-\mathrm{C}$ |
| Bond lengths (pm) | 74.14 | 147.44 | 95.72 | 101.7 | 109.1 |

(2) Ionic bond
(a) Hydrogen present as $\mathrm{H}^{-}$

The hydrogen atom can gain an electron to form the hydride ion $\mathrm{H}^{-}$with the helium electronic configuration

$$
\mathrm{H}+\mathrm{e}^{-} \rightarrow \mathrm{H}^{-} \quad \Delta H=72.8 \mathrm{~kJ} \mathrm{~mol}^{-1}
$$

With the exception of beryllium, all the elements of Groups 1 and 2 react spontaneously when heated in hydrogen gas to give white solid hydrides $\mathrm{M}^{\mathrm{I}} \mathrm{H}$ or $\mathrm{M}^{\mathrm{II}} \mathrm{H}_{2}$. All MH hydrides have the sodium chloride structure, while $\mathrm{MgH}_{2}$ has the rutile structure and $\mathrm{CaH}_{2}, \mathrm{SrH}_{2}$, and $\mathrm{BaH}_{2}$ have the structure of distorted $\mathrm{PbCl}_{2}$. The chemical and physical properties of these solid hydrides indicate that they are ionic compounds.

The hydride anion $\mathrm{H}^{-}$is expected to be very polarizable, and its size changes with the partner in the MH or $\mathrm{MH}_{2}$ compounds. The experimental values of the radius of $\mathrm{H}^{-}$cover a rather wide range:

| Compounds | LiH | NaH | KH | RbH | CsH | $\mathrm{MgH}_{2}$ |
| :--- | :--- | :--- | :--- | :--- | :--- | :--- |
| $r\left(\mathrm{H}^{-}\right)(\mathrm{pm})$ | 137 | 142 | 152 | 154 | 152 | 130 |

From NaH , which has the NaCl structure with cubic unit-cell parameter $a=$ 488 pm , the radius of $\mathrm{H}^{-}$has been calculated as 142 pm .
(b) Hydrogen present as $\mathrm{H}^{+}$

The loss of an electron from a H atom to form $\mathrm{H}^{+}$is an endothermic process:

$$
\mathrm{H}(\mathrm{~g}) \rightarrow \mathrm{H}^{+}(\mathrm{g})+\mathrm{e}^{-} \quad \Delta H=1312.0 \mathrm{~kJ} \mathrm{~mol}^{-1}=13.59 \mathrm{eV}
$$

In reality $\mathrm{H}^{+}$, a bare proton, cannot exist alone except in isolation inside a high vacuum. The radius of $\mathrm{H}^{+}$is about $1.5 \times 10^{-15} \mathrm{~m}$, which is $10^{5}$ times smaller than other atoms. When $\mathrm{H}^{+}$approaches another atom or molecule, it can distort the electron cloud of the latter. Therefore, other than in a gaseous ionic beam, $\mathrm{H}^{+}$must be attached to another atom or molecule that possesses a lone pair of electrons. The proton as an acceptor can be stabilized as in pyramidal hydronium (or hydroxonium) ion $\mathrm{H}_{3} \mathrm{O}^{+}$, tetrahedral $\mathrm{NH}_{4}^{+}$, and linear $\mathrm{H}_{2} \mathrm{~F}^{+}$. These cations generally combine with various anions through ionic bonding to form salts.

The total hydration enthalpy of $\mathrm{H}^{+}$is highly exothermic and much larger than those of other simple charged cations:

$$
\mathrm{H}^{+}(\mathrm{g})+n \mathrm{H}_{2} \mathrm{O}(\ell) \rightarrow \mathrm{H}_{3} \mathrm{O}^{+}(\mathrm{aq}) \quad \Delta H=-1090 \mathrm{~kJ} \mathrm{~mol}^{-1}
$$

(3) Metallic bond

At ultrahigh pressure and low temperature, such as 250 GPa and 77 K , solid molecular hydrogen transforms to a metallic phase, in which the atoms are held together by the metallic bond, which arises from a band-overlap mechanism. Under such extreme conditions, the $\mathrm{H}_{2}$ molecules are converted into a linear chain of hydrogen atoms (or a three-dimensional network). This polymeric $\mathrm{H}_{n}$ structure with a partially filled band (conduction band) is expected to exhibit metallic behavior. Schematically, the band-overlap mechanism may be represented in the following manner:

The physical properties of $\mathrm{H}_{n}$ are most interesting. This material has a nearly opaque appearance and exhibits metallic conduction, and has been suggested to be present in several planets.
(4) The hydrogen bond

The hydrogen bond is usually represented as $\mathrm{X}-\mathrm{H} \cdots \mathrm{Y}$, where X and Y are highly electronegative atoms such as $\mathrm{F}, \mathrm{O}, \mathrm{N}, \mathrm{Cl}$, and C . Note that the description of "donor" and "acceptor" in a hydrogen bond refers to the proton; in the hydrogen bond $\mathrm{X}-\mathrm{H} \cdots \mathrm{Y}$, the $\mathrm{X}-\mathrm{H}$ group acts as a hydrogen donor to acceptor atom Y . In contrast, in a coordination bond the donor atom is the one that bears the electron pair.

Hydrogen bonding can be either intermolecular or intramolecular. For an intramolecular $\mathrm{X}-\mathrm{H} \cdots$ Y hydrogen bond to occur, X and Y must be in favorable spatial configuration in the same molecule. This type of hydrogen bond will be further elaborated in Section 11.2.
(5) Multicenter hydrogen bridged bonds
(a) B-H-B bridged bond

Boranes, carboranes, and metallocarboranes are electron-deficient compounds in which $\mathrm{B}-\mathrm{H}-\mathrm{B}$ three-center two-electron ( $3 c-2 e$ ) bridged bonds are found. The B-H-B bond results from the overlap of two boron $\mathrm{sp}^{3}$ hybrid orbitals and the 1 s orbital of the hydrogen atom, which will be discussed in Chapter 13.
(b) $\mathrm{M}-\mathrm{H}-\mathrm{M}$ and $\mathrm{M}-\mathrm{H}-\mathrm{B}$ bridged bonds

The $3 c-2 e$ hydrogen bridged bonds of type $\mathrm{M}-\mathrm{H}-\mathrm{M}$ and $\mathrm{M}-\mathrm{H}-\mathrm{B}$ can be formed with main-group metals (such as $\mathrm{Be}, \mathrm{Mg}$ and Al ) and transition metals (such as $\mathrm{Cr}, \mathrm{W}, \mathrm{Fe}, \mathrm{Ta}$, and Zr ). Some examples are shown in Fig. 11.1.1.
(a)

(c)

(c) Triply bridged $\left(\mu_{3}-\mathrm{H}\right) \mathrm{M}_{3}$ bond

In this bond type, a H atom is covalently bonded simultaneously to three metal atoms, as shown in Fig. 11.1.1(d).
(6) Hydride coordinate bond

The hydride ion $\mathrm{H}^{-}$as a ligand can donate a pair of electrons to a metal to form a metal hydride. The crystal structures of many metal hydride complexes, such as $\mathrm{Mg}_{2} \mathrm{NiH}_{4}, \mathrm{Mg}_{2} \mathrm{FeH}_{6}$, and $\mathrm{K}_{2} \mathrm{ReH}_{9}$, have been determined. In these compounds, the $\mathrm{M}-\mathrm{H}$ bonds are covalent $\sigma$ coordinate bonds.

## (7) Molecular hydrogen coordinate bond

Molecular hydrogen can coordinate to a transition metal as an intact ligand. The bonding of the $\mathrm{H}_{2}$ molecule to the transition metal atom appears to involve the transfer of $\sigma$ bonding electrons of $\mathrm{H}_{2}$ to a vacant metal d orbital, coupled with synergistic back donation of metal delectrons to the vacant $\sigma^{*}$ antibonding orbital of the $\mathrm{H}_{2}$ molecule. This type of coordinate bond formation weakens the $\mathrm{H}-\mathrm{H}$ covalent bond of the $\mathrm{H}_{2}$ ligand and, in the limit, leads to its cleavage to two H atoms.

## (8) Agostic bond

The existence of the agostic bond $\mathrm{C}-\mathrm{H} \rightharpoonup \mathrm{M}$ has been firmly established by X-ray and neutron diffraction methods. The symbolic representation $\mathrm{C}-\mathrm{H} \rightharpoonup \mathrm{M}$ indicates formal donor interaction of a $\mathrm{C}-\mathrm{H}$ bond with an electron-deficient metal atom M . As in all $3 c-2 e$ bridging systems involving only three valence orbitals, the bonded $\mathrm{C}-\mathrm{H} \longrightarrow \mathrm{M}$ fragment is bent. The agostic bond will be further discussed in Section 11.5.3.

### 11.2 Hydrogen bond

### 11.2.1 Nature and geometry of the hydrogen bond

In a typical hydrogen bonding system, $\mathrm{X}-\mathrm{H} \cdots \mathrm{Y}$, the electron cloud is greatly distorted toward the highly electronegative X atom, so that the thinly shielded, positively charged hydrogen nucleus becomes strongly attracted by the electronegative atom Y. The double- and triple-bonded carbon atoms, which have high electronegativity, can also form hydrogen bonds. Some examples are given below:

The geometry of the hydrogen bond can be described by the parameters $R, r_{1}, r_{2}$, and $\theta$, as shown in Fig. 11.2.1. Numerous experimental studies have established the following generalizations about the geometry of hydrogen bonds:
(a) Most hydrogen bonds $\mathrm{X}-\mathrm{H} \cdots \mathrm{Y}$ are unsymmetric; that is, the hydrogen atom is much closer to X than to Y . A typical example of hydrogen bonding is the interaction between $\mathrm{H}_{2} \mathrm{O}$ molecules in ice- $\mathrm{I}_{\mathrm{h}}$. The data shown below are derived from a neutron diffraction study of deuterated ice- $\mathrm{I}_{\mathrm{h}}$ at 100 K .

(b) Hydrogen bonds $\mathrm{X}-\mathrm{H} \cdots$ Y may be linear or bent, though the linear form is energetically more favorable. However, in the crystalline state the packing of molecules is the deciding factor.
(c) The distance between atoms X and Y is taken as the bond length of the hydrogen bond $\mathrm{X}-\mathrm{H} \cdots \mathrm{Y}$. Similar to all other chemical bonds, the shorter the bond length, the stronger the hydrogen bond. As the bond length $\mathrm{X} \cdots \mathrm{Y}$ shortens, the $\mathrm{X}-\mathrm{H}$ distance is lengthened. In the limit there is a symmetrical hydrogen bond, in which the H atom lies at the mid-point of the $\mathrm{X} \cdots \mathrm{Y}$ line. This is the strongest type of hydrogen bond and occurs only for both X and Y equal to F or O (see Section 11.2.3).
(d) The experimental hydrogen bond length is in general much shorter than the sum of the $\mathrm{X}-\mathrm{H}$ covalent bond length and van der Waals radii of H and Y atoms. For example, the average $\mathrm{O}-\mathrm{H} \cdots \mathrm{O}$ hydrogen bond length is 270 pm , which is shorter than the sum ( 369 pm ) of the $\mathrm{O}-\mathrm{H}$ covalent bond length ( 109 pm ) and van der Waals contact distance of $\mathrm{H} \cdots \mathrm{O}$ ( 120 pm +140 pm ). Table 11.2.1 compares the experimental $\mathrm{X}-\mathrm{H} \cdots$ Y hydrogen

Fig. 11.2.1.
Geometry of the hydrogen bond.

Table 11.2.1. Experimental hydrogen bond lengths and calculated values

| Hydrogen bond | Experimental bond length (pm) | Calculated value $(\mathrm{pm})$ |
| :--- | :--- | :--- |
| F-H $\cdots \mathrm{F}$ | 240 | 360 |
| O-H $\cdots \mathrm{F}$ | 270 | 360 |
| O-H $\cdots \mathrm{O}$ | 270 | 369 |
| O-H $\cdots \mathrm{N}$ | 278 | 375 |
| O-H $\cdots \mathrm{Cl}$ | 310 | 405 |
| N-H $\cdots \mathrm{F}$ | 280 | 360 |
| N-H $\cdots \mathrm{O}$ | 290 | 370 |
| N-H $\cdots \mathrm{N}$ | 300 | 375 |
| N-H $\cdots \mathrm{Cl}$ | 320 | 410 |
| C-H $\cdots \mathrm{O}$ | 320 | 340 |

bond lengths and the calculated values by summing the $\mathrm{X}-\mathrm{H}$ covalent bond length and van der Waals radii of H and Y atoms.
(e) The valence angle $\alpha$ formed between the $\mathrm{H} \cdots \mathrm{Y}$ line and the $\mathrm{Y}-\mathrm{R}$ bond usually varies between $100^{\circ}$ and $140^{\circ}$ :

(f) Normally the H atom in a hydrogen bond is two-coordinate, but there are a fair number of examples of hydrogen bonds with three-coordinate and four-coordinate H atoms. From a survey of $1509 \mathrm{NH} \cdots \mathrm{O}=\mathrm{C}$ hydrogen bonds observed by X-ray and neutron diffraction in 889 organic crystal structures, 304 (about 20\%) are found to be three-coordinate and only six are four-coordinate:

Three-coordinate hydrogen bond

Four-coordinate hydrogen bond
(g) In most hydrogen bonds only one hydrogen atom is directed toward a lone pair of Y, but there are many excepts. For example, in crystalline ammonia each N lone pair accepts three hydrogen atoms, as shown in Fig. 11.2.2(a). The carbonyl O atom in the tetragonal phase of urea forms four acceptor hydrogen bonds. In the inclusion compound $\left[\left(\mathrm{C}_{2} \mathrm{H}_{5}\right)_{4} \mathrm{~N}^{+}\right]_{2} \cdot \mathrm{CO}_{3}^{2-}$. $7\left(\mathrm{NH}_{2}\right)_{2} \mathrm{CS}$, the carbonate ion proves to be the most prolific hydrogen-bond acceptor, being surrounded by twelve convergent NH donor groups from six thiourea molecules to form a hydrogen-bonded aggregate shaped like two concave three-leaved propellers sharing a common core, as illustrated in Fig. 11.2.2(b).

(b)

Fig. 11.2.2.
(a) Interaction between lone pair of $\mathrm{NH}_{3}$ molecule with three neighbors in crystalline ammonia. (b) Carbonate ion forming twelve acceptor hydrogen bonds with six thiourea molecules.

Organic compounds generally conform to the following generalized rules in regard to hydrogen bonding:
(a) All good proton donors and acceptors are utilized in hydrogen bonding.
(b) If intramolecular hydrogen bonds can form a six-membered ring, they will usually do so in preference to the formation of intermolecular hydrogen bonds.
(c) After the formation of intramolecular hydrogen bonds, the remaining set of best proton donors and acceptors tend to form intermolecular hydrogen bonds with one another.

### 11.2.2 The strength of hydrogen bonds

The strongest hydrogen bonds resemble covalent bonds, the weakest ones are like van der Waals interactions, and the majority have energies lying between these two extremes. The strength of a hydrogen bond corresponds to the enthalpy of dissociation of the reaction:

$$
\mathrm{X}-\mathrm{H} \cdots \mathrm{Y} \rightarrow \mathrm{X}-\mathrm{H}+\mathrm{Y} .
$$

Strong and weak hydrogen bonds obviously have very different properties. Table 11.2.2 lists the properties observed for different types of hydrogen bonds.

In ice- $\mathrm{I}_{\mathrm{h}}$, the $\mathrm{O}-\mathrm{H} \cdots \mathrm{O}$ bond energy is $25 \mathrm{~kJ} \mathrm{~mol}^{-1}$, which results from the following interactions:
(a) Electrostatic attraction: this effect reduces the distance between the atoms of $\mathrm{H} \cdots \mathrm{O}$.

$$
\mathrm{O}^{\delta-} \mathrm{H}^{\delta+} \ldots \mathrm{O}^{\delta-} .
$$

(b) Delocalization or covalent bonding: the valence orbitals of H and O atoms overlap with each other, so that the bonding effect involves all three atoms.
(c) Electron cloud repulsion: the sum of the van der Waals radii of hydrogen and oxygen is 260 pm , and in a hydrogen bond the $\mathrm{H} \cdots \mathrm{O}$ distance often approaches to within 180 pm . Thus the normal electron-electron repulsive forces will occur.

## Structural Chemistry of Selected Elements

Table 11.2.2. Properties of very strong, strong, and weak hydrogen bonds

| Property | Very strong | Strong | Weak |
| :---: | :---: | :---: | :---: |
| $\mathrm{X}-\mathrm{H} \cdots \mathrm{Y}$ interaction | mostly covalent | mostly electrostatic | electrostatic |
| Bond lengths | $\mathrm{X}-\mathrm{H} \simeq \mathrm{H}-\mathrm{Y}$ | X-H $<\mathrm{H} \cdots$. Y | X-H \ll H $\cdots$ Y |
| $\mathrm{H} \cdots \mathrm{Y}$ (pm) | 120-150 | 150-220 | 220-320 |
| $X \cdots \mathrm{Y}(\mathrm{pm})$ | 220-250 | 250-320 | 320-400 |
| Bond angles | $175^{\circ}-180^{\circ}$ | $130^{\circ}-180^{\circ}$ | $90^{\circ}-150^{\circ}$ |
| Bond energy ( $\mathrm{kJ} \mathrm{mol}^{-1}$ ) | $>50$ | 15-50 | $<15$ |
| Relative IR $v_{\mathrm{S}}$ vibration shift $\left(\mathrm{cm}^{-1}\right)^{*}$ | >25\% | $10 \sim 25 \%$ | <10\% |
| ${ }^{1} \mathrm{H}$ NMR chemical shift downfield (ppm) | $14 \sim 22$ | $<14$ | - |
| Examples | Acid salts, acids, proton sponges, HF complexes | Acids, alcohols, hydrates, phenols, biological molecules | Weak base, basic salts $\begin{aligned} & \mathrm{C}-\mathrm{H} \cdots \mathrm{O} / \mathrm{N} \\ & \mathrm{O} / \mathrm{N}-\mathrm{H} \cdots \pi \end{aligned}$ |

*Observed $v_{\mathrm{s}}$ relative to $v_{\mathrm{s}}$ for a non-hydrogen bonded $\mathrm{X}-\mathrm{H}$.
(d) Van der Waals forces: as in all intermolecular interactions these forces contribute to the bonding, but their combined effect is relatively small.

The results of a molecular orbital calculation of the energies involved in the $\mathrm{O}-\mathrm{H} \cdots \mathrm{O}$ system are tabulated in Table 11.2.3.

Table 11.2.3. The energy contributions in a $\mathrm{O}-\mathrm{H} \cdots \mathrm{O}$ hydrogen bond

| Type of energy contribution | Energy $\left(\mathrm{kJ} \mathrm{mol}^{-1}\right)$ |
| :--- | :---: |
| (a) Electrostatic | -33.4 |
| (b) Delocalization | -34.1 |
| (c) Repulsion | 41.2 |
| (d) van der Waals energy | -1.0 |
| Total energy | -27.3 |
| Experimental | -25.0 |

### 11.2.3 Symmetrical hydrogen bond

The strongest hydrogen bond occurs in symmetrical O-H-O and F-H-F systems. The linear $\mathrm{HF}_{2}^{-}$ion has the H atom located midway between the two F atoms:

This symmetrical hydrogen bond is highly covalent, which may be viewed as a $3 c-4 e$ system. If the molecular axis is taken along the $z$ direction, the 1 s orbital of the H atom overlaps with the two $2 \mathrm{p}_{z}$ orbitals of the F atoms ( A and
(a)

(b)

Fig. 11.2.3.
Bonding in $\mathrm{HF}_{2}^{-}$: (a) orbital overlap; (b) qualitative MO energy level diagram.
B), as shown in Fig. 11.2.3(a), to form three molecular orbitals:

$$
\begin{aligned}
\psi_{1}(\sigma) & =N_{1}\left[2 \mathrm{p}_{z}(\mathrm{~A})+2 \mathrm{p}_{z}(\mathrm{~B})+c 1 \mathrm{~s}\right] \\
\psi_{2}(n) & =N_{2}\left[2 \mathrm{p}_{z}(\mathrm{~A})-2 \mathrm{p}_{z}(\mathrm{~B})\right] \\
\psi_{3}\left(\sigma^{*}\right) & =N_{3}\left[2 \mathrm{p}_{z}(\mathrm{~A})+2 \mathrm{p}_{z}(\mathrm{~B})-c 1 \mathrm{~s}\right]
\end{aligned}
$$

where $c$ is a weighting coefficient and $N_{1}, N_{2}, N_{3}$ are normalization constants. The ordering of the molecular orbitals is shown qualitatively in Fig. 11.2.3(b). Since there are four valence electrons, the bonding $\left(\psi_{1}\right)$ and nonbonding $\left(\psi_{2}\right)$ molecular orbitals are both occupied to yield a $3 c-4 e$ bond. The bond order and force constant of each $\mathrm{F}-\mathrm{H}$ link in $\mathrm{HF}_{2}^{-}$can be compared with those in the HF molecule:

| Molecule | Bond order | $d(\mathrm{pm})$ | $k\left(\mathrm{~N} \mathrm{~m}^{-1}\right)$ |
| :--- | :--- | :---: | :--- |
| HF | 1 | 93 | 890 |
| $\mathrm{HF}_{2}^{-}$ | 0.5 | 113 | 230 |

In the $\left\{\left[\left(\mathrm{NH}_{2}\right)_{2} \mathrm{CO}\right]_{2} \mathrm{H}\right\}\left(\mathrm{SiF}_{6}\right)$ crystal, there are symmetrical hydrogen bonds of the type $\mathrm{O}-\mathrm{H}-\mathrm{O}$, with bond lengths 242.4 and 244.3 pm in two independent $\left\{\left[\left(\mathrm{NH}_{2}\right)_{2} \mathrm{CO}\right]_{2} \mathrm{H}\right\}^{+}$cations. Figure 11.2.4 shows the structure of the cation.

Fig. 11.2.4.

Fig. 11.2.5.
The hydrogen bond $\mathrm{W}-\mathrm{C} \equiv \mathrm{O} \cdots \mathrm{H}-\mathrm{O}$ in crystalline $\mathrm{W}(\mathrm{CO})_{3}\left(\mathrm{P}^{i} \mathrm{Pr}_{3}\right)_{2}\left(\mathrm{H}_{2} \mathrm{O}\right)$ (THF).

### 11.2.4 Hydrogen bonds in organometallic compounds

In transition metal carbonyls, the $\mathrm{M}-\mathrm{C}=\mathrm{O}$ group acts as a proton acceptor, which interacts with appropriate donor groups to form one or more $\mathrm{C}=\mathrm{O} \cdots \mathrm{H}-$ $\mathrm{X}(\mathrm{X}$ is O or N ) hydrogen bonds. The CO ligand can function in different $\mu_{1}, \mu_{2}$, and $\mu_{3}$ modes, corresponding to a formal $\mathrm{C}-\mathrm{O}$ bond order of 3,2 , and 1 , respectively. Examples of hydrogen bonding formed by metal carbonyl complexes are shown below:

$\mu_{2}$

$\mu_{3}$

When the M atom has a strong back-donation to the $\mathrm{CO} \pi^{*}$ orbital, the basic property of CO increases, and the $\mathrm{O} \cdots \mathrm{H}$ distance shortens. These results are consistent with the sequence of shortened distances from terminal $\mu^{1}$ to $\mu^{3}$ coordinated forms. In such hydrogen bonds, the bond angles of $\mathrm{C}-\mathrm{O} \cdots \mathrm{X}$ are all about $140^{\circ}$. Figure 11.2 .5 shows the hydrogen bond $\mathrm{W}-\mathrm{C} \equiv \mathrm{O} \cdots \mathrm{H}-\mathrm{O}$ in the crystal of $\mathrm{W}(\mathrm{CO})_{3}\left(\mathrm{P}^{i} \mathrm{Pr}_{3}\right)_{2}\left(\mathrm{H}_{2} \mathrm{O}\right)(\mathrm{THF})$, in which the $\mathrm{O} \cdots \mathrm{O}$ bond length is 279.2 pm . Note that the aqua ligand also forms a donor hydrogen with a THF molecule.

In organometallic compounds, the $\mu_{3}-\mathrm{CH}$ and $\mu_{2}-\mathrm{CH}_{2}$ ligands can act as proton donors to form hydrogen bonds, as shown below:

Since the acidity of $\mu_{3}-\mathrm{CH}$ is stronger than that of $\mu_{2}-\mathrm{CH}_{2}$, the length of a $\mu_{3}-\mathrm{CH}$ hydrogen bond is shorter than that of $\mu_{2}-\mathrm{CH}_{2}$.

Neutron diffraction studies have shown that the - CH ligand in the cluster $\left[\mathrm{Co}(\mathrm{CO})_{3}\right]_{3}\left(\mu_{3}-\mathrm{CH}\right)$ forms three hydrogen bonds, with $\mathrm{H} \cdots \mathrm{O}$ distances of 250,253 , and 262 pm . In the compound $\left[\mathrm{CpMn}(\mathrm{CO})_{2}\right]_{2}\left(\mu_{2}-\mathrm{CH}_{2}\right)$, the $\mu_{2}-\mathrm{CH}_{2}$ group forms hydrogen bonds with the O atoms of $\mathrm{Mn}-\mathrm{CO}$ groups, as shown in Fig. 11.2.6.

### 11.2.5 The universality and importance of hydrogen bonds

Hydrogen bonds exist in numerous compounds. The reasons for its universal appearance are as follows:
(a) The abundance of $H, O, N, C$ and halogen elements: Many compounds are composed of $\mathrm{H}, \mathrm{O}, \mathrm{N}, \mathrm{C}$, and halogens, such as water, HX, oxyacids, and organic compounds. These compounds generally contain functional group such as $-\mathrm{OH},-\mathrm{NH}_{2}$, and $>\mathrm{C}=\mathrm{O}$, which readily form hydrogen bonds.
(b) Geometrical requirement of hydrogen bonding: A hydrogen bond does not require rigorous conditions for its formation as in the case for covalent bonding. The bond lengths and group orientations allow for more flexibility and adaptability.
(c) Small bond energy: The hydrogen bond is intermediate in strength between the covalent bond and van der Waals interaction. The small bond energy of the hydrogen bond requires low activation energy in its formation and cleavage. Its relative weakness permits reversibility in reactions involving its formation and a greater subtlety of interaction than is possible with normal covalent bonds.
(d) Intermolecular and intramolecular bonding modes: Hydrogen bonds can form between molecules, within the same molecule, or in a combination of both varieties. In liquids, hydrogen bonds are continuously being broken and reformed at random. Figures 11.2.7 and 11.2.8, respectively, display some structures featuring intermolecular and intramolecular hydrogen bonds.

Hydrogen bonds are important because of the effects they produce:
(a) Hydrogen bonds, especially the intramolecular variety, dictate many chemical properties, influence the conformation of molecules, and often

Fig. 11.2.6.
$\mathrm{C}-\mathrm{H} \cdots \mathrm{O}$ hydrogen bonds between $\mu_{2}-\mathrm{CH}_{2}$ and $\mathrm{Mn}-\mathrm{CO}$ groups in $\left[\mathrm{CpMn}(\mathrm{CO})_{2}\right]_{2}\left(\mu_{2}-\mathrm{CH}_{2}\right)$.

Fig. 11.2.8.
Examples of intramolecular hydrogen bonds.

play a critical role in determining reaction rates. Hydrogen bonds are responsible for stabilization of the three-dimensional architecture of proteins and nucleic acids.
(b) Hydrogen bonds affect IR and Raman frequencies. The $v(\mathrm{X}-\mathrm{H})$ stretching frequency shifts to a lower energy (caused by weakening the $\mathrm{X}-\mathrm{H}$ bond) but increases in width and intensity. For $\mathrm{N}-\mathrm{H} \cdots \mathrm{F}$, the change of frequency is less than $1000 \mathrm{~cm}^{-1}$. For $\mathrm{O}-\mathrm{H} \cdots \mathrm{O}$ and $\mathrm{F}-\mathrm{H} \cdots \mathrm{F}$, the change of frequency is in the range $1500-2000 \mathrm{~cm}^{-1}$. The $v(\mathrm{X}-\mathrm{H})$ bending frequency shifts to higher wavenumbers.
(c) Intermolecular hydrogen bonding in a compound raises the boiling point and frequently the melting point.
(d) If hydrogen bonding is possible between solute and solvent, solubility is greatly increased and often results in infinite solubility. The complete miscibility of two liquids, for example water and ethanol, can be attributed to intermolecular hydrogen bonding.

### 11.3 Non-conventional hydrogen bonds

The conventional hydrogen bond $\mathrm{X}-\mathrm{H} \cdots \mathrm{Y}$ is formed by the proton donor $\mathrm{X}-\mathrm{H}$ with a proton acceptor Y , which is an atom with a lone pair ( X and Y are all highly electronegative atoms such as $\mathrm{F}, \mathrm{O}, \mathrm{N}$, and Cl ). Some non-conventional hydrogen bonds that do not conform to this condition are discussed below:

### 11.3.1 $\quad \mathrm{X}-\mathrm{H} \cdots \pi$ hydrogen bond

In a $\mathrm{X}-\mathrm{H} \cdots \pi$ hydrogen bond, $\pi$ bonding electrons interact with the proton to form a weakly bonded system. The phenyl ring and delocalized $\pi$ system as proton acceptors interact with $\mathrm{X}-\mathrm{H}$ to form $\mathrm{X}-\mathrm{H} \cdots \pi$ hydrogen bonds. The phenyl group is by far the most important among $\pi$-acceptors, and the X $\mathrm{H} \cdots \mathrm{Ph}$ hydrogen bond is termed an "aromatic hydrogen bond." The $\mathrm{N}-\mathrm{H}$ and phenyl groups together form aromatic hydrogen bonds which stabilize the conformation of polypeptide chains. Calculations show that the bond energy of a $\mathrm{N}-\mathrm{H} \cdots$ Ph bond is about $12 \mathrm{~kJ} \mathrm{~mol}{ }^{-1}$. Two major types of $\mathrm{N}-\mathrm{H} \cdots \mathrm{Ph}$ hydrogen bonds generally occur in the polypeptide chains of biomolecules:

Figures 11.3.1(a) and 11.3.1(b) show the structures and hydrogen bonding distances of 2-butyne $\cdot \mathrm{HCl}$ and 2-butyne $\cdot 2 \mathrm{HCl}$, respectively. In 2-butyne $\cdot \mathrm{HCl}$,

Fig. 11.3.1.
The $\mathrm{Cl}-\mathrm{H} \cdots \pi$ hydrogen bonds in (a) 2-butyne $\cdot \mathrm{HCl}$ and (b) 2-butyne $\cdot 2 \mathrm{HCl}$.

Fig. 11.3.2.
$\mathrm{Cl}-\mathrm{H} \cdots \pi$ hydrogen bonds in the crystal of toluene 2 HCl .
(a)

(b)

the distance from Cl to the center of the $\mathrm{C} \equiv \mathrm{C}$ bond is 340 pm . In 2-butyne 2 HCl , the distance from Cl to the center of the $\mathrm{C} \equiv \mathrm{C}$ bond is 347 pm .

The $\mathrm{Cl}-\mathrm{H} \cdots \pi$ hydrogen bond in the crystal structure of toluene $\cdot 2 \mathrm{HCl}$ has been characterized. In this case the $\pi$ bonding electrons of the aromatic ring of toluene serve as the proton acceptor. The distance of the H atom to the ring center is 232 pm, as shown in Fig. 11.3.2.

In addition to $\mathrm{N}-\mathrm{H} \cdots \pi$ and $\mathrm{Cl}-\mathrm{H} \cdots \pi$ hydrogen bonds, there are also $\mathrm{O}-\mathrm{H} \cdots \pi$ and $\mathrm{C}-\mathrm{H} \cdots \pi$ hydrogen bonds in many compounds. Two examples are shown in Figs. 11.3.3(a) and (b). A neutron diffraction study of the crystal structure of 2-acetylenyl-2-hydroxyl adamatane [Fig. 11.3.3(c)] has shown that intermolecular $\mathrm{O}-\mathrm{H} \cdots \mathrm{O}$ and $\mathrm{C}-\mathrm{H} \cdots \mathrm{O}$ hydrogen bonds co-exist [Fig. 11.3.3(d)] with the $\mathrm{O}-\mathrm{H} \cdots \pi$ hydrogen bonds [Fig. 11.3.3(e)].

### 11.3.2 Transition metal hydrogen bond $\mathrm{X}-\mathrm{H} \cdots \mathrm{M}$

The $\mathrm{X}-\mathrm{H} \cdots \mathrm{M}$ hydrogen bond is analogous to a conventional hydrogen bond and involves an electron-rich transition metal M as the proton acceptor in a $3 c-4 e$ interaction. Several criteria that serve to characterize a $3 c-4 e \mathrm{X}-\mathrm{H} \cdots \mathrm{M}$ hydrogen bond are as follows:
(a) The bridging hydrogen is covalently bonded to a highly electronegative atom X and is protonic in nature, enhancing the electrostatic component of the interaction.
(b) The metal atom involved is electron-rich, i.e., typically a late transition metal, with filled d-orbitals that can facilitate the $3 c-4 e$ interaction involving the H atom.
(c) The ${ }^{1} \mathrm{H}$ NMR chemical shift of the bridging H atom is downfield of TMS and shifted downfield relative to the free ligand.
(d) Intermolecular $\mathrm{X}-\mathrm{H} \cdots \mathrm{M}$ interactions have an approximately linear geometry.
(e) Electronically saturated metal complexes (e.g., with 18-electron metal centers) can form such interactions.

Two compounds with $3 c-4 e \mathrm{X}-\mathrm{H} \cdots \mathrm{M}$ hydrogen bonds are shown in Fig. 11.3.4. The dianion $\left\{\left(\mathrm{PtCl}_{4}\right) \cdot \text { cis- }\left[\mathrm{PtCl}_{2}\left(\mathrm{NH}_{2} \mathrm{Me}\right)_{2}\right]\right\}^{2-}$ consists of two square-planar $\mathrm{d}^{8}-\mathrm{Pt}$ centers held together by short intermolecular $\mathrm{N}-\mathrm{H} \cdots \mathrm{Pt}$ and $\mathrm{N}-\mathrm{H} \cdots \mathrm{Cl}$ hydrogen bonds: $\mathrm{H} \cdots$ Pt $226.2 \mathrm{pm}, \mathrm{H} \cdots \mathrm{Cl} 231.8 \mathrm{pm}$. The $\mathrm{N}-\mathrm{H} \cdots \mathrm{Pt}$ bond angle is $167.1^{\circ}$. The presence of the filled $\mathrm{Pt} \mathrm{d}_{z^{2}}$ orbital oriented towards

$\mathrm{C}_{10} \mathrm{H}_{5} \mathrm{NHMe}_{2}$ ).

### 11.3.3 Dihydrogen bond $\mathrm{X}-\mathrm{H} \cdots \mathrm{H}-\mathrm{E}$

Conventional hydrogen bonds are formed between a proton donor, such as an $\mathrm{O}-\mathrm{H}$ or $\mathrm{N}-\mathrm{H}$ group and a proton acceptor, such as oxygen or nitrogen lone pair. In all such cases a nonbonding electron pair acts as the weak base component.

A wide variety of $\mathrm{E}-\mathrm{H} \sigma$ bonds ( $\mathrm{E}=$ boron or transition metal) act unexpectedly as efficient hydrogen bond acceptors toward conventional proton donors, such as $\mathrm{O}-\mathrm{H}$ and $\mathrm{N}-\mathrm{H}$ groups. The resulting $\mathrm{X}-\mathrm{H} \cdots \mathrm{H}-\mathrm{E}$ systems have close $\mathrm{H} \cdots \mathrm{H}$ contacts ( $175-190 \mathrm{pm}$ ) and are termed "dihydrogen bonds."
(a)

(b)

(c)

Their enthalpies of formation are substantial, $13-30 \mathrm{~kJ} \mathrm{~mol}^{-1}$, and lie in the range for conventional H bonds. Some examples are listed below.
(1) $\mathrm{N}-\mathrm{H} \cdots \mathrm{H}-\mathrm{B}$ bond

A comparison of the melting points of the isoelectronic species $\mathrm{H}_{3} \mathrm{C}-\mathrm{CH}_{3}$ $\left(-181^{\circ} \mathrm{C}\right), \mathrm{H}_{3} \mathrm{C}-\mathrm{F}\left(-141^{\circ} \mathrm{C}\right)$ and $\mathrm{H}_{3} \mathrm{~N}-\mathrm{BH}_{3}\left(104^{\circ} \mathrm{C}\right)$ suggests the possibility that unusually strong intermolecular interactions are present in $\mathrm{H}_{3} \mathrm{~N}-\mathrm{BH}_{3}$. As compared to the $\mathrm{H}_{3} \mathrm{C}-\mathrm{F}$ molecule, the less polar $\mathrm{H}_{3} \mathrm{~N}-\mathrm{BH}_{3}$ molecule has a smaller dipole-dipole interaction, and both slack a lone pair to form a conventional hydrogen bond. The abnormally high melting point of $\mathrm{H}_{3} \mathrm{~N}-\mathrm{BH}_{3}$ originates from the presence of $\mathrm{N}-\mathrm{H} \cdots \mathrm{H}-\mathrm{B}$ bonding in the crystalline state.

Many close intermolecular N-H $\cdots \mathrm{H}-\mathrm{B}$ contacts in the range $170-220 \mathrm{pm}$ have been found in various crystal structures. In these dihydrogen bonds, the $(\mathrm{NH}) \cdots \mathrm{H}-\mathrm{B}$ angle is strongly bent, falling in the range $95-120^{\circ}$. Figure 11.3.5(a) shows the (NH) $\cdots \mathrm{H}-\mathrm{B}$ bond between $\mathrm{H}_{3} \mathrm{~N}-\mathrm{BH}_{3}$ molecules.

## (2) $\mathrm{X}-\mathrm{H} \cdots \mathrm{H}-\mathrm{M}$ bonds

X-Ray and neutron diffraction studies have established the presence of transition metal $\mathrm{N}-\mathrm{H} \cdots \mathrm{H}-\mathrm{M}$ and $\mathrm{O}-\mathrm{H} \cdots \mathrm{H}-\mathrm{M}$ dihydrogen bonds, in which the hydride ligand acts as a proton acceptor. Figure 11.3.5(b) shows the dihydrogen bond $\mathrm{N}-\mathrm{H} \cdots \mathrm{H}-\mathrm{Re}$ in the crystal structure of $\mathrm{ReH}_{5}\left(\mathrm{PPh}_{3}\right)_{3} \cdot$ indole $\cdot \mathrm{C}_{6} \mathrm{H}_{6}$. The $\mathrm{H} \cdots \mathrm{H}$ distances are 173.4 and 221.2 pm . Figure 11.3.5(c) shows a similar dihydrogen bond with measured $\mathrm{H} \cdots \mathrm{H}$ distances of 168 and 199 pm in the crystal structure of $\mathrm{ReH}_{5}\left(\mathrm{PPh}_{3}\right)_{2}$ (imidazole).

In the crystal structure of $\left[\mathrm{K}\left(1,10\right.\right.$-diaza-18-crown-6)][IrH $\left.4\left(\mathrm{P}^{i} \mathrm{Pr}_{3}\right)_{2}\right]$, the two kinds of ions form an infinite chain held together by $\mathrm{N}-\mathrm{H} \cdots \mathrm{H}-$ Ir bonds, as shown schematically in Fig. 11.3.6. The observed distance of $\mathrm{H} \cdots \mathrm{H}$ is 207 pm , and the observed $\mathrm{N}-\mathrm{H}$ bond length of 77 pm is likely to be less than the true value. The corrected $\mathrm{N}-\mathrm{H}$ and $\mathrm{H} \cdots \mathrm{H}$ distances are 100 and 185 pm , respectively.

Fig. 11.3.6.
Chain structure of $\left[\mathrm{K}\left(1,10\right.\right.$-diaza-18-crown-6)] $\left[\mathrm{IrH}_{4}\left(\mathrm{P}^{i} \mathrm{Pr}_{3}\right)_{2}\right]$ and relevant dihydrogen bond lengths in $\mathrm{pm} . \mathrm{P}^{i} \mathrm{Pr}_{3} \mathrm{C}$ and H atoms and non-essential crown H atoms have been omitted for clarity.

The $\mathrm{X}-\mathrm{H} \cdots \mathrm{H}-\mathrm{M}$ systems generally tend to lose $\mathrm{H}_{2}$ readily, and indeed such $\mathrm{H} \cdots \mathrm{H}$ bonded intermediates may be involved whenever a hydride undergoes protonation.

### 11.3.4 Inverse hydrogen bond

In the normal hydrogen bond $\mathrm{X}-\mathrm{H} \cdots \mathrm{Y}$, the H atom plays the role of electron acceptor, while the Y atom is the electron donor. The interaction is of the kind

$$
x-H^{\cdots} \stackrel{e}{Y}
$$

In the inverse hydrogen bond, the H atom plays the role of electron donor, while the Y atom becomes the electron acceptor, and the interaction is of the kind

Some examples of inverse hydrogen bonds are presented below:
(1) The so-called "lithium hydrogen bond," $\mathrm{Li}-\mathrm{H} \cdots \mathrm{Li}-\mathrm{H}$, occurs in the hypothetical linear $(\mathrm{LiH})_{2}$ dimer. The inner Li atom is electron-deficient, and the inner H atom is sufficiently electron-rich to act as a donor in the formation of an inverse hydrogen bond. The calculated bond lengths (in pm) and electron donor-acceptor relationship are illustrated below:

The distance $\mathrm{H} \cdots \mathrm{Li}$ is shorter than the sum of the atomic van der Waals radii of H and Li , and the linkage of $\mathrm{Li}-\mathrm{H} \cdots \mathrm{Li}$ is almost linear.

Fig. 11.3.7.
Structure of the adduct $\mathrm{Nb}_{2}(\mathrm{hpp})_{4} \cdot 2 \mathrm{NaEt}_{3} \mathrm{BH}$.

(2) The dihydrogen bond $\mathrm{X}-\mathrm{H} \cdots \mathrm{H}-\mathrm{M}$ may be formally regarded as a normal hydrogen bond

$$
x-H^{\stackrel{e}{Y}}
$$

where Y stands for the hydridic H atom as the electron donor, or an inverse hydrogen bond

$$
M-\overbrace{\mathrm{H}^{\cdots} \cdot{ }^{\mathrm{e}} \mathrm{Y} .}
$$

where Y is the H atom bonded to X .
(3) The inverse hydrogen bond $\mathrm{B}^{-}-\mathrm{H} \cdots \mathrm{Na}^{+}$is found in the adduct of $\mathrm{Na}\left(\mathrm{Et}_{3} \mathrm{BH}\right)$ and $\mathrm{Nb}_{2}(\mathrm{hpp})_{4}$, where hpp is the anion of $1,3,4,6,7,8-$ hexahydro-2H-pyrimido-[1,2-a]-pyrimidine (Hhpp). Figure 11.3 .7 shows the $\mathrm{B}^{-}-\mathrm{H} \cdots \mathrm{Na}^{+}$interaction in the compound $\mathrm{Nb}_{2}(\mathrm{hpp})_{4} \cdot 2 \mathrm{NaEt}_{3} \mathrm{BH}$.

The concept of inverse hydrogen bond is a relatively recent development, and additional varieties of this novel type of interaction may be uncovered in the future.

### 11.4 Hydride complexes

Hydrogen combines with many metals to form binary hydrides $\mathrm{MH}_{x}$. The hydride ion $\mathrm{H}^{-}$has two electrons with the noble gas configuration of He. Binary metal hydrides have the following characteristics:
(1) Most of these hydrides are non-stoichiometric, and their composition and properties depend on the purity of the metals used in the preparation.
(2) Many of the hydride phases exhibit metallic properties such as high electrical conductivity and metallic luster.
(3) They are usually produced by the reaction of metal with hydrogen. Besides the formation of true hydride phases, hydrogen also dissolves in the metal to give a solid solution.

Metal hydrides may be divided into two types: covalent and interstitial. They are discussed in the following two sections.

### 11.4.1 Covalent metal hydride complexes

In recent years, many crystal structures of transition metal hydride complexes have been determined. In compounds such as $\mathrm{CaMgNiH}_{4}, \mathrm{Mg}_{2} \mathrm{NiH}_{4}$, $\mathrm{Mg}_{2} \mathrm{FeH}_{6}$, and $\mathrm{K}_{2} \mathrm{ReH}_{9}, \mathrm{H}^{-}$behaves as an electron-pair donor covalently bonded to the transition metals. The transition metal in the $\mathrm{NiH}_{4}^{2-}, \mathrm{FeH}_{6}^{4-}$, and $\mathrm{ReH}_{9}^{2-}$ anions generally has the favored noble gas electronic configuration with 18 valence electrons. Figure 11.4.1 shows the crystal structure of $\mathrm{CaMgNiH}_{4}$.

The anion $\mathrm{ReH}_{9}^{2-}$ is a rare example of a central metal atom forming nine $2 c$ $2 e$ bonds, which are directed toward the vertices of a tricapped trigonal prism. Figure 11.4.2 shows the structure of $\mathrm{ReH}_{9}{ }^{2-}$, and Table 11.4.1 lists the structures of a number of transition metal hydride complexes. In these complex anions, the distances of transition metal to hydrogen are in the range $150-160 \mathrm{pm}$ for 3d metals and $170-180 \mathrm{pm}$ for 4 d and 5d metals, except for $\mathrm{Pd}(160-170 \mathrm{pm})$ and Pt ( $158-167 \mathrm{pm}$ ).

Low-temperature neutron diffraction analysis of $\mathrm{H}_{4} \mathrm{Co}_{4}\left(\mathrm{C}_{5} \mathrm{Me}_{4} \mathrm{Et}\right)_{4}$ shows that the molecule consists of four face-bridging hydrides attached to a

$$

*The bond lengths are determined by neutron diffraction for M-D.
tetrahedral cobalt metal core, as shown in Fig. 11.4.3. The average distances (in pm ) and angles in the core of the molecule are as follows:

| Co-Co | 257.1 | Co-H | 174.9 |
| :--- | :--- | :--- | :--- |
| H $\cdots$ H | 236.6 | Co-H-Co | $94.6^{\circ}$ | | H-Co-H | $85.1^{\circ}$ |
| :---: | :---: |

The hydride ligands are located off the $\mathrm{Co}-\mathrm{Co}-\mathrm{Co}$ planes by an average distance of 92.3 pm .

Polynuclear platinum and palladium carbonyl clusters containing the bulky tri-tert-butylphosphine ligand are inherently electron-deficient at the metal centers. The trigonal bipyramidal cluster $\left[\mathrm{Pt}_{3} \mathrm{Re}_{2}(\mathrm{CO})_{6}\left(\mathrm{P}^{t} \mathrm{Bu}_{3}\right)_{3}\right]$, as shown in Fig. 11.4.4(a), is electronically unsaturated with a deficit of 10 valence electrons, as it needs 72 valence electrons to satisfy an 18 -electron configuration at

Fig. 11.4.3.
Molecular structure of $\mathrm{H}_{4} \mathrm{Co}_{4}\left(\mathrm{C}_{5} \mathrm{Me}_{4} \mathrm{Et}\right)_{4}$ by neutron diffraction analysis at 20 K .
each metal vertex. The cluster reacts with 3 equivalents of molecular hydrogen at room temperature to give the addition product $\left[\mathrm{Pt}_{3} \mathrm{Re}_{2}(\mathrm{CO})_{6}\left(\mathrm{P}^{t} \mathrm{Bu}_{3}\right)_{3}(\mu-\mathrm{H})_{6}\right]$ in $90 \%$ yield. Single-crystal X-ray analysis showed that the hexahydrido complex has a similar trigonal bipyramidal structure with one hydrido ligand bridging each of the six Pt-Re edges of the cluster core, as illustrated in Fig. 11.4.4(b). The $\mathrm{Pt}-\mathrm{Pt}$ bond lengths are almost the same in both complexes (average values 272.25 pm versus 271.27 pm ), but the $\mathrm{Pt}-\mathrm{Re}$ bonds are much lengthened in the hexahydrido complex (average values 264.83 pm versus 290.92 pm ). The $\mathrm{Pt}-\mathrm{H}$ bonds are significantly shorter than the $\mathrm{Re}-\mathrm{H}$ bonds (average values 160 pm versus 189 pm ).

### 11.4.2 Interstitial and high-coordinate hydride complexes

Most interstitial metal hydrides have variable composition, for example, $\mathrm{PdH}_{x}$ with $x<1$. The hydrogen atoms are assumed to have lost their electrons to the d

Table 11.4.2. Some hydrogen storage systems

| Storage medium | Hydrogen percent by weight | Hydrogen density $\left(\mathrm{kg} \mathrm{dm}^{-1}\right)$ |
| :--- | :--- | :--- |
| $\mathrm{MgH}_{2}$ | 7.6 | 0.101 |
| $\mathrm{Mg}_{2} \mathrm{NiH}_{4}$ | 3.16 | 0.081 |
| $\mathrm{VH}_{2}$ | 2.07 | 0.095 |
| $\mathrm{FeTiH}_{1.95}$ | 1.75 | 0.096 |
| $\mathrm{LaNi}_{5} \mathrm{H}_{6}$ | 1.37 | 0.089 |
| $\mathrm{Liquid} \mathrm{H}_{2}$ | 100 | 0.070 |
| Gaseous H$(10 \mathrm{MPa})$ | 100 | 0.008 |

orbitals of the metal atoms and behave as mobile protons. This model accounts for the mobility of hydrogen in $\mathrm{PdH}_{x}$, the fact that the magnetic susceptibility of palladium falls as hydrogen is added, and that if an electric potential is applied across a filament of $\mathrm{PdH}_{x}$, hydrogen migrates toward the negative electrode.

A striking property of many interstitial metal hydrides is the high rate of hydrogen diffusion through the solid at slightly elevated temperatures. This mobility is utilized in the ultra-purification of $\mathrm{H}_{2}$ by diffusion through a palladium-silver alloy tube.

Hydrogen has the potential to be an important fuel because it has an extremely high energy density per unit weight. It is also a non-polluting fuel, the main combustion product being water. The metallic hydrides, which decompose reversibly to give hydrogen gas and the metals, can be used for hydrogen storage. Table 11.4.2 lists the capacities of some hydrogen storage systems. It is possible to store more hydrogen in the form of these hydrides than in the same volume of liquid hydrogen.

The crystal structure of $\mathrm{MgH}_{2}$ has been determined by neutron diffraction. It has the rutile structure, space group $P 4_{2} / \mathrm{mnm}$, with $a=450.25 \mathrm{pm}, c=$ 301.23 pm , as shown in Fig. 11.4.5. The $\mathrm{Mg}^{2+}$ ion is surrounded octahedrally by six $\mathrm{H}^{-}$anions at 194.8 pm . Taking the radius of $\mathrm{Mg}^{2+}$ as 72 pm (sixcoordinate, Table 4.2.2), the radius of $\mathrm{H}^{-}$(three-coordinate) is calculated to be 123 pm .

Figure 11.4.6 shows the pressure $(P)$ versus composition $(x)$ isotherms for the hydrogen-iron-titanium system. This system is an example of the formation of a ternary hydride from an intermetallic compound.

In the majority of its metal complexes, the hydride ligand normally functions in the $\mu^{1}$ (terminal), $\mu^{2}$ (edge-bridging), and $\mu^{3}$ (triangular face-capping) modes. Research efforts in recent years have led to the syntheses of an increasing number of high-coordinate ( $\mu^{4}, \mu^{5}$, and $\mu^{6}$ ) hydride complexes.

The compounds $\left[\mathrm{Li}_{8}(\mathrm{H})\{\mathrm{N}(2-\mathrm{Py}) \mathrm{Ph}\}_{6}\right]^{+}\left[\mathrm{Li}_{\left.\left(\mathrm{Me}_{2} \mathrm{Al}^{t} \mathrm{Bu}_{2}\right)_{2}\right]^{-} \text {and } \mathrm{Li}_{7}(\mathrm{H})[\mathrm{N}(2-}\right.$ Py) Ph$]_{6}$ are examples of molecular species that contain a $\mu^{6}$-hydride ligand surrounded by an assembly of main-group metal ions. The cation $\left[\mathrm{Li}_{8}(\mathrm{H})\{\mathrm{N}(2-\right.$ Py) Ph$\left.\}_{6}\right]^{+}$encapsulates a $\mathrm{H}^{-}$ion within an octahedron composed of Li atoms, the average $\mathrm{Li}-\mathrm{H}$ distance being 201.5 pm , as shown in Fig. 11.4.7(a). In molecular $\mathrm{Li}_{7}(\mathrm{H})[\mathrm{N}(2-\mathrm{Py}) \mathrm{Ph}]_{6}$, the $\mathrm{H}^{-}$ion is enclosed in a distorted octahedral coordination shell, as shown in Fig. 11.4.7(b). The average Li-H distance is 206 pm . The seventh Li atom is located at a much longer $\mathrm{Li} \cdots \mathrm{H}$ distance of 249 pm .

Fig. 11.4.6.
$P-x$ isotherms for the $\mathrm{FeTiH}_{x}$ alloy. The upper curve corresponds to the equilibrium pressure as hydrogen is added stepwise to the alloy; the lower curve corresponds to the equilibrium pressure as hydrogen is removed stepwise from the hydride.

Neutron diffraction analysis of the hydrido cluster complex $\left[\mathrm{H}_{2} \mathrm{Rh}_{13}(\mathrm{CO})_{24}\right]^{3-}$ at low temperature has revealed a hexagonal close-packed metal skeleton in which each surface Rh atom is coordinated by one terminal and two bridging carbonyls. The two hydride ligands occupy two of the six square-pyramidal sites on the surface, each being slightly displaced from the plane of four basal Rh atoms toward the central Rh atom of the $\mathrm{Rh}_{13}$ cluster core (Fig. 11.4.8(a)). For either $\mu^{5}$-hydride, the axial Rh (central)-H distance is shorter (average 184 pm ) than the four Rh (surface)- H distances (average 197 pm ).

Fig. 11.4.7.
Structure of main-group metal hydride complexes: (a) $\left[\mathrm{Li}_{8}(\mathrm{H})\{\mathrm{N}(2-\mathrm{Py}) \mathrm{Ph}\}_{6}\right]^{+}$, (b) $\mathrm{Li}_{7}(\mathrm{H})[\mathrm{N}(2-\mathrm{Py}) \mathrm{Ph}]_{6}$; the broken line indicates a weak interaction.

DFT calculations, as well as X-ray and neutron diffraction studies, have established the first existence of a four-coordinate interstitial hydride ligand. In the isomorphous tetranuclear lanthanide polyhydride complexes $\left[\mathrm{C}_{5} \mathrm{Me}_{4}\left(\mathrm{SiMe}_{3}\right)\right]_{4} \mathrm{Ln}_{4} \mathrm{H}_{8}(\mathrm{Ln}=\mathrm{Lu}, \mathrm{Y})$, the tetrahedral $\mathrm{Ln}_{4} \mathrm{H}_{8}$ cluster core adopts a pseudo $C_{3 \mathrm{v}}$ configuration with a body-centered $\mu^{4}$, one face-capping $\mu^{3}$, and six edge-bridging $\mu^{2}$ hydride ligands. The molecular structure of the yttrium(III) complex is shown in Fig. 11.4.8(b).

### 11.5 Molecular hydrogen $\left(\mathrm{H}_{2}\right)$ coordination compounds and $\sigma$-bond complexes

### 11.5.1 Structure and bonding of $\mathrm{H}_{2}$ coordination compounds

The activation of hydrogen by a metal center is one of the most important chemical reactions. The $\mathrm{H}-\mathrm{H}$ bond is strong ( $436 \mathrm{~kJ} \mathrm{~mol}^{-1}$ ), so that $\mathrm{H}_{2}$ addition to unsaturated organic and other compounds must be mediated by metal centers whose roles constitute the basis of catalytic hydrogenation. In catalytic mechanisms, hydride complexes formed by the cleavage of $\mathrm{H}_{2}$ are regarded as key intermediates.

The first isolable transition metal complex containing a coordinated $\mathrm{H}_{2}$ molecule is $\mathrm{W}(\mathrm{CO})_{3}\left[\mathrm{P}\left(\mathrm{CHMe}_{2}\right)_{3}\right]_{2}\left(\mathrm{H}_{2}\right)$. X-ray and neutron diffraction studies and a variety of spectroscopic methods have confirmed that it possesses a $\eta^{2}-\mathrm{H}_{2}$ ligand, as shown in Fig. 11.5.1.

The resulting geometry about the W atom is that of a regular octahedron. The $\mathrm{H}_{2}$ molecule is symmetrically coordinated in an $\eta^{2}$ mode with an average W-H distance of 185 pm (X-ray) and 175 pm (neutron) at $-100^{\circ} \mathrm{C}$. The $\mathrm{H}-\mathrm{H}$ distance is 75 pm (X-ray) and 82 pm (neutron), slightly longer than that of the free $\mathrm{H}_{2}$ molecule ( 74 pm ).

The side-on bonding of $\mathrm{H}_{2}$ to the metal involves the transfer of $\sigma$ bonding electrons of $\mathrm{H}_{2}$ to a vacant metal d orbital (or hybrid orbital), together with the transfer of electrons from a filled metal d orbital into the empty $\sigma^{*}$ orbital of $\mathrm{H}_{2}$, as shown in Fig. 11.5.2. This synergistic (mutually assisting) bonding mode is similar to that of CO and ethylene with metal atoms. The $\pi$ back donation from

metal to $\sigma^{*}$ orbital on $\mathrm{H}_{2}$ is consistent with the fact that $\mathrm{H}-\mathrm{H}$ bond cleavage is facilitated by electron-rich metals.

Table 11.5.1. $\mathrm{H} \cdots \mathrm{H}$ bond distances $\left(\mathrm{d}_{\mathrm{HH}}\right)$ determined by neutron diffraction for $\mathrm{H}_{2}$ coordination compounds

| $\mathrm{H}_{2}$ Coordination compound | $\mathrm{d}_{\mathrm{HH}}^{*}(\mathrm{pm})$ |
| :---: | :---: |
| $\mathrm{Mo}(\mathrm{Co})(\mathrm{dppe})_{2}\left(\mathrm{H}_{2}\right)$ | 73.6 (84) |
| $\left[\mathrm{FeH}\left(\mathrm{H}_{2}\right)(\text { dppe })_{2}\right]^{+}$ | 81.6 |
| $\mathrm{W}(\mathrm{CO})_{3}\left(\mathrm{P}^{i} \mathrm{Pr}_{3}\right)_{2}\left(\mathrm{H}_{2}\right)$ | 82 |
| $\left[\mathrm{RuH}\left(\mathrm{H}_{2}\right)(\mathrm{dppe})_{2}\right]^{+}$ | 82 (94) |
| $\mathrm{FeH}_{2}\left(\mathrm{H}_{2}\right)\left(\mathrm{PEtPh}_{2}\right)_{3}$ | 82.1 |
| $\left[\mathrm{OsH}\left(\mathrm{H}_{2}\right)(\mathrm{dppe})_{2}\right]^{+}$ | 97 |
| $\left[\mathrm{Cp}^{*} \mathrm{OsH}_{2}\left(\mathrm{H}_{2}\right)\left(\mathrm{PPh}_{3}\right)\right]^{+}$ | 101 |
| $\left[\mathrm{Cp}^{*} \mathrm{OsH}_{2}\left(\mathrm{H}_{2}\right)\left(\mathrm{AsPh}_{3}\right)\right]^{+}$ | 108 |
| $\left[\mathrm{Cp}^{*} \mathrm{Ru}(\mathrm{dppm})\left(\mathrm{H}_{2}\right)\right]^{+}$ | 108 (110) |
| cis- $\left.\mathrm{IrCl}_{2} \mathrm{H}\left(\mathrm{H}_{2}\right)\left(\mathrm{P}^{i} \mathrm{Pr}_{3}\right)_{2}\right]$ | 111 |
| trans-[ $\left.\mathrm{OsCl}\left(\mathrm{H}_{2}\right)(\mathrm{dppe})_{2}\right]^{+}$ | 122 |
| $\left[\mathrm{Cp}^{*} \mathrm{OsH}_{2}\left(\mathrm{H}_{2}\right)\left(\mathrm{PCy}_{3}\right)\right]^{+}$ | 131 |
| $\left[\mathrm{Os}(\mathrm{en})_{2}\left(\mathrm{H}_{2}\right)(\text { acetate })\right]^{+}$ | 134 |
| $\mathrm{ReH}_{5}\left(\mathrm{H}_{2}\right)\left(\mathrm{P}(p \text {-tolyl })_{3}\right]_{2}$ | 135.7 |
| $\left[\mathrm{OsH}_{3}\left(\mathrm{H}_{2}\right)\left(\mathrm{PPhMe}_{2}\right)_{3}\right]^{+}$ | 149 |

* Uncorrected for effects of vibrational motion; the corrected values are given in parentheses.

The structure of trans- $\left[\mathrm{Fe}\left(\eta^{2}-\mathrm{H}_{2}\right)(\mathrm{H})\left(\mathrm{PPh}_{2} \mathrm{CH}_{2} \mathrm{CH}_{2} \mathrm{PPh}_{2}\right)\right] \mathrm{BPh}_{4}$ has been determined by neutron diffraction at 20 K . The coordination environment about the Fe atom is shown in Fig. 11.5.3. This is the first conclusive demonstration of the expected difference between a hydride and a $\mathrm{H}_{2}$ molecule in coordination to the same metal center. The $\mathrm{H}-\mathrm{H}$ bond distance is 81.6 pm and the $\mathrm{H}-\mathrm{Fe}$ bond length is 161.6 pm , which is longer than the terminal $\mathrm{H}-\mathrm{Fe}$ distance of 153.5 pm .

A large number of $\mathrm{H}_{2}$ coordination compounds have been identified and characterized. Table 11.5.1 lists the $\mathrm{H} \cdots \mathrm{H}$ distances $\left(\mathrm{d}_{\mathrm{HH}}\right)$ determined by neutron diffraction for some of these complexes. The $\mathrm{H} \cdots \mathrm{H}$ distances ranges from 82 to 160 pm , beyond which a complex is generally regarded to be a classical hydride. A "true" dihydrogen complex can be considered to have $\mathrm{d}_{\mathrm{HH}}<100 \mathrm{pm}$, and the complexes with $\mathrm{d}_{\mathrm{HH}}>100 \mathrm{pm}$ are more hydride-like in their properties and have highly delocalized bonding.

Fig. 11.5.2.
Bonding in $\mathrm{M}-\eta^{2}-\mathrm{H}_{2}$. Arrow indicates direction of donation.

Fig. 11.5.3.
Coordination of the Fe atom in trans-[ $\mathrm{Fe}\left(\eta^{2}\right.$ $\left.\left.\mathrm{H}_{2}\right)(\mathrm{H})\left(\mathrm{PPh}_{2} \mathrm{CH}_{2} \mathrm{CH}_{2} \mathrm{PPh}_{2}\right)\right] \mathrm{BPh}_{4}$.

The $\mathrm{H}_{2}$ molecule can act as an electron donor in combination with a proton to yield a $\mathrm{H}_{3}^{+}$species:

The existence of $\mathrm{H}_{3}^{+}$has been firmly established by its mass spectrum: $\mathrm{H}_{3}^{+}$has a relative molecular mass of 3.0235 , which differs from those of HD (3.0219) and T (3.0160). The $\mathrm{H}_{3}^{+}$species has the shape of an equilateral triangle and is stabilized by a $3 c-2 e$ bond.

The higher homologs $\mathrm{H}_{5}^{+}, \mathrm{H}_{7}^{+}$, and $\mathrm{H}_{9}^{+}$have also been identified by mass spectroscopy. These species are $10^{2}$ to $10^{3}$ times more abundant than the evenmember species $\mathrm{H}_{2 n}^{+}(n=2,3,4, \ldots)$ in mass spectral measurements. The structures of $\mathrm{H}_{5}^{+}, \mathrm{H}_{7}^{+}$, and $\mathrm{H}_{9}^{+}$are shown below:

### 11.5.2 $\mathrm{X}-\mathrm{H} \sigma$-bond coordination metal complexes

By analogy to the well characterized $\eta^{2}-\mathrm{H}_{2}$ complexes, methane and silane can coordinate to the metal in an $\mu^{2}$-fashion via a $\mathrm{C}-\mathrm{H} \sigma$ bond and a Si- $\mathrm{H} \sigma$ bond:

Transition metal complexes with a variety of $\sigma$-coordinated silane ligands have been extensively investigated. The molecular structure of $\operatorname{Mo}\left(\eta^{2}-\mathrm{H}-\right.$ $\left.\mathrm{SiH}_{2} \mathrm{Ph}\right)(\mathrm{CO})\left(\mathrm{Et}_{2} \mathrm{PCH}_{2} \mathrm{CH}_{2} \mathrm{PEt}_{2}\right)_{2}$, as shown in Fig. 11.5.4(a), exhibits $\eta^{2}$ coordination of the $\mathrm{Si}-\mathrm{H}$ bond at a coordination site cis to the CO ligand. The distances (in pm) and angles of the $\mathrm{Si}-\mathrm{H}$ coordinate bond are $\mathrm{Si}-\mathrm{H} 177, \mathrm{Mo}-\mathrm{H}$ 170, Mo-Si 250.1, Mo-H-Si $92^{\circ}$, and Mo-Si-H 42.6 ${ }^{\circ}$. The $\mathrm{SiH}_{2} \mathrm{Ph}_{2}$ ana$\log , \mathrm{Mo}\left(\eta^{2}-\mathrm{H}-\mathrm{SiHPh}_{2}\right)(\mathrm{CO})\left(\mathrm{Et}_{2} \mathrm{PCH}_{2} \mathrm{CH}_{2} \mathrm{PEt}_{2}\right)_{2}$, as shown in Fig. 11.5.4(b), exhibits a similar structure with $\mathrm{Si}-\mathrm{H} 166$, Mo-H 204, and Mo-Si 256.4.

Two molecules can be combined to form an ion-pair through a $\sigma$ coordination bond, in which one molecule provides its $\mathrm{X}-\mathrm{H}(\mathrm{X}=\mathrm{B}, \mathrm{C}, \mathrm{N}, \mathrm{O}, \mathrm{Si}) \sigma$ bonding electrons to a transition metal atom (such as Zr ) of another molecule. A good example is $\left[\left(\mathrm{C}_{5} \mathrm{Me}_{5}\right)_{2} \mathrm{Zr}^{+} \mathrm{Me}\right]\left[\mathrm{B}^{-} \mathrm{Me}\left(\mathrm{C}_{6} \mathrm{~F}_{5}\right)_{3}\right]$, whose structure is shown in Fig. 11.5.5. This bonding type is called an intermolecular pseudo-agostic (IPA) interaction.

### 11.5.3 Agostic bond

The agostic bond is an intramolecular $3 c-2 e \mathrm{C}-\mathrm{H} \rightharpoonup \mathrm{M}$ bond, with the vacant metal orbital accepting an electron pair from the $\mathrm{C}-\mathrm{H} \sigma$ bonding orbital. The term "agostic" denotes the intramolecular coordination of $\mathrm{C}-\mathrm{H}$ bonds to transition metals and is derived from a Greek word meaning "to clasp, to draw toward, to hold to oneself." The term "agostic" should not be used to describe external ligand binding solely through a $\sigma$ bond, which is best referred to as $\sigma$-bonded coordinate binding. Agostic bonds may be broadly understood in the following way. Many transition-metal compounds have less than an 18-electron count at the metal center, and thus are formally unsaturated. One way in which this deficiency may be alleviated is to increase the coordination number at the transition metal by clasping a H atom of a coordinated organic ligand. Therefore, the agostic bond generally occurs between carbon-hydrogen groups and transition-metal centers in organometallic compounds, in which a H atom is covalently bonded simultaneously to both a C atom and to a transition-metal atom. An agostic bond is generally written as $\mathrm{C}-\mathrm{H} \rightarrow \mathrm{M}$, where the "half arrow"

indicates formal donation of two electrons from the $\mathrm{C}-\mathrm{H}$ bond to the M vacant orbital. As in all $3 c-2 e$ bridging systems involving only three valence orbitals, the $\mathrm{C}-\mathrm{H} \rightharpoonup \mathrm{M}$ fragment is bent and the agostic bond can be more accurately represented by

Fig. 11.5.4.
Structure of (a) $\mathrm{Mo}\left(\eta^{2}-\mathrm{H}-\right.$
$\left.\mathrm{SiH}_{2} \mathrm{Ph}\right)(\mathrm{CO})\left(\mathrm{Et}_{2} \mathrm{PCH}_{2} \mathrm{CH}_{2} \mathrm{PEt}_{2}\right)_{2}$ and (b) $\mathrm{Mo}\left(\eta^{2}-\mathrm{H}-\right.$ $\left.\mathrm{SiHPh}_{2}\right)(\mathrm{CO})\left(\mathrm{Et}_{2} \mathrm{PCH}_{2} \mathrm{CH}_{2} \mathrm{PEt}_{2}\right)_{2}$ (bond lengths in pm ).

## Structural Chemistry of Selected Elements

The agostic C-H distance is in the range $113-19 \mathrm{pm}$, about 5-10\% longer than a non-bridging $\mathrm{C}-\mathrm{H}$ bond; the $\mathrm{M}-\mathrm{H}$ distance is also elongated by $10-20 \%$ relative to a normal terminal M-H bond. Usually NMR spectroscopy can be used for the diagnosis of static agostic systems which exhibit low $J\left(\mathrm{C}-\mathrm{H}_{\alpha}\right)$ values owing to the reduced $\mathrm{C}-\mathrm{H}_{\alpha}$ bond order. Typical values of $J\left(\mathrm{C}-\mathrm{H}_{\alpha}\right)$ are in the range of $60-90 \mathrm{~Hz}$, which are significantly lower than those $(120-30 \mathrm{~Hz})$ expected for $\mathrm{C}\left(\mathrm{sp}^{3}\right)-\mathrm{H}$ bonds.
The $\mathrm{C}-\mathrm{H} \triangle \mathrm{M}$ agostic bond is analogous to a $\mathrm{X}-\mathrm{H} \cdots \mathrm{Y}$ hydrogen bond, in the sense that the strength of the M-H linkage, as measured by its internuclear distance, is variable, and correlates with the changes in $\mathrm{C}-\mathrm{H}$ distance on the ligand. There are, however, two important differences. Firstly, in a hydrogen bond the H atom is attracted by an electronegative acceptor atom, but the strength of an agostic bond is stronger for more electropositive metals. Secondly, the hydrogen bond is a $3 c-4 e$ system, but the agostic bond is a $3 c-2 e$ system.

The agostic interaction is considered to be important in such reactions as $\alpha$ elimination, $\beta$-hydrogen elimination, and orthometalation. For example, in a $\beta$ hydrogen elimination, a H atom on the $\beta$ - C atom of an alkyl group is transferred to the metal atom and an alkene is eliminated. This reaction proceeds through an agostic-bond intermediate, as shown below:

The discovery of agostic bonding has led to renewed interest in the ligand behavior of simple organic functional groups, such as the methyl group. The $\mathrm{C}-\mathrm{H}$ group used to be regarded as an inert spectator, but now $\mathrm{C}-\mathrm{H}$ containing hydrocarbon ligand systems are recognized as being capable of playing important roles in complex stereochemical reactions.

Agostic bonding has been extended to include general $\mathrm{X}-\mathrm{H}-\mathrm{M}$ systems, in which X may be $\mathrm{B}, \mathrm{N}, \mathrm{Si}$, as well as C . The principal types of compounds with agostic bonds are shown in Fig. 11.5.6.

Figure 11.5 .7 shows the molecular structures of some transition metal complexes in which agostic bonding has been characterized by either X ray or neutron diffraction. Structural data for these compounds are listed in Table 11.5.2.

Many complexes containing P-, N -, or O-containing ligands can also form agostic bonds:

Agostic interactions involving phosphines are quite significant because they possess residual binding sites for other small molecules such as $\mathrm{H}_{2}$, and phosphine groups play crucial roles in many homogeneous catalysts. Figure 11.5.8(a)

shows the structure of $\mathrm{W}(\mathrm{CO})_{3}\left(\mathrm{PCy}_{3}\right)_{2}$, in which the $\mathrm{W} \leftharpoonup \mathrm{H}$ distance is 224.0 pm and the $\mathrm{W} \cdots \mathrm{C}$ distance is 288.4 pm . Figure 11.5.8(b) shows the structure of $\left[\operatorname{IrH}\left(\eta^{2}-\mathrm{C}_{6} \mathrm{H}_{4} \mathrm{P}^{t} \mathrm{Bu}_{2}\right)\left(\mathrm{P}^{t} \mathrm{Bu}_{2} \mathrm{Ph}\right)\right]^{+}$in its $\left[\mathrm{BAr}_{4}\right]^{-}$salt, in which the $\mathrm{Ir} \leftharpoonup \mathrm{H}$ distance is 203.2 pm and the $\mathrm{Ir} \cdots \mathrm{C}$ distance is 274.5 pm .

### 11.5.4 Structure and bonding of $\sigma$ complexes

Recent studies have established the following generalizations regarding $\sigma$ (sigma-bond) complexes:
(1) The $\mathrm{X}-\mathrm{H}(\mathrm{X}=\mathrm{B}, \mathrm{C}, \mathrm{Si})$ bonds in some ligand molecules, like the $\mathrm{H}-\mathrm{H}$ bond in $\mathrm{H}_{2}$, provide their $\sigma$ bonding electron pairs to bind the ligands to metal centers. They form intermolecular coordination compounds (i.e., sigmabond complexes) or intramolecular coordination compounds (i.e., agostic-bond complexes). All such compounds involve non-classical $3 c-2 e$ bonding and are collectively termed $\sigma$ complexes.

(2) An understanding of the bonding nature in the $\sigma$ complexes has extended the coordination concept to complement the classical Werner-typer donation of a lone pair and the $\pi$-electron donation of unsaturated ligands.

Werner-type complex

$\pi$ complex

$\sigma$ complex

Fig. 11.5.9.
Electron donation in (a) $\pi$ complexes and (b) $\sigma$ complexes. The filled orbitals are shaded.
(3) In $\sigma$ complexes, the $\sigma$ ligand is side-on ( $\eta^{2}$ mode) bonded to the metal (M) to form a $3 c-2 e$ bond. The electron donation in $\sigma$ complexes is analogous to that in $\pi$ complexes. The transition metals can uniquely stabilize the $\sigma$ ligands and $\pi$ ligands due to back donation from their d orbitals, as shown in Fig. 11.5.9. The main-group metals, lacking electrons in their outer d orbitals, do not form stable $\sigma$ complexes.
(4) $\mathrm{H}-\mathrm{H}$ and $\mathrm{X}-\mathrm{H}$ are the strong covalent bonds. These bonds can be weakened and even broken by $\sigma$ coordination to the transition metal and back donation from the metal to the $\sigma^{*}$ orbitals. The lengthening and eventual cleavage of a $\sigma$ bond by binding it to M are dependent on the electronic character of M , which is influenced by the other ligands on M . In the $\sigma$ complexes, the $\mathrm{H} \cdots \mathrm{H}$ and $\mathrm{X} \cdots \mathrm{H}$ distances can vary greatly. The gradual conversion of a metal dihydrogen $\sigma$ complex to a dihydride is indicated by the following scheme:

(5) There are two completely different pathways for the cleavage of $\mathrm{H}-\mathrm{H}$ bonds: oxidative addition and heterolytic cleavage. Both pathways have been identified in catalytic hydrogenation and may also be applicable to other types of $\mathrm{X}-\mathrm{H} \sigma$ bond activation such as $\mathrm{C}-\mathrm{H}$ cleavage.

Back donation in the $\sigma$ complexes is the crucial component in both aiding the binding of $\mathrm{H}_{2}$ to M and activating the $\mathrm{H}-\mathrm{H}$ bond toward cleavage. If the back donation becomes too strong, the $\sigma$ bond breaks to form a dihydride due to over-population of the $\mathrm{H}_{2}$ antibonding orbital. It is notable that back donation controls $\sigma$-bond activation toward cleavage and a $\sigma$ bond cannot be broken solely by sharing its electron pair with a vacant metal d orbital. Although $\sigma$ interaction is generally the predominant bonding component in a $\sigma$ complex, it is unlikely to be stable at room temperature without at least a small amount of back donation.

## Structural Chemistry of Alkali and Alkaline-Earth Metals

### 12.1 Survey of the alkali metals

The alkali metals - lithium, sodium, potassium, rubidium, cesium, and francium - are members of Group 1 of the Periodic Table, and each has a single $n \mathrm{~s}^{1}$ valence electron outside a rare gas core in its ground state. Some important properties of alkali metals are given in Table 12.1.1.

With increasing atomic number, the alkali metal atoms become larger and the strength of metallic bonding, enthalpy of atomization $\left(\Delta H_{\mathrm{at}}\right)$, melting point $(\mathrm{mp})$, standard enthalpy of fusion ( $\Delta H_{\text {fus }}$ ) and boiling point (bp) all progressively decrease. The elements show a regular gradation in physical properties down the group.

The radii of the metals increase with increasing atomic number and their atomic sizes are the largest in their respective periods. Such features lead to relatively small first ionization energy $\left(I_{1}\right)$ for the atoms. Thus the alkali metals are highly reactive and form $\mathrm{M}^{+}$ions in the vast majority of their compounds. The very high second ionization energy $\left(I_{2}\right)$ prohibits formation of the $\mathrm{M}^{2+}$ ions. Even though the electron affinities $(Y)$ indicate only mild exothermicity, $\mathrm{M}^{-}$ions can be produced for all the alkali metals (except Li ) under carefully controlled conditions.

Table 12.1.1. Some properties of alkali metals*

| Property | Li | Na | K | Rb | Cs |

[^5]The chemistry of the alkali metals has in the past attracted little attention as the metals have a fairly restricted coordination chemistry. However, interesting and systematic study has blossomed over the past 25 years, largely prompted by two major developments: the growing importance of lithium in organic synthesis and materials science, and the exploitation of macrocyclic ligands in the formation of complexed cations. Section 12.4 deals with the use of complexed cations in the generation of alkalides and electrides.

### 12.2 Structure and bonding in inorganic alkali metal compounds

### 12.2.1 Alkali metal oxides

The following types of binary compounds of alkali metals (M) and oxygen are known:
(a) Oxides: $\mathrm{M}_{2} \mathrm{O}$;
(b) Peroxides: $\mathrm{M}_{2} \mathrm{O}_{2}$;
(c) Superoxides: $\mathrm{MO}_{2}\left(\mathrm{LiO}_{2}\right.$ is stable only in matrix at 15 K$)$;
(d) Ozonides: $\mathrm{MO}_{3}$ (except Li);
(e) Suboxides (low-valent oxides): $\mathrm{Rb}_{6} \mathrm{O}, \mathrm{Rb}_{9} \mathrm{O}_{2}, \mathrm{Cs}_{3} \mathrm{O}, \mathrm{Cs}_{4} \mathrm{O}, \mathrm{Cs}_{7} \mathrm{O}$, and $\mathrm{Cs}_{11} \mathrm{O}_{3}$; and
(f) Sesquioxides: $\mathrm{M}_{2} \mathrm{O}_{3}$ : These are probably mixed peroxide-superoxides in the form of $\mathrm{M}_{2} \mathrm{O}_{2} \cdot 2 \mathrm{MO}_{2}$.

The structures and properties of the alkali metal oxides are summarized in Table 12.2.1.

Suboxides exist for the larger alkali metals. The crystal structures of all binary suboxides (except $\mathrm{Cs}_{3} \mathrm{O}$ ) as well as the structures of $\mathrm{Cs}_{11} \mathrm{O}_{3} \mathrm{Rb}, \mathrm{Cs}_{11} \mathrm{O}_{3} \mathrm{Rb}_{2}$, and $\mathrm{Cs}_{11} \mathrm{O}_{3} \mathrm{Rb}_{7}$ have been determined by single-crystal X-ray analysis. The structural data are listed in Table 12.2.2. All structures conform to the following rules:
(a) Each O atom occupies the center of an octahedron composed of Rb or Cs atoms.
(b) Face sharing of two such octahedra results in the cluster $\mathrm{Rb}_{9} \mathrm{O}_{2}$, and three equivalent octahedra form the cluster $\mathrm{Cs}_{11} \mathrm{O}_{3}$, as shown in Fig. 12.2.1.
(c) The $\mathrm{O}-\mathrm{M}$ distances are near the values expected for $\mathrm{M}^{+}$and $\mathrm{O}^{2-}$ ions. The ionic character of the M atoms is reflected by the short intracluster $\mathrm{M}-\mathrm{M}$ distances.
(d) The intercluster M-M distances are comparable to the distances in metallic Rb and Cs .
(e) The $\mathrm{Rb}_{9} \mathrm{O}_{2}$ or $\mathrm{Cs}_{11} \mathrm{O}_{3}$ clusters and additional alkali metals atoms form compounds of new stoichiometries. Some crystal structures have the intercluster space filled by metal atoms of the same kind, such as $\left(\mathrm{Cs}_{11} \mathrm{O}_{3}\right) \mathrm{Cs}_{10}$ shown in Fig. 12.2.2(a), or by metal atoms of a different kind, such as $\left(\mathrm{Cs}_{11} \mathrm{O}_{3}\right) \mathrm{Rb}$ and $\left(\mathrm{Cs}_{11} \mathrm{O}_{3}\right) \mathrm{Rb}_{7}$ illustrated in Figs. 12.2.2(b) and (c), respectively.

The bonding within the alkali metal suboxides is illustrated by comparing the interatomic distances in the compounds $\mathrm{Rb}_{9} \mathrm{O}_{2}$ and $\mathrm{Cs}_{11} \mathrm{O}_{3}$ with those in

## Structural Chemistry of Selected Elements

the "normal" oxides and in metallic Rb and Cs . The M-O distances nearly match the sum of ionic radii. The large intercluster M-M distances correspond to the distances in elemental $\mathrm{M}(\mathrm{Rb}$ and Cs$)$. Therefore, the formulations $\left(\mathrm{Rb}^{+}\right)_{9}\left(\mathrm{O}^{2-}\right)_{2}\left(\mathrm{e}^{-}\right)_{5}$ and $\left(\mathrm{Cs}^{+}\right)_{11}\left(\mathrm{O}^{2-}\right)_{3}\left(\mathrm{e}^{-}\right)_{5}$, where $\mathrm{e}^{-}$denotes an electron, represent a rather realistic description of the bonding in these clusters. Their

stability is attributable to consolidation by strong $\mathrm{O}-\mathrm{M}$ and weak $\mathrm{M}-\mathrm{M}$ bonds. All the alkali metal suboxides exhibit metallic luster and are good conductors.
(a)

(b)

(c)

Thus the electrons in $\mathrm{M}-\mathrm{M}$ bonding states do not stay localized within the clusters but are delocalized throughout the crystal due to the close contacts between the clusters.

### 12.2.2 Lithium nitride

Among the alkali metals, only lithium reacts with $\mathrm{N}_{2}$ at room temperature and normal atmospheric pressure to give red-brown, moisture-sensitive lithium nitride $\mathrm{Li}_{3} \mathrm{~N}$ ( $\alpha$-form), which has a high ionic conductivity.

Table 12.2.2. Structural data of alkali metal suboxides

| Compounds | Space group | Structural feature |
| :--- | :--- | :--- |
| $\mathrm{Rb}_{9} \mathrm{O}_{2}$ | $P 2_{1} / m$ | $\mathrm{Rb}_{9} \mathrm{O}_{2}$ cluster, Fig. 12.1.1(a) |
| $\mathrm{Rb}_{6} \mathrm{O}$ | $P 6_{3} / m$ | $\left(\mathrm{Rb}_{9} \mathrm{O}_{2}\right) \mathrm{Rb}_{3}$; three Rb atoms per $\mathrm{Rb}_{9} \mathrm{O}_{2}$ cluster |
| $\mathrm{Cs}_{11} \mathrm{O}_{3}$ | $P 2_{1} / c$ | $\mathrm{Cs}_{11} \mathrm{O}_{3}$ cluster, Fig. 12.1.1(b) |
| $\mathrm{Cs} \mathrm{Cs}_{4} \mathrm{O}$ | $P n a 2_{1}$ | $\left(\mathrm{Cs}_{11} \mathrm{O}_{3}\right) \mathrm{Cs}$; one Cs atom per $\mathrm{Cs}_{11} \mathrm{O}_{3}$ cluster |
| $\mathrm{Cs} \mathrm{O}_{3}$ | $P 6 m 2$ | $\left(\mathrm{Cs}_{11} \mathrm{O}_{3}\right) \mathrm{Cs}_{10}$; ten Cs atoms per $\mathrm{Cs}_{11} \mathrm{O}_{3}$ cluster, Fig. 12.2.2(a) |
| $\mathrm{Cs}_{11} \mathrm{O}_{3} \mathrm{Rb}$ | $P m n 2_{1}$ | One Rb atom per $\mathrm{Cs}_{11} \mathrm{O}_{3}$ cluster, Fig. 12.2.2(b) |
| $\mathrm{Cs}_{11} \mathrm{O}_{3} \mathrm{Rb}_{2}$ | $P 2_{1} / c$ | Two Rb atoms per $\mathrm{Cs}_{11} \mathrm{O}_{3}$ cluster |
| $\mathrm{Cs}_{11} \mathrm{O}_{3} \mathrm{Rb}_{7}$ | $P 2_{1} 2_{1} 2_{1}$ | Seven Rb atoms per $\mathrm{Cs}_{11} \mathrm{O}_{3}$ cluster, Fig. 12.2.2(c) |

The $\alpha$ form of $\mathrm{Li}_{3} \mathrm{~N}$ is made up of planar $\mathrm{Li}_{2} \mathrm{~N}$ layers, in which the Li atoms form a simple hexagonal arrangement, as in the case of the carbon layer in graphite, with a nitrogen atom at the center of each ring, as shown in Fig. 12.2.3(a). These layers are stacked and are linked by additional Li atoms midway between the N atoms of adjacent overlapping layers. Figure 12.2.3(b)

Fig. 12.2.2.
Unit-cell projections showing the atomic arrangements in some low-valent alkali metal oxides: (a) $\left(\mathrm{Cs}_{11} \mathrm{O}_{3}\right) \mathrm{Cs}_{10}$, (b) $\left(\mathrm{Cs}_{11} \mathrm{O}_{3}\right) \mathrm{Rb}$, (c) $\left(\mathrm{Cs}_{11} \mathrm{O}_{3}\right) \mathrm{Rb}_{7}$. The open, blackened, and shaded circles represent $\mathrm{Cs}, \mathrm{O}$, and Rb atoms, respectively.

## Structural Chemistry of Selected Elements

(a)
shows a hexagonal unit cell, with $a=364.8 \mathrm{pm}, c=387.5 \mathrm{pm}$. The Li-N distance is 213 pm within a layer, and 194 pm between layers.
$\alpha-\mathrm{Li}_{3} \mathrm{~N}$ is an ionic compound, in which the $\mathrm{N}^{3-}$ ion has a much greater size than the $\mathrm{Li}^{+}$ion $\left[r_{\mathrm{N}^{3}-} 146 \mathrm{pm}, r_{\mathrm{Li}^{+}} 59 \mathrm{pm}(\mathrm{CN}=4)\right]$. The crystal structure is very loosely packed, and conductivity arises from $\mathrm{Li}^{+}$vacancies within the $\mathrm{Li}_{2} \mathrm{~N}$ layers. The interaction between the carrier ions $\left(\mathrm{Li}^{+}\right)$and the fixed ions $\left(\mathrm{N}^{3-}\right)$ is relatively weak, so that ion migration is quite effective.

### 12.2.3 Inorganic alkali metal complexes

## (1) Structural features of alkali metal complexes

A growing number of alkali metal complexes $(\mathrm{MX} \cdot x \mathrm{~L})_{n}(\mathrm{M}=\mathrm{Li}, \mathrm{Na}, \mathrm{K} ; \mathrm{X}=$ halogens, $\mathrm{OR}, \mathrm{NR}_{2}, \cdots ; \mathrm{L}=$ neutral molecules) are known. It is now generally recognized that the $\mathrm{M}-\mathrm{X}$ bonds in these complexes are essentially ionic or have a high degree of ionic character. This bonding character accounts for the following features of these complexes:
(a) Most alkali metal complexes have an inner ionic core, and at the same time frequently form molecular species. The ionic interaction leads to large energies of association that stabilize the formation of complexes. The outer molecular fragments prevent the continuous growth of MX to form an ionic lattice. This characteristic has been rationalized in terms of the relatively large size and low charge of the cations $\mathrm{M}^{+}$. According to this view, the stability of alkali metal complexes should diminish in the sequence $\mathrm{Li}>$ $\mathrm{Na}>\mathrm{K}>\mathrm{Rb}>\mathrm{Cs}$, and this is frequently observed.
(b) The electrostatic association favors the formation of the $\mathrm{M}^{+} \mathrm{X}^{-}$ion pairs, and it is inevitable that such ion pairs will associate, so as to delocalize the electronic charges. The most efficient way of accomplishing this is by ring formation. If the $\mathrm{X}^{-}$groups are relatively small and for the most part coplanar with the ring, then stacking of rings can occur. For example, two dimers are connected to give a cubane-like tetramer, and two trimers lead to a hexagonal prismatic hexamer.
(c) In the ring structures, the bond angles at $\mathrm{X}^{-}$are acute. Hence the formation of larger rings would reduce repulsion between $\mathrm{X}^{-}$ions and between $\mathrm{M}^{+}$ions.
(d) Since the alkali metal complexes are mostly discrete molecules with an ionic core surrounded by organic peripheral groups, they have relatively low melting points and good solubility in weakly polar organic solvents. These properties have led to some practical applications; for example, lithium

(b)

(c)

(d)

(e)

complexes are used as low-energy electrolytic sources of metals, in the construction of portable batteries, and as halogenating agents and specific reagents in organic syntheses.

## (2) Lithium alkoxides and aryloxides

Anionic oxygen donors display a strong attraction for $\mathrm{Li}^{+}$ions and usually adopt typical structures of their aggregation state, as shown in Figs 12.2.4(a)-(c). Figure 12.2.4(a) shows the dimeric structure of $\left[\mathrm{Li}(\mathrm{THF})_{2} \mathrm{OC}\left(\mathrm{NMe}_{2}\right)(c-2,4,6-\right.$ $\left.\left.\mathrm{C}_{7} \mathrm{H}_{6}\right)\right]_{2}$, in which $\mathrm{Li}^{+}$is four-coordinated by the oxygen atoms from two THF ligands and two alkoxides $\mathrm{OC}\left(\mathrm{NMe}_{2}\right)\left(c-2,4,6-\mathrm{C}_{7} \mathrm{H}_{6}\right)$. The $\mathrm{Li}-\mathrm{O}$ distances are 188 and 192 pm for the bridging oxygen of the enolate, and 199 pm for THF. Figure 12.2.4(b) shows the tetrameric cubane-type structure of $\left[\mathrm{Li}(\mathrm{THF}) \mathrm{OC}\left(\mathrm{CH}^{t} \mathrm{Bu}\right) \mathrm{OMe}_{4}\right.$. The $\mathrm{Li}-\mathrm{O}$ distances are 196 pm (enolate) and 193 pm (THF). Figure 12.2.4(c) shows the hexagonal-prismatic structure of $\left[\mathrm{LiOC}\left(\mathrm{CH}_{2}\right)^{t} \mathrm{Bu}\right]_{6}$. The $\mathrm{Li}-\mathrm{O}$ distances are 190 pm (av.) in the six-membered ring of one stack, and 195 pm (av.) between the six-membered rings.

Figures 12.2.4(d) and (e) show the structures of $(\mathrm{LiOPh})_{2}(18$-crown-6) and $\left[(\mathrm{LiOPh})_{2}(15 \text {-crown-5) }]_{2}\right.$. In the former, there is a central dimeric $(\mathrm{Li}-\mathrm{O})_{2}$ unit. Owing to its larger size, 18 -crown- 6 can coordinate both $\mathrm{Li}^{+}$ions, each through three oxygen atoms ( $\mathrm{Li}-\mathrm{O} 215 \mathrm{pm}$, av.). These $\mathrm{Li}^{+}$ions are bridged by phenoxide groups ( $\mathrm{Li}-\mathrm{O} 188 \mathrm{pm}$ ). The structure of the latter has a very similar $(\mathrm{LiOPh})_{2}$ core ( $\mathrm{Li}-\mathrm{O} 187$ and 190 pm ). Each $\mathrm{Li}^{+}$ion is coordinated to another -OPh group as well as one ether oxygen from a 15-crown- 5 donor. This ether oxygen atom also connected to a further $\mathrm{Li}^{+}$ion whose coordination is completed by the remaining four oxygen donors of the 15 -crown- 5 ligands.

Fig. 12.2.4.

## (3) Lithium amides

The structures of lithium amides are characterized by a strong tendency for association. Monomeric structures are observed only in the presence of very bulky groups at nitrogen and/or donor molecules that coordinate strongly to lithium. In the dimeric lithium amides, the $\mathrm{Li}^{+}$ion is usually simultaneously coordinated by N atoms and other atoms. The trimer $\left[\mathrm{LiN}\left(\mathrm{SiMe}_{3}\right)_{2}\right]_{3}$ has a planar cyclic arrangement of its $\mathrm{Li}_{3} \mathrm{~N}_{3}$ core. The $\mathrm{Li}-\mathrm{N}$ bonds are 200 pm long with internal angles of $148^{\circ}$ at Li and $92^{\circ}$ at N (average values). Figure 12.2.5 shows the structures of some higher aggregates of lithium amides.
(a) The tetramer $(\mathrm{LiTMP})_{4}(\mathrm{TMP}=2,2,6,6$-tetramethylpiperidinide $)$ has a planar $\mathrm{Li}_{4} \mathrm{~N}_{4}$ core with a nearly linear angle $\left(168.5^{\circ}\right)$ at Li and an internal angle of $101.5^{\circ}$ at N . The average $\mathrm{Li}-\mathrm{N}$ distance is 200 pm , as shown in Fig. 12.2.5(a).
(b) The tetrameric molecule $\mathrm{Li}_{4}(\mathrm{TMEDA})_{2}\left[c-\mathrm{N}\left(\mathrm{CH}_{2}\right)_{4}\right]\left(\right.$ TMEDA $=N, N^{\prime}-$ tetramethylenediamine) has a ladder structure in which adjacent $\mathrm{Li}_{2} \mathrm{~N}_{2}$ rings share edges with further aggregation blocked by TMEDA coordination, as shown in Fig. 12.2.5(b).
(c) The hexameric $\left[\mathrm{Li}\left\{c-\mathrm{N}\left(\mathrm{CH}_{2}\right)_{6}\right\}\right]_{6}$ has a stacked structure, as shown in Fig. 12.2.5(c). This involves the association of two $\left[\mathrm{Li}-c-\mathrm{N}\left(\mathrm{CH}_{2}\right)_{6}\right]_{3}$ units to form a hexagonal-prismatic $\mathrm{Li}_{6} \mathrm{~N}_{6}$ unit, in which all N atoms have the relatively rare coordination number of five.
(d) The basic framework in $\left[\left\{\mathrm{LiN}\left(\mathrm{SiMe}_{3}\right)\right\}_{3} \mathrm{SiR}\right]_{2}\left(\mathrm{R}=\mathrm{Me},{ }^{t} \mathrm{Bu}\right.$ and Ph$)$ is derived from the dimerization of a trisamidosilane. It exhibits molecular
$D_{3 d}$ symmetry, as shown in Fig. 12.2.5(d). Each of the three $\mathrm{Li}^{+}$ions in a monomeric unit is coordinated by two N atoms in a chelating fashion, and linkage of units occurs through single $\mathrm{Li}-\mathrm{N}$ contacts. This causes all N atoms to be five-coordinate, which leads to weakening of the $\mathrm{Li}-\mathrm{N}$ and $\mathrm{Si}-\mathrm{N}$ bonds.
(e) Figure 12.2.5(e) shows the core structure of $\left[\mathrm{LiNH}^{t} \mathrm{Bu}\right]_{8}$, in which planar $\mathrm{Li}_{2} \mathrm{~N}_{2}$ ring units are connected to form a discrete prismatic ladder molecule.
(f) Figure 12.2 .5 (f) shows the centrosymmetric core structure of $\left[\mathrm{Li}_{12} \mathrm{O}_{2} \mathrm{Cl}_{2}\right.$ $\left.(\operatorname{ImN})_{8}(\mathrm{THF})_{4}\right] \cdot 8(\mathrm{THF})$, which consists of a folded $\mathrm{Li}_{4} \mathrm{~N}_{2} \mathrm{O}_{2}$ ladder in which the central $\mathrm{O}_{2}^{2-}$ ion is connected to two Li centers. The two adjacent $\mathrm{Li}_{4} \mathrm{ClN}_{3}$ ladders are connected with the central $\mathrm{Li}_{4} \mathrm{~N}_{2} \mathrm{O}_{2}$ unit via $\mathrm{Li}-\mathrm{O}$, $\mathrm{Li}-\mathrm{Cl}$ and $\mathrm{Li}-\mathrm{N}$ interactions. The bond distances are

$$
\begin{array}{llrl}
\mathrm{Li}-\mathrm{N} & 195.3-218.3 \mathrm{pm}, & \mathrm{Li}-\mathrm{O} & 191.7-259.3 \mathrm{pm} \\
\mathrm{Li}-\mathrm{Cl} & 238.5-239.6 \mathrm{pm}, & \mathrm{O}-\mathrm{O} & 154.4 \mathrm{pm} .
\end{array}
$$

In this structure, Li atoms are four-coordinated, and N atoms are four- or five-coordinated.

## (4) Lithium halide complexes

In view of the very high lattice energy of LiF, there is as yet no known complex that contains LiF and a Lewis base donor ligand. However, a range of crystalline fluorosilyl-amide and -phosphide complexes that feature significant $\mathrm{Li} \cdots \mathrm{F}$ contacts have been synthesized and characterized. For example, $\left\{\left[{ }^{t} \mathrm{Bu}_{2} \mathrm{Si}(\mathrm{F})\right]_{2} \mathrm{~N}\right\} \mathrm{Li}$ -2THF has a heteroatomic ladder core, as shown in Fig. 12.2.6(a), and dimeric $\left.\left[{ }^{t} \mathrm{Bu}_{2} \mathrm{SiP}(\mathrm{Ph})(\mathrm{F}) \mathrm{Li}\right) \cdot 2 \mathrm{THF}\right]_{2}$ contains an eight-membered heteroatomic ring.

A large number of complexes containing the halide salts $\mathrm{LiX}(\mathrm{X}=\mathrm{Cl}, \mathrm{Br}$, and I) have been characterized in the solid state. The structures of some of these complexes are shown in Figs. 12.2.6(b)-(f).

In the center of the cubane complex $[\mathrm{LiCl} \cdot \mathrm{HMPA}]_{4}\left(\mathrm{HMPA}\right.$ is $\left.\left(\mathrm{Me}_{2} \mathrm{~N}\right)_{3} \mathrm{P}=\mathrm{O}\right)$, each $\mathrm{Li}^{+}$is bonded to three $\mathrm{Cl}^{-}$and one oxygen of HMPA, as shown in Fig. 12.2.6(b). The complex $(\mathrm{LiCl})_{6}(\mathrm{TMEDA})_{2}$ has a complicated polymeric structure based on a $(\mathrm{LiCl})_{6}$ core, as shown in Fig. 12.2.6(c). Tetrameric $[\mathrm{LiBr}]_{4} \cdot 6\left[2,6-\mathrm{Me}_{2} \mathrm{Py}\right]$ has a staggered ladder structure, as shown

(d) $[\mathrm{LiBr}]_{4} \cdot 6\left[2,6-\mathrm{Me}_{2} \mathrm{Py}\right]$,
(e) $\left[\mathrm{Li}_{6} \mathrm{Br}_{4}\left(\mathrm{Et}_{2} \mathrm{O}\right)_{10}\right]^{2+}$, and
(f) $[\mathrm{LiBr} \cdot \mathrm{THF}]_{n}$.
in Fig. 12.2.6(d). In the complex $\left[\mathrm{Li}_{6} \mathrm{Br}_{4}\left(\mathrm{Et}_{2} \mathrm{O}\right)_{10}\right]^{2+} .2\left[\mathrm{Ag}_{3} \mathrm{Li}_{2} \mathrm{Ph}_{6}\right]^{-}$, the hexametallic dication contains a $\mathrm{Li}_{6} \mathrm{Br}_{4}$ unit which can be regarded as two three-rung ladders sharing their terminal Br anions, as shown in Fig. 12.2.6(e). The structure of oligomeric $[\mathrm{LiBr} \cdot \mathrm{THF}]_{n}$ is that of a unique corrugated ladder, in which $[\mathrm{LiBr}]_{2}$ units are linked together by $\mu_{3}-\mathrm{Br}$ bridges, as shown in Fig. 12.2.6(f). Polymeric ladder structures have also been observed for a variety of other alkali metal organometallic derivatives.

## (5) Lithium salts of heavier heteroatom compounds

Lithium can be coordinated by heavier main-group elements, such as $\mathrm{S}, \mathrm{Se}, \mathrm{Te}$, Si , and P atoms, to form complexes. In the complex $\left[\mathrm{Li}_{2}(\mathrm{THF})_{2} \mathrm{Cp}^{*} \mathrm{TaS}_{3}\right]_{2}$, the monomeric unit consists of a pair of four-membered $\mathrm{Ta}-\mathrm{S}-\mathrm{Li}-\mathrm{S}$ rings sharing a common Ta-S edge. Dimerization occurs through further Li-S linkages, affording a hexagonal-prismatic skeleton, as shown in Figure 12.2.7(a). The bond lengths are $\mathrm{Li}-\mathrm{S} 248 \mathrm{pm}(\mathrm{av}$.$) and \mathrm{Ta}-\mathrm{S} 228 \mathrm{pm}(\mathrm{av}$.$) . Figure 12.2.7(b) shows$ the core structure of $\mathrm{Li}(\mathrm{THF})_{3} \mathrm{SeMes}^{*}$ (Mes* $=2,4,6-\mathrm{C}_{6} \mathrm{H}_{2} \mathrm{R}_{3}$, where R is a bulky group such as $\mathrm{Bu}^{t}$ ) which has $\mathrm{Li}-\mathrm{Se}$ bond length 257 pm . Figure 12.2.7(c) shows the core structure of the dimeric complex $\left[\mathrm{Li}(\mathrm{THF})_{2} \mathrm{TeSi}\left(\mathrm{SiMe}_{3}\right)_{3}\right]_{2}$, in which the distances of bridging Li-Te bonds are 282 and 288 pm .

Some lithium silicide complexes have been characterized. The complex $\mathrm{Li}(\mathrm{THF})_{3} \mathrm{SiPh}_{3}$ displays a terminal $\mathrm{Li}-\mathrm{Si}$ bond that has a length of 267 pm , which is the same as that in $\mathrm{Li}(\mathrm{THF})_{3} \mathrm{Si}_{\mathrm{i}}\left(\mathrm{SiMe}_{3}\right)$. Figure 12.2.7(d) shows the core structure of $\mathrm{Li}(\mathrm{THF})_{3} \mathrm{SiPh}_{3}$. There is no interaction between Li and the phenyl rings. The $\mathrm{C}-\mathrm{Si}-\mathrm{C}$ bond angles are smaller ( $101.3^{\circ} \mathrm{av}$.) than the ideal tetrahedral value, while the $\mathrm{Li}-\mathrm{Si}-\mathrm{C}$ angles are correspondingly larger ( $116.8^{\circ}$ av.). This indicates the existence of a lone pair on silicon.

Figures 12.2.7(e)-(g) show the core structures of three lithium phosphide complexes. $\mathrm{Li}\left(\mathrm{Et}_{2} \mathrm{O}\right)_{2}\left(\mathrm{P}^{t} \mathrm{Bu}\right)_{2}\left(\mathrm{Ga}_{2}^{t} \mathrm{Bu}_{3}\right)$ has a puckered $\mathrm{Ga}_{2} \mathrm{P}_{2}$ four-membered ring, in which one Ga atom is four- and the other three-coordinated, as shown in Fig. 12.2.7(e). The Li-P bond length is 266 pm (av.).

The polymeric complex $\left[\mathrm{Li}\left(\mathrm{Et}_{2} \mathrm{O}\right) \mathrm{PPh}_{2}\right]_{n}$ has a backbone of alternating Li and P chain, as shown in Fig. 12.2.7(f). The bond length of Li-P is 248 pm (av.) and $\mathrm{Li}-\mathrm{O}$ is 194 pm (av.). Figure $12.2 .7(\mathrm{~g})$ shows the core structure of $\left[\mathrm{LiP}\left(\mathrm{SiMe}_{3}\right)_{2}\right]_{4}(\mathrm{THF})_{2}$, which has a ladder structure with $\mathrm{Li}-\mathrm{P}$ bond length $253 \mathrm{pm}(\mathrm{av}$.$) .$

## (6) Sodium coordination complexes

Recent development in the coordination chemistry of Group 1 elements has extended our knowledge of their chemical behavior and provided many interesting new structural types. Three examples among known sodium coordination complexes are presented below:
(a) A rare example of a bimetallic imido complex is the triple-stacked $\mathrm{Li}_{4} \mathrm{Na}_{2}\left[\mathrm{~N}=\mathrm{C}(\mathrm{Ph})\left({ }^{t} \mathrm{Bu}\right)\right]_{6}$. This molecule has six metal atoms in a triplelayered stack of four-membered $\mathrm{M}_{2} \mathrm{~N}_{2}$ rings, with the outer rings containing lithium and the central ring containing sodium. In the structure, lithium is three-coordinated and sodium is four-coordinated, as shown in Fig. 12.2.8(a).
(b) The large aggregate $\left[\mathrm{Na}_{8}\left(\mathrm{OCH}_{2} \mathrm{CH}_{2} \mathrm{OCH}_{2} \mathrm{CH}_{2} \mathrm{OMe}\right)_{6}\left(\mathrm{SiH}_{3}\right)_{2}\right]$ has been prepared and characterized. The eight sodium atoms form a cube, the faces of which are capped by the alkoxo oxygen atoms of the six $\left(\mathrm{OCH}_{2} \mathrm{CH}_{2} \mathrm{OCH}_{2} \mathrm{CH}_{2} \mathrm{OMe}\right)$ ligands, which are each bound to four sodium atoms with $\mathrm{Na}-\mathrm{O}$ distances in the range 230-242 pm. The sodium and oxygen atoms constitute the vertices of an approximate rhombododecahedron. Six of eight sodium atoms are five-coordinated by oxygen atoms, and each of the other two Na atoms is bonded by a $\mathrm{SiH}_{3}^{-}$group, which has inverted $C_{3 \mathrm{v}}$ symmetry with $\mathrm{Na}-\mathrm{Si}-\mathrm{H}$ bond angles of $58^{\circ}-62^{\circ}$, as shown in Fig. 12.2.8(b).
(a)

Fig. 12.2.8.
Structures of
(a) $\mathrm{Li}_{4} \mathrm{Na}_{2}\left[\mathrm{~N}=\mathrm{C}(\mathrm{Ph})\left({ }^{t} \mathrm{Bu}\right)\right]_{6}$ (the Ph and ${ }^{t} \mathrm{Bu}$ groups are not shown), and (b) $\left[\mathrm{Na}_{8}\left(\mathrm{OCH}_{2} \mathrm{CH}_{2} \mathrm{OCH}_{2} \mathrm{CH}_{2} \mathrm{OMe}\right)_{6}\left(\mathrm{SiH}_{3}\right)_{2}\right]$.

Fig. 12.2.9.
Structure of $\left[\mathrm{Na}_{11}\left(\mathrm{O}^{t} \mathrm{Bu}\right)_{10}(\mathrm{OH})\right]$.

Despite the strange appearance of the $\mathrm{SiH}_{3}^{-}$configuration in this complex, $a b$ initio calculations conducted on the simplified model compound $(\mathrm{NaOH})_{3} \mathrm{NaSiH}_{3}$ indicate that the form with inverted hydrogens is 6 kJ mol $^{-1}$ lower in energy than the un-inverted form. The results suggest that electrostatic interaction, rather than agostic interaction between the $\mathrm{SiH}_{3}$ group and its three adjacent Na neighbors, stabilizes the inverted form.
(c) The complex $\left[\mathrm{Na}_{11}\left(\mathrm{O}^{t} \mathrm{Bu}\right)_{10}(\mathrm{OH})\right]$ is obtained from the reaction of sodium tert-butanolate with sodium hydroxide. Its structure features a 21 -vertex cage constructed from eleven sodium cations and ten tert-butanolate anions, with an encapsulated hydroxide ion in its interior, as shown in Fig. 12.2.9. In the lower part of the cage, eight sodium atoms constitute a square antiprism, and four of the lower triangular faces are each capped by a $\mu_{3}-\mathrm{O}^{t} \mathrm{Bu}$ group. The $\mathrm{Na}_{4}$ square face at the bottom is capped by a $\mu_{4}-\mathrm{O}^{t} \mathrm{Bu}$ group, and the upper $\mathrm{Na}_{4}$ square face is capped in an inverted fashion by the $\mu_{4}-\mathrm{OH}^{-}$ group. Thus the $\mathrm{OH}^{-}$group resides within a $\mathrm{Na}_{8}$-core, and it also forms an $\mathrm{O}-\mathrm{H} \cdots \mathrm{O}$ hydrogen bond of length 297.5 pm . The $\mathrm{Na}-\mathrm{O}$ distances in the 21-vertex cage are in the range of 219-43 pm.

### 12.3 Structure and bonding in organic alkali metal compounds

### 12.3.1 Methyllithium and related compounds

Lithium readily interacts with hydrocarbon $\pi$ systems such as olefins, arenes, and acetylenes at various sites simultaneously. Lithium reacts with organic halides to give alkyllithium or aryllithium derivatives in high yield. Therefore, a wide variety of organolithium reagents can be made. These organolithium compounds are typically covalent species, which can be sublimed, distilled in a vacuum, and dissolved in many organic solvents. The $\mathrm{Li}-\mathrm{C}$ bond is a strong polarized covalent bond, so that organolithium compounds serve as sources

of anionic carbon, which can be replaced by $\mathrm{Si}, \mathrm{Ge}, \mathrm{Sn}, \mathrm{Pb}, \mathrm{Sb}$, or Bi . When $\mathrm{Sn}\left(\mathrm{C}_{6} \mathrm{H}_{5}\right)_{3}$ or $\mathrm{Sb}\left(\mathrm{C}_{6} \mathrm{H}_{11}\right)_{2}$ groups are used to replace $\mathrm{CH}_{3}, \mathrm{CMe}_{3}$ or $\mathrm{C}\left(\mathrm{SiMe}_{3}\right)_{3}$ in organolithium compounds, new species containing $\mathrm{Li}-\mathrm{Sn}$ or $\mathrm{Li}-\mathrm{Sb}$ bonds are formed.

Methyllithium, the simplest organolithium compound, is tetrameric. The $\mathrm{Li}_{4}\left(\mathrm{CH}_{3}\right)_{4}$ molecule with $T_{\mathrm{d}}$ symmetry may be described as a tetrahedral array of four Li atoms with a methyl C atom located above each face of the tetrahedron, as shown in Fig. 12.3.1(a). The bond lengths are Li-Li 268 pm and $\mathrm{Li}-\mathrm{C}$ 231 pm , and the bond angle $\mathrm{Li}-\mathrm{C}-\mathrm{Li}$ is $68.3^{\circ}$.

Vinyllithium, $\mathrm{LiHC}=\mathrm{CH}_{2}$, has a similar tetrameric structure in the crystalline state with a THF ligand attached to each lithium atom [Fig. 12.3.1(b)]. In THF solution vinyllithium is tetrameric as well. The internuclear $\mathrm{Li}-\mathrm{H}$ distances are in agreement with those calculated from the two-dimensional NMR ${ }^{6} \mathrm{Li},{ }^{1} \mathrm{H}$ HOSEY spectra.

When steric hindrance is minimal, organolithium compounds tend to form tetrameric aggregates with a tetrahedral $\mathrm{Li}_{4}$ core. Figures 12.3.2(a)-(d) show the structures of some examples: (a) $(\mathrm{LiBr})_{2} \cdot\left(\mathrm{CH}_{2} \mathrm{CH}_{2} \mathrm{CHLi}_{2} \cdot 4 \mathrm{Et}_{2} \mathrm{O}\right.$, (b) $\left(\mathrm{PhLi} \cdot \mathrm{Et}_{2} \mathrm{O}\right)_{3} \cdot \mathrm{LiBr}$, (c) $\left[\mathrm{C}_{6} \mathrm{H}_{4} \mathrm{CH}_{2} \mathrm{~N}\left(\mathrm{CH}_{3}\right)_{2} \mathrm{Li}\right]_{4}$, and (d) $\left.{ }^{t}{ }^{t} \mathrm{BuC} \equiv \mathrm{CLi}\right)_{4}(\mathrm{THF})_{4}$. In these complexes, the $\mathrm{Li}-\mathrm{C}$ bond lengths range from 219 to 253 pm , with an average value of 229 pm , while the $\mathrm{Li}-\mathrm{Li}$ distances lie in the range 242-263 pm (average 256 pm ). The $\mathrm{Li}-\mathrm{C}$ bond lengths are slightly longer than those for the terminally bonded organolithium compounds. This difference may be attributed to multicenter bonding in the tetrameric structures.

### 12.3.2 $\pi$-Complexes of lithium

The interactions between Li atom and diverse $\pi$ systems yield many types of lithium $\pi$ complexes. Figures 12.3.3(a)-(c) show the schematic representation of the core structures of some $\pi$ complexes of lithium, and Fig. 12.3.3(d) shows the molecular structure of $\left[\mathrm{C}_{2} \mathrm{P}_{2}\left(\mathrm{SiMe}_{3}\right)_{2}\right]^{2-} \cdot 2\left[\mathrm{Li}^{+}(\mathrm{DME})\right](\mathrm{DME}=$ dimethoxyethane).
(a) $\mathrm{Li}\left[\mathrm{Me}_{2} \mathrm{~N}\left(\mathrm{CH}_{2}\right)_{2} \mathrm{NMe}_{2}\right] \cdot\left[\mathrm{C}_{5} \mathrm{H}_{2}\left(\mathrm{SiMe}_{3}\right)_{3}\right]$ : In the cyclopentadienyllithium complex, the Li atom is coordinated by the planar Cp ring and by one chelating TMEDA ligand. The $\mathrm{Li}-\mathrm{C}$ distances are 226 to 229 pm (average value 227 pm ).
(b) $\mathrm{Li}_{2}\left[\mathrm{Me}_{2} \mathrm{~N}\left(\mathrm{CH}_{2}\right)_{2} \mathrm{NMe}_{2}\right] \cdot \mathrm{C}_{10} \mathrm{H}_{8}$ : In the naphthalene-lithium complex, each Li atom is coordinated by one $\eta^{6}$ six-membered ring and a chelating TEMDA ligand. The two Li atoms are not situated directly opposite to

Structures of some $\pi$ complexes of sodium and potassium:
(a) $\mathrm{Na}_{2}\left[\mathrm{Ph}_{2} \mathrm{C}=\mathrm{CPh}_{2}\right] \cdot 2 \mathrm{Et}_{2} \mathrm{O}$,
(b) $\mathrm{Na}\left(\mathrm{C}_{5} \mathrm{H}_{5}\right)($ en $)$, and (c) $\mathrm{K}\left[\mathrm{C}_{5} \mathrm{H}_{4}\left(\mathrm{SiMe}_{3}\right)\right]$.

### 12.3.3 $\pi$-Complexes of sodium and potassium

Many $\pi$ complexes of sodium and potassium have been characterized. The Na and K atoms of these complexes are polyhapto-bonded to the ring $\pi$ systems, and frequently attached to two or more rings to give infinite chain structures. Figure 12.3 .4 shows the structures of some $\pi$ complexes of sodium and potassium.

In the structure of $\mathrm{Na}_{2}\left[\mathrm{Ph}_{2} \mathrm{C}=\mathrm{CPh}_{2}\right] \cdot 2 \mathrm{Et}_{2} \mathrm{O}$, the two halves of the $\left[\mathrm{Ph}_{2} \mathrm{C}=\mathrm{CPh}_{2}\right]^{2-}$ dianion twist through $56^{\circ}$ relative to each other, and the central $\mathrm{C}=\mathrm{C}$ bond is lengthened to 149 pm as compared to $136 \mathrm{pm}^{2} \mathrm{Ph}_{2} \mathrm{C}=\mathrm{CPh}_{2}$. The coordination of $\mathrm{Na}(1)$ involves the $>\mathrm{C}=\mathrm{C}<\pi$ bond and two adjacent $\pi$ bonds. The two $\mathrm{Et}_{2} \mathrm{O}$ ligands are also coordinated to it. The $\mathrm{Na}(2)$ is sandwiched between two phenyl rings in a bent fashion, and further interacts with a $\pi$ bond in the third ring, as shown in Fig. 12.3.4(a). The $\mathrm{Na}(1)-\mathrm{C}$ and $\mathrm{Na}(2)-\mathrm{C}$ distances lie in the ranges $270-282 \mathrm{pm}$ and $276-309 \mathrm{pm}$, respectively.

Figure 12.3.4(b)-(c) show the structures of $\mathrm{Na}\left(\mathrm{C}_{5} \mathrm{H}_{5}\right)(\mathrm{en})$ and $\mathrm{K}\left[\mathrm{C}_{5} \mathrm{H}_{4}\right.$ $\left(\mathrm{SiMe}_{3}\right)$ ], respectively. In these complexes, each metal ( Na or K ) atom is centrally positioned between two bridging cyclopentadienyl rings, leading to a bent sandwich polymeric zigzag chain structure. The sodium atom is further coordinated by an ethylenediamine ligand, and the potassium atom interacts with an additional Cp ring of a neighboring chain.

## Structural Chemistry of Selected Elements

### 12.4 Alkalides and electrides

### 12.4.1 Alkalides

The alkali metals can be dissolved in liquid ammonia, and also in other solvents such as ethers and organic amines. Solutions of the alkali metals (except Li) contain solvated $\mathrm{M}^{-}$anions as well as solvated $\mathrm{M}^{+}$cations:

$$
2 \mathrm{M}(\mathrm{~s}) \rightleftharpoons \mathrm{M}^{+}(\text {solv })+\mathrm{M}^{-}(\text {solv })
$$

Successful isolation of stable solids containing these alkalide anions depends on driving the equilibrium to the right and then on protecting the anion from the polarizing effects of the cation. Both goals have been realized by using macrocyclic ethers (crown ethers and cryptands). The oxa-based cryptands such as 2.2.2-crypt (also written as C222) are particularly effective in encapsulating $\mathrm{M}^{+}$cations.

Alkalides are crystalline compounds that contain the alkali metal anions, $\mathrm{M}^{-}$ $\left(\mathrm{Na}^{-}, \mathrm{K}^{-}, \mathrm{Rb}^{-}\right.$, or $\mathrm{Cs}^{-}$). The first alkalide compound $\mathrm{Na}^{+}(\mathrm{C} 222) \cdot \mathrm{Na}^{-}$was synthesized and characterized by Dye in 1974.

Elemental sodium dissolves only very slightly ( $\sim 10^{-6} \mathrm{~mol} \mathrm{~L}^{-1}$ ) in ethylamine, but when C222 is added, the solubility increases dramatically to 0.2 $\mathrm{mol} \mathrm{L} \mathrm{L}^{-1}$, according to the equation

$$
2 \mathrm{Na}(\mathrm{~s})+\mathrm{C}(222) \longrightarrow \mathrm{Na}^{+}(\mathrm{C} 222)+\mathrm{Na}^{-} .
$$

When cooled to $-15^{\circ} \mathrm{C}$ or below, the solution deposits shiny, gold-colored thin hexagonal crystals of $\left[\mathrm{Na}^{+}(\mathrm{C} 222)\right] \cdot \mathrm{Na}^{-}$. Single-crystal X-ray analysis shows that two sodium atoms are in very different environments in the crystal. One is located inside the cryptand at distances from the nitrogen and oxygen atoms characteristic of a trapped $\mathrm{Na}^{+}$cation. The other is a sodium anion (natride), $\mathrm{Na}^{-}$, which is located far away from all other atoms. Figure 12.4 .1 shows the cryptated sodium cation with its six nearest natrides in the crystals. The close analogy of the natride ion with an iodide ion is brought out clearly by comparing $\left[\mathrm{Na}^{+}(\mathrm{C} 222)\right] \cdot \mathrm{Na}^{-}$with $\left[\mathrm{Na}^{+}(\mathrm{C} 222)\right] \cdot \mathrm{I}^{-}$.

Fig. 12.4.1.
The cryptated sodium cation surrounded by six natride anions in crystalline $\left[\mathrm{Na}^{+}(\mathrm{C} 222)\right] \cdot \mathrm{Na}^{-}$.

Table 12.4.1. Radii of alkali metal anions from structure of alkalides and alkali metals*

* HMHCY stands for hexamethyl hexacyclen, which is the common name of $1,4,7,10,13,16$-hexaaza-$1,4,7,10,13,16$-hexamethyl cyclooctadecane. Here $r_{M}{ }_{(\min )}$ is the distance between an anion and its nearest hydrogen atoms minus the van der Waals radius of hydrogen ( 120 pm ), while $r_{M}-(a v)$ is the average radius over the nearest hydrogen atoms; the numbers in the brackets are the numbers of hydrogen atoms for averaging. Similarly, $d_{\text {atom }}$ is the interatomic distance in the metal; $r_{\mathrm{M}^{-}}$is equal to $d_{\text {atom }}$ minus $r_{\mathrm{M}^{+}}$.

More than 40 alkalide compounds that contain the anions $\mathrm{Na}^{-}, \mathrm{K}^{-}, \mathrm{Rb}^{-}$, or $\mathrm{Cs}^{-}$have been synthesized, and their crystal structures have been determined. Table 12.4.1 lists the calculated radii of alkali metal anions from structures of alkalides and alkali metals. The values of $r_{\mathrm{M}^{-}(a v)}$ derived from alkalides and $r_{\mathrm{M}^{-}}$from the alkali metals are in good agreement.

### 12.4.2 Electrides

The counterparts to alkalides are electrides, which are crystalline compounds with the same type of complexed $\mathrm{M}^{+}$cations, but the $\mathrm{M}^{-}$anions are replaced by entrapped electrons that usually occupy the same sites. The crystal structures of several electrides are known: $\mathrm{Li}^{+}(\mathrm{C} 211) \mathrm{e}^{-}, \mathrm{K}^{+}(\mathrm{C} 222) \mathrm{e}^{-}, \mathrm{Rb}^{+}(\mathrm{C} 222) \mathrm{e}^{-}$, $\mathrm{Cs}^{+}(18 \mathrm{C} 6)_{2} \mathrm{e}^{-}, \mathrm{Cs}^{+}(15 \mathrm{C} 5)_{2} \mathrm{e}^{-}$, and $\left[\mathrm{Cs}^{+}(18 \mathrm{C} 6)(15 \mathrm{C} 5) \mathrm{e}^{-}\right]_{6}(18 \mathrm{C} 6)$. Comparison of the structures of the complexed cation in the natride $\mathrm{Li}^{+}(\mathrm{C} 211) \mathrm{Na}^{-}$ and the electride $\mathrm{Li}^{+}(\mathrm{C} 211) \mathrm{e}^{-}$shows that the geometric parameters are virtually identical, as shown in Fig. 12.4.2, supporting the assumption that the "excess" electron density in the electride does not penetrate substantially into the cryptand cage. In $\mathrm{Cs}^{+}(18 \mathrm{C} 6)_{2} \mathrm{Na}^{-}$and $\mathrm{Cs}^{+}(18 \mathrm{C} 6)_{2} \mathrm{e}^{-}$, not only are the complexed cation geometries the same, but the crystal structures are also very similar, the major difference being a slightly larger anionic site for $\mathrm{Na}^{-}$ than for $\mathrm{e}^{-}$.

Electrides made with crown ethers and oxa-based cryptands are generally unstable above $-40^{\circ} \mathrm{C}$, since the ether linkages are vulnerable to electron capture and reductive cleavage. Using a specifically designed pentacyclic tripiperazine cryptand TripPip222 [molecular structure displayed

in Fig. 12.4.3(a)], the pair of isomorphous compounds $\mathrm{Na}^{+}$(TripPip222) $\mathrm{Na}^{-}$ and $\mathrm{Na}^{+}$(TripPip222) ${ }^{-}$have been synthesized and fully characterized. This air-sensitive electride is stable up to about $40^{\circ} \mathrm{C}$ before it begins to decompose into a mixture of the sodide and the free complexant.

While the trapped electron could be viewed as the simplest possible anion, there is a significant difference between alkalides and electrides. Whereas the large alkali metal anions are confined to the cavities, only the probability density of a trapped electron can be defined. The electronic wavefunction can extend into all regions of space, and electron density tends to seek out the void spaces provided by the cavities and by intercavity channels.

tripiperazine cryptand TripPip222
(a)

(b)

Figure 12.4.3(b) displays the cavity-channel geometry in the crystal structure of $\mathrm{Rb}^{+}(\mathrm{C} 222) \mathrm{e}^{-}$, in which the dominant void space consists of parallel zigzag chains of cavities $S$ and large channels A (diameter 260 pm ) along the $a$-direction, which are connected at the "corners" by narrower channel B of diameter 115 pm to form "ladder-like" one-dimensional chains along $a$. Adjacent chains are connected along $b$ by channels C of diameter 104 pm and along $c$ by channels with diameter of 72 pm . Thus the void space in the crystal comprises a three-dimensional network of cavities and channels. The inter-electron coupling in adjacent cavities depends on the extent of overlap of the electronic wavefunction. The dimensionalities, diameters, and lengths of the channels that
connect the cavities play major roles. These structural features are consistent with the nature of wave-particle duality of the electron.

Removal of enclathrated oxygen ions from the cavities in a single crystal of $12 \mathrm{CaO} \cdot 7 \mathrm{Al}_{2} \mathrm{O}_{3}$ leads to the formation of the thermally and chemically stable electride $\left[\mathrm{Ca}_{24} \mathrm{Al}_{28} \mathrm{O}_{64}\right]^{4+}\left(\mathrm{e}^{-}\right)_{4}$.

### 12.5 Survey of the alkaline-earth metals

Beryllium, magnesium, calcium, strontium, barium, and radium constitute Group 2 in the Periodic Table. These elements (or simply the $\mathrm{Ca}, \mathrm{Sr}$, and Ba triad) are often called alkaline-earth metals. Some important properties of group 2 elements are summarized in Table 12.5.1.

All group 2 elements are metals, but an abrupt change in properties between Be and Mg occurs as Be shows anomalous behavior in forming mainly covalent compounds. Beryllium most frequently displays a coordination number of four, usually tetrahedral, in which the radius of $\mathrm{Be}^{2+}$ is 27 pm . The chemical behavior of magnesium is intermediate between that of Be and the heavier elements, and it also has some tendency for covalent bond formation.

With increasing atomic number, the group 2 metals follow a general trend in decreasing values of $I_{1}$ and $I_{2}$ except for Ra, whose relatively high $I_{1}$ and $I_{2}$ are attributable to the 6 s inert pair effect. Also, high $I_{3}$ values for all members of the group preclude the formation of the +3 oxidation state.

As the atomic number increases, the electronegativity decreases. In the organic compounds of group 2 elements, the polarity of the $\mathrm{M}-\mathrm{C}$ bond increases in the order

$$
\mathrm{BeR}_{2}<\mathrm{MgR}_{2}<\mathrm{CaR}_{2}<\mathrm{SrR}_{2}<\mathrm{BaR}_{2}<\mathrm{RaR}_{2}
$$

This is due to the increasing difference between the $\chi_{s}$ of carbon (2.54) and those of the metals. The tendency of these compounds to aggregate also increases in the same order. The $\mathrm{BeR}_{2}$ and $\mathrm{MgR}_{2}$ compounds are linked in the solid phase

Table 12.5.1. Properties of group 2 elements

| Property | Be | Mg | Ca | Sr | Ba | Ra |

| mp of MCl |  |  |  |  |  |  |

via $\mathrm{M}-\mathrm{C}-\mathrm{M} 3 c-2 e$ covalent bonds to form polymeric chains, while $\mathrm{CaR}_{2}$ to $\mathrm{RaR}_{2}$ form three-dimensional network structures in which the $\mathrm{M}-\mathrm{C}$ bonds are largely ionic.

All the $\mathrm{M}^{2+}$ ions are smaller and considerably less polarizable than the isoelectronic $\mathrm{M}^{+}$ions, as the higher effective nuclear charge binds the remaining electrons tightly. Thus the effect of polarization of cations on the properties of their salts are less important. $\mathrm{Ca}, \mathrm{Sr}, \mathrm{Ba}$, and Ra form a closely allied series in which the properties of the elements and their compounds vary systematically with increasing size in much the same manner as in the alkali metals.

The melting points of group 2 metal chlorides $\mathrm{MCl}_{2}$ increase steadily, and this trend is in sharp contrast to the alkali metal chlorides: $\mathrm{LiCl}(883 \mathrm{~K}), \mathrm{NaCl}$ (1074 $\mathrm{K}), \mathrm{KCl}(1045 \mathrm{~K}), \mathrm{RbCl}(990 \mathrm{~K})$, and $\mathrm{CsCl}(918 \mathrm{~K})$. This is due to several subtle factors: (a) the nature of bonding varies from covalent (Be) to ionic (Ba); (b) from Be to Ra the coordination number increases, so the Madelung constants, the lattice energies, and the melting points also increase; (c) the radius of $\mathrm{Cl}^{-}$ is large ( 181 pm ), whereas the radii of $\mathrm{M}^{2+}$ are small, and in the case of metal coordination, an increase in the radius of $\mathrm{M}^{2+}$ reduces the $\mathrm{Cl}^{-} \cdots \mathrm{Cl}^{-}$ repulsion.

### 12.6 Structure of compounds of alkaline-earth metals

### 12.6.1 Group 2 metal complexes

The coordination compounds of the alkaline-earth metals are becoming increasingly important to many branches of chemistry and biology. A considerable degree of structural diversity exists in these compounds, and monomers up to nonametallic clusters and polymeric species are known.

Beryllium, in view of its small size and simple set of valence orbitals, almost invariably exhibits tetrahedral four-coordination in its compounds. Figure 12.6.1(a) shows the structure of $\mathrm{Be}_{4} \mathrm{O}\left(\mathrm{NO}_{3}\right)_{6}$. The central oxygen atom is tetrahedrally surrounded by four Be atoms, and each Be atom is in turn tetrahedrally surrounded by four O atoms. The six nitrate groups are attached symmetrically to the six edges of the tetrahedron. This type of structure also appears in $\mathrm{Be}_{4} \mathrm{O}\left(\mathrm{CH}_{3} \mathrm{COO}\right)_{6}$.

Magnesium shows a great tendency to form complexes with ligands which have oxygen and nitrogen donor atoms, often displaying six-coordination, and its compounds are more polar than those of beryllium. The structure of hexameric $\left[\mathrm{MgPSi}^{t} \mathrm{Bu}_{3}\right]_{6}$ is based on a $\mathrm{Mg}_{6} \mathrm{P}_{6}$ hexagonal drum, with $\mathrm{Mg}-\mathrm{P}$ distances varying between 247 and 251 pm in the six-membered $\mathrm{Mg}_{3} \mathrm{P}_{3}$ ring, and 250 and 260 pm between the two rings, as shown in Fig. 12.6.1(b).

Calcium, strontium, and barium form compounds of increasing ionic character with higher coordination numbers, of which six to eight are particularly common. The complex $\mathrm{Ca} 9\left(\mathrm{OCH}_{2} \mathrm{CH}_{2} \mathrm{OMe}\right)_{18}\left(\mathrm{HOCH}_{2} \mathrm{CH}_{2} \mathrm{OMe}\right)_{2}$ has an interesting structure: the central $\mathrm{Ca}_{9}\left(\mu_{3}-\mathrm{O}\right)_{8}\left(\mu_{2}-\mathrm{O}\right)_{8} \mathrm{O}_{20}$ skeleton is composed of three six-coordinate Ca atoms and six seven-coordinate Ca atoms that can be viewed as filling the octahedral holes in two close-packed oxygen layers, as shown in Fig. 12.6.1(c). The distances of $\mathrm{Ca}-\mathrm{O}$ are $\mathrm{Ca}-\left(\mu_{3}-\mathrm{O}\right) 239 \mathrm{pm}$, $\mathrm{Ca}-\left(\mu_{2}-\mathrm{O}\right) 229 \mathrm{pm}$ and $\mathrm{Ca}-\mathrm{O}_{\text {ether }} 260 \mathrm{pm}$.
(a)

Fig. 12.6.1.
Structures of some coordination compounds of alkaline-earth metals: (a) $\mathrm{Be}_{4} \mathrm{O}\left(\mathrm{NO}_{3}\right)_{6}$, (b) $\left[\mathrm{MgPSi}^{t} \mathrm{Bu}_{3}\right]_{6}$, (c) $\mathrm{Ca}_{9}\left(\mathrm{OCH}_{2} \mathrm{CH}_{2} \mathrm{OMe}\right)_{18}\left(\mathrm{HOCH}_{2} \mathrm{CH}_{2} \mathrm{OMe}\right)_{2}$ and (d) $\left[\mathrm{BaI}(\mathrm{BHT})(\mathrm{THF})_{3}\right]_{2}$.

In the dimeric complex $\left[\mathrm{BaI}(\mathrm{BHT})(\mathrm{THF})_{3}\right]_{2}[\mathrm{BHT}=2,6$-di-t-butyl-4methylphenol, $\mathrm{C}_{6} \mathrm{H}_{2} \mathrm{Me}^{t} \mathrm{Bu}_{2}(\mathrm{OH})$, the coordination geometry around the Ba atom is distorted octahedral, with the two bridging iodides, the BHT, and a THF ligand in one plane, and two additional THF molecules lying above and below the plane, as shown in Fig. 12.6.1(d). The bond distances are Ba-I 344 pm, Ba-OAr 241 pm (av).

Many interesting coordination compounds of Group 2 elements have been synthesized in recent years. For example, the cation $\left[\mathrm{Ba}\left(\mathrm{NH}_{3}\right)_{n}\right]^{2+}$ is generated in the course of reducing the fullerenes $\mathrm{C}_{60}$ and $\mathrm{C}_{70}$ with barium in liquid ammonia. In the $\left[\mathrm{Ba}\left(\mathrm{NH}_{3}\right)_{7}\right] \mathrm{C}_{60} \cdot \mathrm{NH}_{3}$ crystal, the $\mathrm{Ba}^{2+}$ cation is surrounded by seven $\mathrm{NH}_{3}$ ligands at the vertices of a monocapped trigonal antiprism, and the $\mathrm{C}_{60}$ dianion is well ordered. In the $\left[\mathrm{Ba}\left(\mathrm{NH}_{3}\right)_{9}\right] \mathrm{C}_{70} \cdot 7 \mathrm{NH}_{3}$ crystal, the coordination geometry around $\mathrm{Ba}^{2+}$ is a distorted tricapped trigonal prism, with $\mathrm{Ba}-\mathrm{N}$ distances in the range 289-297 pm; the fullerene $\mathrm{C}_{70}$ units are linked into slightly zigzag linear chains by single $\mathrm{C}-\mathrm{C}$ bonds with length 153 pm .

### 12.6.2 Group 2 metal nitrides

The crystals of $\mathrm{M}\left[\mathrm{Be}_{2} \mathrm{~N}_{2}\right](\mathrm{M}=\mathrm{Mg}, \mathrm{Ca}, \mathrm{Sr})$ are composed of complex anion layers with covalent bonds between Be and N atoms. For example, $\mathrm{Mg}\left[\mathrm{Be}_{2} \mathrm{~N}_{2}\right]$ contains puckered six-membered rings in the chair conformation. These rings are condensed into single nets and are further connected to form double layers,

Fig. 12.6.2.
Crystal structures of (a) $\mathrm{Mg}\left[\mathrm{Be}_{2} \mathrm{~N}_{2}\right]$ and (b) $\mathrm{Ca}\left[\mathrm{Be}_{2} \mathrm{~N}_{2}\right]$. Small circles represent Be , large circles N , while circles between layers are either Mg or Ca .

(a)

(b)
in which the Be and N atoms are alternately linked. In this way, each beryllium atom is tetrahedrally coordinated by nitrogens, while each nitrogen occupies the apex of a trigonal pyramid whose base is made of three Be atoms, and a fourth Be atom is placed below the base. Thus the nitrogen atoms are each coordinated by an inverse tetrahedron of Be atoms and occupy positions at the outer boundaries of a double layer, as shown in Fig. 12.6.2(a). The BeN bond lengths are $178.4 \mathrm{pm}(3 \times)$ and 176.0 pm . The magnesium atoms are located between the anionic double layers, and each metal center is octahedrally surrounded by nitrogens with $\mathrm{Mg}-\mathrm{N} 220.9 \mathrm{pm}$.

The ternary nitrides $\mathrm{Ca}\left[\mathrm{Be}_{2} \mathrm{~N}_{2}\right]$ and $\mathrm{Sr}\left[\mathrm{Be}_{2} \mathrm{~N}_{2}\right]$ are isostructural. The crystal structure contains planar layers which consist of four- and eight-membered rings in the ratio of 1:2. The layers are stacked with successive slight rotation of each about the common normal, forming octagonal prismatic voids in the interlayer region. The eight-coordinated $\mathrm{Ca}^{2+}$ ions are accommodated in the void space, as shown in Fig. 12.6.2(b). The $\mathrm{Be}-\mathrm{N}$ bond lengths within the layers are $163.2 \mathrm{pm}(2 \times)$ and 165.7 pm . The $\mathrm{Ca}-\mathrm{N}$ distance is 268.9 pm .

### 12.6.3 Group 2 low-valent oxides and nitrides

## (1) $\quad\left(\mathrm{Ba}_{2} \mathrm{O}\right) \mathrm{Na}$

Similar to the alkali metals, the alkaline-earth metals can also form low-valent oxides. The first crystalline compound of this type is $\left(\mathrm{Ba}_{2} \mathrm{O}\right) \mathrm{Na}$, which belongs to space group Cmma with $a=659.1, b=1532.7, c=693.9 \mathrm{pm}$, and $Z=4$. In the crystal structure, the O atom is located inside a $\mathrm{Ba}_{4}$ tetrahedron. Such [ $\mathrm{Ba}_{4} \mathrm{O}$ ] units share trans edges to form an infinite chain running parallel to the $a$ axis. The $\left[\mathrm{Ba}_{4 / 2} \mathrm{O}\right]_{\infty}$ chains are in parallel alignment and separated by the Na atoms, as illustrated in Fig. 12.6.3. Within each chain, the $\mathrm{Ba}-\mathrm{O}$ bond length is 252 pm , being shorter than the corresponding distance of 277 pm in crystalline barium oxide. The interatomic distances between Ba and Na atoms lie in the range $421-433 \mathrm{pm}$, which are comparable with the values in the binary alloys BaNa and $\mathrm{BaNa}_{2}$ ( 427 and 432 pm , respectively).

## (2) $\left[\mathrm{Ba}_{6} \mathrm{~N}\right]$ cluster and related compounds

When metallic barium is dissolved in liquid sodium or $\mathrm{K} / \mathrm{Na}$ alloy in an inert atmosphere of nitrogen, an extensive class of mixed alkali metal-barium

subnitrides can be prepared. They contain $\left[\mathrm{Ba}_{6} \mathrm{~N}\right]$ octahedra that exist either as discrete entities or are condensed into finite clusters and infinite arrays.

Discrete $\left[\mathrm{Ba}_{6} \mathrm{~N}\right]$ clusters are found in the crystal structure of $\left(\mathrm{Ba}_{6} \mathrm{~N}\right) \mathrm{Na}_{16}$, as shown in Fig. 12.6.4. $\left(\mathrm{Ba}_{6} \mathrm{~N}\right) \mathrm{Na}_{16}$ crystallizes in space group $\operatorname{Im} \overline{3} m$ with $a=1252.7 \mathrm{pm}$ and $Z=2$. The Na atoms are located between the cluster units, in a manner analogous to that in the low-valent alkali metal suboxides.

The series of barium subnitrides $\mathrm{Ba}_{3} \mathrm{~N}$, $\left(\mathrm{Ba}_{3} \mathrm{~N}\right) \mathrm{Na}$, and $\left(\mathrm{Ba}_{3} \mathrm{~N}\right) \mathrm{Na}_{5}$ are characterized by parallel infinite $\left(\mathrm{Ba}_{6 / 2} \mathrm{~N}\right)_{\infty}$ chains each composed of trans face-sharing octahedral $\left[\mathrm{Ba}_{6} \mathrm{~N}\right]$ clusters. Figure 12.6.5(a) shows the crystal structure of $\mathrm{Ba}_{3} \mathrm{~N}$ projected along a sixfold axis. In the crystal structure of $\left(\mathrm{Ba}_{3} \mathrm{~N}\right) \mathrm{Na}$, the sodium atoms are located in between the $\left(\mathrm{Ba}_{6 / 2} \mathrm{~N}\right)_{\infty}$ chains, as shown in Fig. 12.6.5(b). In contrast, since $\left(\mathrm{Ba}_{3} \mathrm{~N}\right) \mathrm{Na}_{5}$ has a much higher sodium content, the $\left(\mathrm{Ba}_{6 / 2} \mathrm{~N}\right)_{\infty}$ chains are widely separated from one another by the additional Na atoms, as illustrated in Fig. 12.6.5(c).

## (3) $\left[\mathrm{Ba}_{14} \mathrm{CaN}_{6}\right]$ cluster and related compounds

The $\left[\mathrm{Ba}_{14} \mathrm{CaN}_{6}\right]$ cluster can be considered as a Ca -centered $\mathrm{Ba}_{8}$ cube with each face capped by a Ba atom, and the six N atoms are each located inside a $\mathrm{Ba}_{5}$ tetragonal pyramid, as shown in Fig. 12.6.6. The structure can be viewed alternatively as a cluster composed of the fusion of six N -centered Ba 5 Ca octahedra sharing a common Ca vertex. In the synthesis of this type of cluster compounds, variation of the atomic ratio of the $\mathrm{Na} / \mathrm{K}$ binary alloy system leads to a series of compounds of variable stoichiometry: $\left[\mathrm{Ba}_{14} \mathrm{CaN}_{6}\right] \mathrm{Na}_{x}$ with $x=7,8,14,17,21$

Fig. 12.6.3.
Crystal structure of $\left(\mathrm{Ba}_{2} \mathrm{O}\right) \mathrm{Na}$. The $\left[\mathrm{Ba}_{4 / 2} \mathrm{O}\right]_{\infty}$ chains are seen end-on.

Fig. 12.6.4.
Arrangement of the $\left(\mathrm{Ba}_{6} \mathrm{~N}\right)$ clusters in the crystal structure of $\left(\mathrm{Ba}_{6} \mathrm{~N}\right) \mathrm{Na}_{16}$.

and 22. This class of compounds can be considered as composed of an ionically bonded $\left[\mathrm{Ba}_{8}^{2+} \mathrm{Ca}^{2+} \mathrm{N}_{6}^{3-}\right]$ nucleus surrounded by $\mathrm{Ba}_{6} \mathrm{Na}_{x}$ units, which interact with the nucleus mainly via metallic bonding.

### 12.7 Organometallic compounds of group 2 elements

There are numerous organometallic compounds of Group 2 elements, and in this section only the following three typical species are described.

### 12.7.1 Polymeric chains

Dimethylberyllium, $\mathrm{Be}\left(\mathrm{CH}_{3}\right)_{2}$, is a polymeric white solid containing infinite chains, as shown in Fig. 12.7.1(a). Each Be center is tetrahedrally coordinated and can be considered to be $\mathrm{sp}^{3}$ hybridized. As the $\mathrm{CH}_{3}$ group only contributes one orbital and one electron to the bonding, there are insufficient electrons to form normal $2 c-2 e$ bonds between the Be and C atoms. In this electron-deficient system, the BeCBe bridges are $3 c-2 e$ bonds involving $\mathrm{sp}^{3}$ hybrid atomic orbitals from two Be atoms and one C atom, as shown in Fig. 12.7.1(b).

The polymeric structures of $\mathrm{BeH}_{2}$ and $\mathrm{BeCl}_{2}$ are similar to that of $\mathrm{Be}\left(\mathrm{CH}_{3}\right)_{2}$. The $3 c-2 e$ bonding in $\mathrm{BeH}_{2}$ is analogous to that in $\mathrm{Be}\left(\mathrm{CH}_{3}\right)_{2}$. But in $\mathrm{BeCl}_{2}$ there are sufficient valence electrons to form normal $2 c-2 e \mathrm{Be}-\mathrm{Cl}$ bonds.

### 12.7.2 Grignard reagents

Grignard reagents are widely used in organic chemistry. They are prepared by the interaction of magnesium with an organic halide in ethers. Grignard reagents

(a)

(b)

are normally assigned the simple formula RMgX , but this is an oversimplification as solvation is important. The isolation and structural determination of several crystalline RMgX compounds have demonstrated that the essential structure is RMgX •(solvent) ${ }_{n}$. Figure 12.7 .2 shows the molecular structure of $\left(\mathrm{C}_{2} \mathrm{H}_{5}\right) \mathrm{MgBr} \cdot 2\left(\mathrm{C}_{2} \mathrm{H}_{5}\right)_{2} \mathrm{O}$, in which the central Mg atom is surrounded by one ethyl group, one bromine atom, and two diethyl ether molecules in a distorted tetrahedral configuration. The bond distances are $\mathrm{Mg}-\mathrm{C} 215 \mathrm{pm}$, $\mathrm{Mg}-\mathrm{Br} 248 \mathrm{pm}$, and $\mathrm{Mg}-\mathrm{O} 204 \mathrm{pm}$. The latter is among the shortest $\mathrm{Mg}-\mathrm{O}$ distances known.

In a Grignard compound the carbon atom bonded to the electropositive Mg atom carries a partial negative charge. Consequently a Grignard reagent is an extremely strong base, with its carbanion-like alkyl or aryl portion acting as a nucleophile.

### 12.7.3 Alkaline-earth metallocenes

The alkaline-earth metallocenes exhibit various structures, depending on the sizes of the metal atoms. In $\mathrm{Cp}_{2} \mathrm{Be}$, the $\mathrm{Be}^{2+}$ ion is $\eta^{5} / \eta^{1}$ coordinated between two Cp rings, as shown in Fig. 12.7.3(a). The mean Be-C distances are 193 and 183 pm for $\eta^{5}$ and $\eta^{1} \mathrm{Cp}$ rings, respectively. In contrast, $\mathrm{Cp}_{2} \mathrm{Mg}$ adopts a typical sandwich structure, as shown in Fig. 12.7.3(b). The mean Mg-C distance is 230 pm . In the crystalline state, the two parallel rings have a staggered conformation.

The compounds $\mathrm{Cp}_{2} \mathrm{Ca}, \mathrm{Cp}^{*} \mathrm{Sr}$ and $\mathrm{Cp}^{*} \mathrm{Ba}$ exhibit a different coordination mode, as the two Cp rings are not aligned in a parallel fashion like $\mathrm{Cp}_{2} \mathrm{Mg}$, but

THF, (e) $\mathrm{Ba}_{2}(\mathrm{COT})\left[\mathrm{C}_{5} \mathrm{H}\left(\mathrm{CHMe}_{2}\right)_{4}\right]_{2}$.

are bent with respect to each other making a $\mathrm{Cp}_{\text {(centroid) }}-\mathrm{M}-\mathrm{Cp}_{\text {(centroid) }}$ angle of $147^{\circ}-154^{\circ}$. The positive charge of the $\mathrm{M}^{2+}$ ion is not only shared by two $\eta^{5}$-bound Cp rings, but also by other ligands. $\mathrm{In}_{\mathrm{Cp}}^{2} 2 \mathrm{Ca}$, apart from the two $\eta^{5}-\mathrm{Cp}$ ligands, there are significant $\mathrm{Ca}-\mathrm{C}$ contacts to $\eta^{3}$ - and $\eta^{1}-\mathrm{Cp}$ rings, as shown in Figure 12.7.3(c). In $\mathrm{Sr}\left[\mathrm{C}_{5} \mathrm{H}_{3}\left(\mathrm{SiMe}_{3}\right)_{2}\right]_{2}$.THF, apart from the two $\eta^{5}$ - Cp rings, a THF ligand is coordinated to the $\mathrm{Sr}^{2+}$ ion, as shown in Fig. 12.7.3(d). The $\mathrm{Ba}^{2+}$ ion has the largest size among the alkaline-earth metals, and accordingly it can be coordinated by a planar $\mathrm{COT}\left(\mathrm{C}_{8} \mathrm{H}_{8}\right)$ ring bearing two negative charges. Figure 12.7.3(e) shows the structure of a triple-decker sandwich complex of barium, $\mathrm{Ba}_{2}(\mathrm{COT})\left[\mathrm{C}_{5} \mathrm{H}\left(\mathrm{CHMe}_{2}\right)_{4}\right]_{2}$, in which the mean $\mathrm{Ba}-\mathrm{C}$ distances are 296 and 300 pm for the $\eta^{5}-\mathrm{Cp}$ ring and $\eta^{8}$-COT ring, respectively.

### 12.8 Alkali and alkaline-earth metal complexes with inverse crown structures

The term "inverse crown ether" refers to a metal complex in which the roles of the central metal core and the surrounding ether oxygen ligand sites in a conventional crown ether complex are reversed. An example of an inverse crown ether is the organosodium-zinc complex $\mathrm{Na}_{2} \mathrm{Zn}_{2}\left\{\mathrm{~N}\left(\mathrm{SiMe}_{3}\right)_{2}\right\}_{4}(\mathrm{O})$ shown in Fig. 12.8.1(a). The general term "inverse crown" is used when the central core of this type of complex comprises non-oxygen atoms, or more than just a single O atom. Two related inverse crowns with cationic ( $\mathrm{Na}-\mathrm{N}-\mathrm{Mg}-\mathrm{N}-)_{2}$ rings that encapsulate peroxide and alkoxide groups, respectively, are shown in Figs. 12.8.1(b) and (c). The octagonal macrocycle in $\mathrm{Na}_{2} \mathrm{Mg}_{2}\left\{\mathrm{~N}\left(\mathrm{SiMe}_{3}\right)_{2}\right\}_{4}\left(\mathrm{OOct}^{n}\right)_{2}$ takes the chair form with the $\mathrm{Na}-\mathrm{OOct}^{n}$ groups displaced on either side of the plane defined by the N and Mg atoms. Each alkoxide O atom interacts with both Mg atoms to produce a perfectly planar

(b) $\mathrm{Na}_{2} \mathrm{Mg}_{2}\left\{\mathrm{~N}\left(\mathrm{SiMe}_{3}\right)_{2}\right\}_{4}\left(\mathrm{O}_{2}\right)$,
(c) $\mathrm{Na}_{2} \mathrm{Mg}_{2}\left\{\mathrm{~N}\left(\mathrm{SiMe}_{3}\right)_{2}\right\}_{4}\left(\mathrm{OOct}^{n}\right)_{2}$,
(d) cluster core of $\left\{(\mathrm{THF}) \mathrm{NaMg}\left(\operatorname{Pr}_{2}^{i} \mathrm{~N}\right)(\mathrm{O})\right\}_{6}$; the THF ligand attached to each Na atom and the isopropyl groups are omitted for clarity.
$(\mathrm{MgO})_{2}$ ring. The $\mathrm{Mg}-\mathrm{O}$ and $\mathrm{Na}-\mathrm{O}_{\text {syn }}$ bond lengths are 202.7(2)-203.0(2) and 256.6(1)-247.2(2) pm, respectively; the non-bonded $\mathrm{Na} \cdots \mathrm{O}_{\text {anti }}$ distances lie in the range 310.4(1)-320.4(2) pm.

Figure 12.8.1(d) shows the structure of a hexameric "super" inverse crown ether $\left\{(\mathrm{THF}) \mathrm{NaMg}\left(\operatorname{Pr}_{2}^{i} \mathrm{~N}\right)(\mathrm{O})\right\}_{6}$, which consists of a $S_{6}$-symmetric hexagonal prismatic $\mathrm{Mg}_{6} \mathrm{O}_{6}$ cluster with six external four-membered rings constructed with $\mathrm{Na}-\mathrm{THF}$ and $\operatorname{Pr}_{2}^{i} \mathrm{~N}$ appendages.

Table 12.8.1. Compositions of some inverse crowns containing organic guest species

| Group 1 metal | Group 2 metal | Amide ion | Core moiety | Host ring size |
| :--- | :--- | :--- | :--- | :--- |
| 4 Na | 2 Mg | 6 TMP | $\mathrm{C}_{6} \mathrm{H}_{3} \mathrm{Me}^{2-}$ | 12 |
| 4 Na | 2 Mg | 6 TMP | $\mathrm{C}_{6} \mathrm{H}_{4}^{2-}$ | 12 [Fig. 2.7.5(a)] |
| 6 K | 6 Mg | 12 TMP | $6 \mathrm{C}_{6} \mathrm{H}_{5}^{-}$ | 24 |
| 6 K | 6 Mg | 12 TMP | $6 \mathrm{C}_{6} \mathrm{H}_{4} \mathrm{Me}^{-}$ | 24 |
| 4 Na | 4 Mg | $8 \mathrm{Pr}_{2}^{i} \mathrm{~N}$ | $\mathrm{Fe}\left(\mathrm{C}_{5} \mathrm{H}_{3}\right)_{2}^{4-}$ | 12 [Fig. 2.7.5(b)] |

A remarkable series of inverse crown compounds featuring organic guest moieties encapsulated within host-like macrocyclic rings composed of sodium/potassium and magnesium ions together with anionic amide groups, such as $\mathrm{TMP}^{-}(\mathrm{TMPH}=2,2,6,6$-tetramethylpiperidine $)$ and $\operatorname{Pr}_{2}^{i} \mathrm{~N}^{-}\left(\operatorname{Pr}_{2}^{i} \mathrm{NH}=\right.$ diisopropylamine), have been synthesized and characterized. Table 12.8.1 lists some examples of this class of inverse crown molecules.

Figure 12.8.2(a) shows the molecular structure of $\mathrm{Na}_{4} \mathrm{Mg}_{2}(\mathrm{TMP})_{6}\left(\mathrm{C}_{6} \mathrm{H}_{4}\right)$, in which the N atom of each tetramethylpiperidinide is bonded to two metal atoms to form a cationic $12-m e m b e r e d ~(~ N a-N-N a-N-M g-N-)_{2}$ ring. The mixed metal macrocyclic amide acts as a host that completely encloses a 1,4deprotonated benzenediide guest species whose naked carbon atoms are each stabilized by a covalent $\mathrm{Mg}-\mathrm{C}$ bond and a pair of $\mathrm{Na} \cdots \mathrm{C} \pi$ interactions.

Fig. 12.8.2.
Molecular structures of two centrosymmetric inverse crown molecules containing organic cores:
(a) $\mathrm{Na}_{4} \mathrm{Mg}_{2}(\mathrm{TMP})_{6}\left(\mathrm{C}_{6} \mathrm{H}_{4}\right)$,
(b) $\mathrm{Na}_{4} \mathrm{Mg}_{4}\left({ }^{i} \mathrm{Pr}_{2} \mathrm{~N}\right)_{8}\left[\mathrm{Fe}\left(\mathrm{C}_{5} \mathrm{H}_{3}\right)_{2}\right]$.

The $\mathrm{Na} \cdots \mathrm{C} \pi$ interactions are indicated by broken lines.

Figure 12.8.2(b) shows the molecular structure of $\mathrm{Na}_{4} \mathrm{Mg}_{4}\left(\operatorname{Pr}_{2}^{i} \mathrm{~N}\right)_{8}$ [ $\mathrm{Fe}\left(\mathrm{C}_{5} \mathrm{H}_{3}\right)_{2}$ ]. Each amido N atom is bound to one Na and one Mg atom to form a 16 -membered macrocyclic ring, which accommodates the ferrocene$1,1^{\prime}, 3,3^{\prime}$-tetrayl residue at its center. The deprotonated 1,3 -positions of each cyclopentadienyl ring of the ferrocene moiety are each bound to a pair of Mg atoms by $\mathrm{Mg}-\mathrm{C}$ covalent bonds, and the 1,2,3-positions further interact with three Na atoms via three different kinds of $\mathrm{Na} \cdots \mathrm{C} \pi$ bonds.

## Structural Chemistry of Group 13 Elements

### 13.1 Survey of the group 13 elements

Boron, aluminum, gallium, indium, and thallium are members of group 13 of the Periodic Table. Some important properties of these elements are given in Table 13.1.1.

From Table 13.1.1, it is seen that the inner electronic configurations of the group 13 elements are not identical. The $n s^{2} n p^{1}$ electrons of B and Al lie outside a rare gas configuration, while the $n s^{2} n p^{1}$ electrons of Ga and In are outside the $\mathrm{d}^{10}$ subshell, and those of Tl lie outside the $4 \mathrm{f}^{14} 5 \mathrm{~d}^{10}$ core. The increasing effective nuclear charge and size contraction, which occur during successive filling of $d$ and $f$ orbitals, combine to make the outer $s$ and $p$ electrons of Ga , In, and Tl more strongly held than expected by simple extrapolation from B to Al . Thus there is a small increase in ionization energy between Al and Ga , and between In and Tl . The drop in ionization energy between Ga and In mainly

[^6]reflects the fact that both elements have a completely filled inner shell and the outer electrons of In are further from the nucleus.

The +3 oxidation state is characteristic of group 13 elements. However, as in the later elements of this groups, the trend in $I_{2}$ and $I_{3}$ shows increases at Ga and Tl , leading to a marked increase in stability of their +1 oxidation state. In the case of Tl , this is termed the 6 s inert-pair effect. Similar effects are observed for Pb (group 14) and Bi (group 15), for which the most stable oxidation states are +2 and +3 , respectively, rather than +4 and +5 .

Because of the 6 s inert-pair effect, many $\mathrm{Tl}^{+}$compounds are found to be more stable than the corresponding $\mathrm{Tl}^{3+}$ compounds. The progressive weakening of $\mathrm{M}^{3+}$ - X bonds from B to Tl partly accounts for this. Furthermore, the relativistic effect (as described in Section 2.4.3) is another factor which contributes to the inert-pair effect.

### 13.2 Elemental Boron

The uniqueness of structure and properties of boron is a consequence of its electronic configuration. The small number of valence electrons (three) available for covalent bond formation leads to "electron deficiency," which has a dominant effect on boron chemistry.

Boron is notable for the complexity of its elemental crystalline forms. There are many reported allotropes, but most are actually boron-rich borides. Only two have been completely elucidated by X-ray diffraction, namely $\alpha$-R12 and $\beta$-R105; here R indicates the rhombohedral system, and the numeral gives the number of atoms in the primitive unit cell. In addition, $\alpha$-T50 boron (T denotes the tetragonal system) has been reformulated as a carbide or nitride, $\mathrm{B}_{50} \mathrm{C}_{2}$ or $\mathrm{B}_{50} \mathrm{~N}_{2}$, and $\beta$-T192 boron is still not completely elucidated. These structures all contain icosahedral $\mathrm{B}_{12}$ units, which in most cases are accompanied by other boron atoms lying outside the icosahedral cages, and the linkage generates a three-dimensional framework.

The $\alpha$-R12 allotrope consists of an approximately cubic closest packing arrangement of icosahedral $\mathrm{B}_{12}$ units bound to each other by covalent bonds. The parameters of the rhombohedral unit cell are $a=505.7 \mathrm{pm}, \alpha=58.06^{\circ}$ ( $60^{\circ}$ for regular ccp). In space group $R \overline{3} m$, the unit cell contains one $\mathrm{B}_{12}$ icosahedron. A layer of interlinked icosahedra perpendicular to the threefold symmetry axis is illustrated in Fig. 13.2.1. There are 12 neighboring icosahedra for each icosahedron: six in the same layer, and three others in each of the upper and lower layers, as shown in Fig. 9.6.21(b).

The $\mathrm{B}_{12}$ icosahedron is a regular polyhedron with 12 vertices, 30 edges, and 20 equilateral triangular faces, with $B$ atoms located at the vertices, as shown in Fig. 13.2.2. The $\mathrm{B}_{12}$ icosahedron is a basic structural unit in all isomorphic forms of boron and in some polyhedral boranes such as $\mathrm{B}_{12} \mathrm{H}_{12}^{2-}$. It has 36 valence electrons; note that each line joining two B atoms (mean $\mathrm{B}-\mathrm{B}$ distance 177 pm ) in Fig. 13.2.2 does not represent a normal two-center two-electron ( $2 c-2 e$ ) covalent bond.

When the total number of valence electrons in a molecular skeleton is less than the number of valence orbitals, the formation of normal $2 c-2 e$ covalent

## Fig. 13.2.1.

A close-packed layer of interlinked icosahedra in the crystal structure of $\alpha$-rhomobohedral boron. The lines meeting at a node (not a B atom) represents a $\mathrm{BBB} 3 c-2 e$ bond linking three $\mathrm{B}_{12}$ icosahedra.

Fig. 13.2.2.

Fig. 13.2.3.
The BBB $3 c-2 e$ bond: (a) three atoms share an electron pair, and (b) simplified representation of $3 c-2 e$ bond.

bonds is not feasible. In this type of electron-deficient compound, three-center two-electron ( $3 c-2 e$ ) bonds generally occur, in which three atoms share an electron pair. Thus one $3 c-2 e$ bond serves to compensate for the shortfall of four electrons and corresponds to a bond valence value of 2, as illustrated for a BBB bond in Fig. 13.2.3.

In a closo- $\mathrm{B}_{n}$ skeleton, there are only three $2 c-2 e$ covalent bonds and $(n-2)$ BBB $3 c-2 e$ bonds. (This will be derived in Section 13.4.) For an icosahedral $\mathrm{B}_{12}$ unit, there are three $\mathrm{B}-\mathrm{B} 2 c-2 e$ bonds and ten BBB $3 c-2 e$ bonds, as shown in Fig. 13.2.4.

(b)

The 36 electrons in the $\mathrm{B}_{12}$ unit may be partitioned as follow: 26 electrons are used to form bonds within an icosahedron, and the remaining ten

(b)

electrons to form the intericosahedral bonds. In the structure of $\alpha-\mathrm{R} 12$ boron, each icosahedron is surrounded by six icosahedra in the same layer and forms six $3 c-2 e$ bonds [see Fig. 9.6.21(b)], in which every B atom contributes $2 / 3$ electron, so each icosahedron uses $6 \times 2 / 3=4$ electrons. Each icosahedron is bonded by normal $2 c-2 e \mathrm{~B}-\mathrm{B}$ bonds to six icosahedra in the upper and lower layers, which need six electrons. The number of bonding electrons in an icosahedron of $\alpha$-R12 boron is therefore $26+4+6=36$.

The $\beta$-R105 boron allotrope has a much more complex structure with 105 B atoms in the unit cell (space group $R \overline{3} m, a=1014.5 \mathrm{pm}, \alpha=65.28^{\circ}$ ). A basic building unit in the crystal structure is the $\mathrm{B}_{84}$ cluster illustrated in Fig. 13.2.5(a); it can be considered as a central $\mathrm{B}_{12 \mathrm{a}}$ icosahedron linked radially to $12 \mathrm{~B}_{6}$ half-icosahedra (or pentagonal pyramids), each attached like an inverted umbrella to an icosahedral vertex, as shown in Fig. 13.2.5(b).

The basal B atoms of adjacent pentagonal pyramids are interconnected to form a $\mathrm{B}_{60}$ icosahedron that resembles fullerene- $\mathrm{C}_{60}$. The large $\mathrm{B}_{60}$ icosahedron encloses the $B_{12 a}$ icosahedron, and the resulting $B_{84}$ cluster can be formulated as $B_{12 \mathrm{a}} @ \mathrm{~B}_{12} @ \mathrm{~B}_{60}$. Additionally, a six-coordinate B atom lies at the center of symmetry between two adjacent $\mathrm{B}_{10}$ condensed units, and the crystal structure is an intricate coordination network resulting from the linkage of $\mathrm{B}_{10}-\mathrm{B}-\mathrm{B}_{10}$ units and $\mathrm{B}_{84}$ clusters, such that all 105 atoms in the unit cell except one are the vertices of fused icosahedra. Further details and the electronic structure of $\beta$-R105 boron are described in Section 13.4.6.

Fig. 13.2.4.
Chemical bonds in the $\mathrm{B}_{12}$ icosahedron (one of many possible canonical forms): three $2 c-2 e$ bonds between $1-10,3-12$, and 5-11; ten BBB $3 c-2 e$ bonds between $1-2-7,2-3-7,3-4-9, \ldots$

Fig. 13.2.5.

Black circles represent the central $\mathrm{B}_{12 \mathrm{a}}$ icosahedron, shaded circles represent the $B$ atoms connecting the surface 60 B atoms to the central $B_{12 a}$ unit; (b) each vertex of inner $\mathrm{B}_{12 \mathrm{a}}$ is connected to a pentagonal pyramidal $\mathrm{B}_{6}$ unit (only two adjoining $\mathrm{B}_{6}$ units are shown).

### 13.3 Borides

Solid borides have high melting points, exceptionally high hardness, excellent wear resistance, and good immunity to chemical attack, which make them industrially important with uses as refractory materials and in rocket cones and turbine blades. Some metal borides have been found to exhibit superconductivity.

### 13.3.1 Metal borides

A large number of metal borides have been prepared and characterized. Several hundred binary metal borides $\mathrm{M}_{x} \mathrm{~B}_{y}$ are known. With increasing boron content, the number of $\mathrm{B}-\mathrm{B}$ bonds increases. In this manner, isolated B atoms, $\mathrm{B}-\mathrm{B}$ pairs, fragments of boron chains, single chains, double chains, branched chains, and hexagonal networks are formed, as illustrated in Fig. 13.3.1. Table 13.3.1 summarizes the stoichiometric formulas and structures of metal borides.

In boron-rich compounds, the structure can often be described in terms of a three-dimensional network of boron clusters (octahedra, icosahedra, and cubooctahedra), which are linked to one another directly or via non-cluster atoms.

The metal atoms are accommodated in cages between the octahedra or icosahedra, thereby providing external bonding electrons to the electron-deficient boron network.

The structures of some metal borides in Table 13.3.1 are discussed below.

## (1) $\mathbf{M g B}_{2}$ and $\mathrm{AlB}_{2}$

Magnesium boride $\mathrm{MgB}_{2}$ was discovered in 2001 to behave as a superconductor at $T_{\mathrm{c}}=39 \mathrm{~K}$, and its physical properties are similar to those of $\mathrm{Nb}_{3} \mathrm{Sn}$ used in the construction of high-field superconducting magnets in NMR spectrometers. $\mathrm{MgB}_{2}$ crystallizes in the hexagonal space group P6/mmm with $a=308.6$, $c=352.4 \mathrm{pm}$, and $Z=1$. The Mg atoms are arranged in a close-packed layer, and the B atoms form a graphite-like layer with a B-B bond length of $a /(3)^{1 / 2}=178.2 \mathrm{pm}$. These two kinds of layers are interleaved along the $c$ axis, as shown in Fig. 13.3.1(f). In the resulting crystal structure, each B atom is located inside a $\mathrm{Mg}_{6}$ trigonal prism, and each Mg atom is sandwiched between two planar hexagons of B atoms that constitute a $\mathrm{B}_{12}$ hexagonal prism, as illustrated in Fig. 13.3.2. $\mathrm{AlB}_{2}$ has the same crystal structure with a B-B bond length of 175 pm .

## (2) $\mathrm{LaB}_{4}$

Figure 13.3.3(a) shows a projection of the tetragonal structure of $\mathrm{LaB}_{4}$ along the $c$ axis. The chains of $\mathrm{B}_{6}$ octahedra are directly linked along the $c$ axis and joined laterally by pairs of $\mathrm{B}_{2}$ atoms in the $a b$ plane to form a three-dimensional skeleton. In addition, tunnels accommodating the La atoms run along the $c$ axis.

## (3) $\mathbf{C a B}_{6}$

The cubic hexaboride $\mathrm{CaB}_{6}$ consists of $\mathrm{B}_{6}$ octahedra, which are linked directly in all six orthogonal directions to give a rigid but open framework, and the Ca atoms occupy cages each surrounded by 24 B atoms, as shown in Fig. 13.3.3(b).

The number of valence electrons for a $\mathrm{B}_{6}$ unit can be counted as follows: six electrons are used to form six $B-B$ bonds between the $B_{6}$ units, and the closo $-\mathrm{B}_{6}$ skeleton is held by three $\mathrm{B}-\mathrm{B} 2 c-2 e$ bonds and four BBB $3 c-2 e$ bonds, which require 14 electrons. The total number is $6+14=20$ electrons per $B_{6}$ unit. Thus in the $\mathrm{CaB}_{6}$ structure each $\mathrm{B}_{6}$ unit requires the transfer of two electrons from metal atoms. However, the complete transfer of 2e per $\mathrm{B}_{6}$ unit is not mandatory for a three-dimensional crystal structure, and theoretical calculations for $\mathrm{MB}_{6}$ $(\mathrm{M}=\mathrm{Ca}, \mathrm{Sr}, \mathrm{Ba})$ indicate a net transfer of only 0.9 e to 1.0 e . This also explains

(b)

why metal-deficient phases $\mathrm{M}_{1-x} \mathrm{~B}_{6}$ remain stable and why the alkali metal K can also form a hexaboride.

## (4) High boron-rich metal borides

In high boron-rich metal borides, there are two types of $\mathrm{B}_{12}$ units in their crystal structures: one is cubo-octahedral $\mathrm{B}_{12}$ found in $\mathrm{YB}_{12}$, as shown in Fig. 13.3.4(a); the other is icosahedral $\mathrm{B}_{12}$ in $\mathrm{NaB}_{12}$, as shown in Fig. 13.3.4(b). These two structural types can be interconverted by small displacements of the B atoms. The arrows shown in Fig. 13.3.4(a) represent the directions of the displacements.

## (5) Rare-earth metal borides

The ionic radii of the rare-earth metals have a dominant effect on the structure types of their crystalline borides, as shown in Table 13.3.2.

The "radius" of the 24 -coordinate metal site in $\mathrm{MB}_{6}$ is too large ( $\mathrm{M}-\mathrm{B}$ distances are in the range of $215-25 \mathrm{pm}$ ) to be comfortably occupied by the later (smaller) lanthanide elements $\mathrm{Ho}, \mathrm{Er}, \mathrm{Tm}$, and Lu , and these elements form $\mathrm{MB}_{4}$ compounds instead, where the $\mathrm{M}-\mathrm{B}$ distances vary within the range of 185-200 pm.
$\mathrm{YB}_{66}$ crystallizes in space group $F m \overline{3} c$ with $a=2344 \mathrm{pm}$ and $Z=24$. The basic structural unit is a thirteen-icosahedra $\mathrm{B}_{156}$ giant cluster in which a central $B_{12}$ icosahedron is surrounded by twelve $B_{12}$ icosahedra; the $B-B$ bond distances within the icosahedra are $171.9-185.5 \mathrm{pm}$, and the intericosahedra

Table 13.3.2. Variation of structural types with the ionic radii of rare-earth metals

| Cation | radii $(\mathrm{pm})$ | Structural type |  |  |  |  |
| :--- | :---: | :---: | :---: | :---: | :---: | :---: |
|  |  |  | $\mathrm{YB}_{12}$ | $\mathrm{AlB}_{2}$ | $\mathrm{YB}_{66}$ | $\mathrm{ThB}_{4}$ |
|  |  |  | $\mathrm{CaB}_{6}$ |  |  |  |
| $\mathrm{Eu}^{2+}$ | 130 |  |  |  |  | + |
| $\mathrm{La}^{3+}$ | 116.0 |  |  |  | + | + |
| $\mathrm{Ce}^{3+}$ | 114.3 |  |  |  | + | + |

| $\mathrm{Ho}^{3+}$ | 101.5 | + | + | + | + |  |
| $\mathrm{Er}^{3+}$ | 100.4 | + | + | + | + |  |
| $\mathrm{Tm}^{3+}$ | 99.4 | + | + | + | + |  |
| $\mathrm{Yb}^{3+}$ | 98.5 | + | + | + | + |  |
| $\mathrm{Lu}^{3+}$ | 97.7 | + | + | + | + |  |

distances vary between 162.4 and 182.3 pm . Packing of the eight $\mathrm{B}_{12} \subset\left(\mathrm{~B}_{12}\right)_{12}$ giant clusters in the unit cell generates channels and non-icosahedral bulges that accommodate the remaining 336 boron atoms in a statistical distribution. The yttrium atom is coordinated by twelve boron atoms belonging to four icosahedral faces and up to eight boron atoms located within a bulge.

### 13.3.2 Non-metal borides

Boron forms a large number of non-metal borides with oxygen and other nonmetallic elements. The principal oxide of boron is boric oxide, $\mathrm{B}_{2} \mathrm{O}_{3}$. Fused $\mathrm{B}_{2} \mathrm{O}_{3}$ readily dissolves many metal oxides to give borate glasses. Its major application is in the glass industry, where borosilicate glasses find extensive use because of their small coefficient of thermal expansion and easy workability. Borosilicate glasses include Pyrex glass, which is used to manufacture most laboratory glassware. The chemistry of borates and related oxo complexes will be discussed in Section 13.5.

## (1) Boron carbides and related compounds

The potential usefulness of boron carbides has prompted intensive studies of the system $\mathrm{B}_{1-x} \mathrm{C}_{x}$ with $0.1 \leq x \leq 0.2$. The carbides of composition $\mathrm{B}_{13} \mathrm{C}_{2}$ and $\mathrm{B}_{4} \mathrm{C}$, as well as the related compounds $\mathrm{B}_{12} \mathrm{P}_{2}$ and $\mathrm{B}_{12} \mathrm{As}_{2}$, all crystallize in the rhombohedral space group $R \overline{3} m$. The structure of $\mathrm{B}_{13} \mathrm{C}_{2}$ is derived from $\alpha-\mathrm{R} 12$ boron with the addition of a linear $\mathrm{C}-\mathrm{B}-\mathrm{C}$ linking group along the [111] direction, as shown in Fig. 13.3.5. The structure of $\mathrm{B}_{4} \mathrm{C}(a=520 \mathrm{pm}, \alpha=$ $66^{\circ}$ ) has been shown to be $\mathrm{B}_{11} \mathrm{C}(\mathrm{CBC})$ rather than $\mathrm{B}_{12}(\mathrm{CCC})$, with statistical distribution of a C atom over the vertices of the $\mathrm{B}_{11} \mathrm{C}$ icosahedron. For boron phosphide and boron arsenide, a two-atom P-P or As-As link replaces the three-atom chain in the carbides.

## (2) Boron nitrides

The common form of BN has an ordered layer structure containing hexagonal rings, as shown in Fig. 13.3.6(a). The layers are arranged so that a $B$ atom in one layer lies directly over a N atom in the next, and vice versa. The $\mathrm{B}-\mathrm{N}$ distance within a layer is 145 pm , which is shorter than the distance of 157 pm for a $\mathrm{B}-\mathrm{N}$ single bond, implying the presence of $\pi$-bonding. The interlayer distance of 330 pm is consistent with van der Waals interactions. Boron nitride is a good lubricant that resembles graphite. However, unlike graphite, BN is white and an electrical insulator. This difference can be interpreted in terms of band theory, as the band gap in boron nitride is considerably greater than that in graphite because of the polarity of the $\mathrm{B}-\mathrm{N}$ bond.

Fig. 13.3.6.
Structures of BN: (a) graphite-like; (b) diamond-like (borazon).

(b)

Heating the layered form of BN at $\sim 2000 \mathrm{~K}$ and $>50$ kbar pressure in the presence of a catalytic amount of $\mathrm{Li}_{3} \mathrm{~N}$ or $\mathrm{Mg}_{3} \mathrm{~N}_{2}$ converts it into a more dense polymorph with the zinc blende structure, as shown in Fig. 13.3.6(b). This cubic form of BN is called borazon, which has a hardness almost equal to that of diamond and is used as an abrasive.
As the BN unit is isoelectronic with $\mathrm{C}_{2}$ fragment, replacement of the latter by the former in various organic compounds leads to azaborane structural analogs. Some examples are shown below. Planar borazine (or borazole) $\mathrm{B}_{3} \mathrm{~N}_{3} \mathrm{H}_{6}$ is stabilized by $\pi$-delocalization, but it is much more reactive than benzene in view of the partial positive and negative charges on the N and B atoms, respectively.

## (3) Boron halides

Boron forms numerous binary halides, of which the monomeric trihalides $\mathrm{BX}_{3}$ are volatile and highly reactive. These planar molecules differ from aluminum halides, which form $\mathrm{Al}_{2} \mathrm{X}_{6}$ dimers with a complete valence octet on Al . The difference between $B X_{3}$ and $A l_{2} X_{6}$ is due to the smallness of the $B$ atom. The B atom uses its $\mathrm{sp}^{2}$ hybrid orbitals to form $\sigma$ bonds with the X atoms, leaving the remaining empty $2 p_{z}$ orbital to overlap with three filled $p_{z}$ orbitals of the X atoms. This generates delocalized $\pi$ orbitals, three of which are filled with electrons. Thus there is some double-bond character in the $\mathrm{B}-\mathrm{X}$ bonding that stabilizes the planar monomer. Table 13.3.3 lists some physical properties of $\mathrm{BX}_{3}$ molecules. The energy of the $\mathrm{B}-\mathrm{F}$ bond in $\mathrm{BF}_{3}$ is $645 \mathrm{~kJ} \mathrm{~mol}^{-1}$, which is consistent with its multiple-bond character.

All $\mathrm{BX}_{3}$ compounds behave as Lewis acids, the strength of which is determined by the strength of the aforementioned delocalized $\pi$ bonding; the stronger it is, the molecule more easily retains its planar configuration and the acid strength is weaker. Because of the steadily weakening of $\pi$ bonding in going from $\mathrm{BF}_{3}$ to $\mathrm{BI}_{3}, \mathrm{BF}_{3}$ is a weaker acid and $\mathrm{BI}_{3}$ is stronger. This order is the reverse of that predicated when the electronegativity and size of the halogens are considered: the high electronegativity of fluorine could be expected to make $\mathrm{BF}_{3}$ more receptive to receiving a lone pair from a Lewis base, and the small size of fluorine would least inhibit the donor's approach to the boron atom.

Salts of tetrafluoroborate, $\mathrm{BF}_{4}^{-}$, are readily formed by adding a suitable metal fluoride to $\mathrm{BF}_{3}$. There is a significant lengthening of the $\mathrm{B}-\mathrm{F}$ bond from 130 pm in planar $\mathrm{BF}_{3}$ to 145 pm in tetrahedral $\mathrm{BF}_{4}^{-}$.

Among the boron halides, $\mathrm{B}_{4} \mathrm{Cl}_{4}$ is of interest as both $\mathrm{B}_{4} \mathrm{H}_{4}$ and $\mathrm{B}_{4} \mathrm{H}_{4}^{2-}$ do not exist. Figure 13.3 .7 shows the molecular structure of $\mathrm{B}_{4} \mathrm{Cl}_{4}$, which has a tetrahedral $\mathrm{B}_{4}$ core consolidated by four terminal $\mathrm{B}-\mathrm{Cl} 2 c-2 e$ bonds and four BBB $3 c-2 e$ bonds on four faces. This structure is further stabilized by $\sigma-\pi$ interactions between the lonepairs of Cl atoms and BBB $3 c-2 e$ bonds. The

## Structural Chemistry of Selected Elements

bond length of $\mathrm{B}-\mathrm{Cl}$ is 170 pm , corresponding to a single bond, and the bond length of $\mathrm{B}-\mathrm{B}$ is also 170 pm .

### 13.4 Boranes and carboranes

### 13.4.1 Molecular structure and bonding

Boranes and carboranes are electron-deficient compounds with interesting molecular geometries and characteristic bonding features.

## (1) Molecular structure of boranes and carboranes

Figures 13.4.1 and 13.4.2 show the structures of some boranes and carboranes, respectively, that have been established by X-ray and electron diffraction methods.

(c)

Fig. 13.4.3.
The $3 c-2 e$ BHB bond: (a) orbitals overlap, (b) relative energies, and (c) simple representation.

## (2) Bonding in boranes

In simple covalent bonding theory, there are four bonding types in boranes: (a) normal $2 c-2 e \mathrm{~B}-\mathrm{B}$ bond, (b) normal $2 c-2 e \mathrm{~B}-\mathrm{H}$ bond, (c) $3 c-2 e \mathrm{BBB}$ bond (described in Fig. 13.2.4), and (d) $3 c-2 e$ BHB bond.

The $3 c-2 e$ BHB bond is constructed from two orbitals of $\mathrm{B}_{1}$ and $\mathrm{B}_{2}$ atoms ( $\psi_{\mathrm{B}_{1}}$ and $\psi_{\mathrm{B}_{2}}$, which are sp ${ }^{x}$ hybrids) and $\psi_{\mathrm{H}}$ (1s orbital) of the H atom. The combinations of these three atomic orbitals result in three molecular orbitals:

$$
\begin{aligned}
& \psi_{1}=\frac{1}{2} \psi_{\mathrm{B}_{1}}+\frac{1}{2} \psi_{\mathrm{B}_{2}}+\frac{1}{(2)^{1 / 2}} \psi_{\mathrm{H}} \\
& \psi_{2}=\frac{1}{(2)^{1 / 2}}\left(\psi_{\mathrm{B}_{1}}-\psi_{\mathrm{B}_{2}}\right) \\
& \psi_{3}=\frac{1}{2} \psi_{\mathrm{B}_{1}}+\frac{1}{2} \psi_{\mathrm{B}_{2}}-\frac{1}{(2)^{1 / 2}} \psi_{\mathrm{H}} .
\end{aligned}
$$

The orbital overlaps and relative energies are illustrated in Fig. 13.4.3. Note that $\psi_{1}, \psi_{2}$, and $\psi_{3}$ are bonding, nonbonding, and antibonding molecular orbitals, respectively. For the $3 c-2 e \mathrm{BHB}$ bond, only $\psi_{1}$ is filled with electrons.

## (3) Topological description of boranes

The overall bonding in borane molecules or anions is sometimes represented by a 4-digit code introduced by Lipscomb, the so-called styx number, where $s$ is the number of $3 c-2 e$ BHB bonds, $t$ is the number of $3 c-2 e \mathrm{BBB}$ bonds, $y$ is the number of normal $\mathrm{B}-\mathrm{B}$ bonds, and $x$ is the number of $\mathrm{BH}_{2}$ groups.

$s$

$t$

$y$
y
$x$

The molecular structural formulas of some boranes and their styx codes are shown in Fig. 13.4.4.

Fig. 13.4.4.
Molecular structural formulas and styx codes of some boranes.

$\mathrm{B}_{6} \mathrm{H}_{10}$ 4220

6122

The following simple rules must hold for the borane structures:
(a) Each B atom has at least a terminal H atom attached to it.
(b) Every pair of boron atoms which are geometric neighbors must be connected by a B-B, BHB, or BBB bond.
(c) Every boron atom uses four valence orbitals in bonding to achieve an octet configuration.
(d) No two boron atoms may be bonded together by both $2 c-2 e \mathrm{~B}-\mathrm{B}$ and $3 c-2 e$ BBB bonds, or by both $2 c-2 e \mathrm{~B}-\mathrm{B}$ and $3 c-2 e$ BHB bonds.

### 13.4.2 Bond valence in molecular skeletons

The geometry of a molecule is related to the number of valence electrons in it. According to the valence bond theory, organic and borane molecules composed of main-group elements owe their stability to the filling of all four valence orbitals ( $n$ s and $n \mathrm{p}$ ) of each atom, with eight valence electrons provided by the atom and those bonded to it. Likewise, transition-metal compounds achieve stability by filling the nine valence orbitals $[(n-1) \mathrm{d}, n \mathrm{~s}$, and $n \mathrm{p}]$ of each transition-metal atom with 18 electrons provided by the metal atom and the surrounding ligands. In molecular orbital language, the octet and 18-electron rules are rationalized in terms of the filling of all bonding and nonbonding molecular orbitals and the existence of a large HOMO-LUMO energy gap.

Consider a molecular skeleton composed of $n$ main-group atoms, $\mathrm{M}_{n}$, which takes the form of a chain, ring, cage, or framework. Let $g$ be the total number of valence electrons of the molecular skeleton. When a covalent bond is formed between two M atoms, each of them effectively gains one electron in its valence shell. In order to satisfy the octet rule for the whole skeleton, $\frac{1}{2}(8 n-g)$ electron pairs must be involved in bonding between the M atoms. The number of these bonding electron pairs is defined as the "bond valence" $b$ of the molecular skeleton:

$$
\begin{equation*}
b=\frac{1}{2}(8 n-g) . \tag{13.4.1}
\end{equation*}
$$

When the total number of valence electrons in a molecular skeleton is less than the number of valence orbitals, the formation of normal $2 c-2 e$ covalent bonds is insufficient to compensate for the lack of electrons. In this type of electron-deficient compound there are usually found $3 c-2 e$ bonds, in which three atoms share an electron pair. Thus one $3 c-2 e$ bond serves to compensate for the lack of four electrons and corresponds to a bond valence value of 2 , as discussed in 13.2.

There is an enormous number of compounds that possess metal-metal bonds. A metal cluster may be defined as a polynuclear compound in which there are substantial and directed bonds between the metal atoms. The metal atoms of a cluster are also referred to as skeletal atoms, and the remaining non-metal atoms and groups are considered as ligands.

According to the 18 -electron rule, the bond valence of a transition metal cluster is

$$
\begin{equation*}
b=\frac{1}{2}(18 n-g) . \tag{13.4.2}
\end{equation*}
$$

If the bond valence $b$ calculated from (13.4.1) and (13.4.2) for a cluster $\mathrm{M}_{n}$ matches the number of connecting lines drawn between pairs of adjacent atoms in a conventional valence bond structural formula, the cluster is termed "electron-precise."

For a molecular skeleton consists of $n_{1}$ transition-metal atoms and $n_{2}$ maingroup atoms, such as transition-metal carboranes, its bond valence is

$$
\begin{equation*}
b=\frac{1}{2}\left(18 n_{1}+8 n_{2}-g\right) . \tag{13.4.3}
\end{equation*}
$$

The bond valence $b$ of a molecular skeleton can be calculated from expressions (13.4.1) to (13.4.3), in which $g$ represents the total number of valence electrons in the system. The $g$ value is the sum of:
(1) the number of valence electrons of the $n$ atoms that constitute the molecular skeleton $\mathrm{M}_{n}$,
(2) the number of electrons donated by the ligands to $\mathrm{M}_{n}$, and
(3) the number of net positive or negative charges carried by $\mathrm{M}_{n}$, if any.

The simplest way to count the $g$ value is to start from uncharged skeletal atoms and uncharged ligands. Ligands such as $\mathrm{NH}_{3}, \mathrm{PR}_{3}$, and CO each supply two electrons. Non-bridging halogen atoms, H atom, and $\mathrm{CR}_{3}$ and $\mathrm{SiR}_{3}$ groups are one-electron donors. A $\mu_{2}$-bridging halogen atom contributes three electrons, and a $\mu_{3}$ bridging halogen atom donates five electrons. Table 13.4.1 lists the number of electrons contributed by various ligands, depending on their coordination modes.

### 13.4.3 Wade's rules

For boranes and carboranes, the terms closo, nido, arachno, and hypho are used to describe their molecular skeletons with reference to a series of increasingly open deltahedra. Boranes of the nido, arachno, and hypho types are compounds based on formulas $\mathrm{B}_{n} \mathrm{H}_{n+4}, \mathrm{~B}_{n} \mathrm{H}_{n+6}$, and $\mathrm{B}_{n} \mathrm{H}_{n+8}$, respectively. The structures

Stuctural Chemitry of Selected
of nido-boranes are analogous to the corresponding closo compounds with the exception that one vertex is missing. For example, in $\mathrm{B}_{5} \mathrm{H}_{9}$, five B atoms are located at the vertices of an octahedron whereas the sixth vertex is empty. Likewise, the arrangement of $n$ skeletal atoms of arachno compounds is referred to a deltahedron having ( $n+2$ ) vertices; for instance, the B atoms in $\mathrm{B}_{4} \mathrm{H}_{10}$ lie at four vertices of an octahedron in which two adjacent vertices are not occupied. For hypothetical $\mathrm{B}_{n} \mathrm{H}_{n+8}$ and its isoelectronic equivalent $\mathrm{B}_{n} \mathrm{H}_{n+6}{ }^{2-}$, the cluster skeleton is a $n$-vertex deltahedron with three missing vertices.

Figure 13.4.5 shows the relations between (a) closo- $\mathrm{B}_{7} \mathrm{H}_{7}^{2-}$, (b) nido- $\mathrm{B}_{6} \mathrm{H}_{10}$, and (c) arachno- $\mathrm{B}_{5} \mathrm{H}_{11}$. The structure of closo- $\mathrm{B}_{7} \mathrm{H}_{7}^{2-}$ is a pentagonal bipyramid. In nido $-\mathrm{B}_{6} \mathrm{H}_{10}$, the B atoms are located at six vertices of the pentagonal bipyramid, and one vertex on the $C_{5}$ axis is not occupied. In arachno- $\mathrm{B}_{5} \mathrm{H}_{11}$, two vertices of the pentagonal bipyramid, one axial and one equatorial, are not occupied.

Historically, a scheme of skeletal electron-counting was developed to rationalize the structures of boranes and their derivatives, to which the following Wade's rules are applicable.

(b)

Fig. 13.4.6.
Molecular structures of some hypho cluster systems: (a) $\mathrm{B}_{5} \mathrm{H}_{9}\left(\mathrm{PMe}_{3}\right)_{2}$; (b) $\left(\mathrm{NCCH}_{2}\right) \mathrm{C}_{3} \mathrm{~B}_{6} \mathrm{H}_{12}^{-}$; (c) $\left[\mu^{2}-\left\{\mathrm{C}(\mathrm{CN})_{2}\right\}_{2}\right] \mathrm{C}_{2} \mathrm{~B}_{7} \mathrm{H}_{12}^{-}$. In carboranes (b) and (c), for clarity only bridging and extra H atoms are included, and all exo H atoms attached to the vertices are omitted.
(1) A closo-deltahedral cluster with $n$ vertices is held together by $(n+1)$ bonding electron pairs.
(2) A nido-deltahedral cluster with $n$ vertices is held together by $(n+2)$ bonding electron pairs.
(3) An arachno-deltahedral cluster with $n$ vertices is held together by $(n+3)$ bonding electron pairs.
(4) A hypho-deltahedral cluster with $n$ vertices is held together by $(n+4)$ bonding electron pairs.

Boranes and carboranes of the hypho type are quite rare. The prototype hypho-borane $\mathrm{B}_{5} \mathrm{H}_{11}^{2-}$ has been isolated, and its proposed structure is analogous to that of the isoelectronic analog $\mathrm{B}_{5} \mathrm{H}_{9}\left(\mathrm{PMe}_{3}\right)_{2}$ (Fig. 13.4.6(a)), which was established by X-ray crystallography. The 9-vertex hypho tricarbaborane cluster anion $\left(\mathrm{NCCH}_{2}\right)-1,2,5-\mathrm{C}_{3} \mathrm{~B}_{6} \mathrm{H}_{12}{ }^{-}$shown in Fig. 13.4.6(b) has 13 skeletal pairs, and accordingly it may be considered as derived from an icosahedron with three missing vertices. Similarly, in endo-6-endo-7-[ $\left.\mu^{2}-\left\{\mathrm{C}(\mathrm{CN})_{2}\right\}_{2}\right]$-arachno-$6,8-\mathrm{C}_{2} \mathrm{~B}_{7} \mathrm{H}_{12}^{-}$[Fig. 13.4.6(c)], the $\mathrm{C}_{2} \mathrm{~B}_{7}$-fragment of the cluster anion can be viewed as a 13 -electron pair, 9 -vertex hypo system with an exo-polyhedral TCNE substituent bridging a C atom and $\mathrm{a} B$ atom at the open side.

### 13.4.4 Chemical bonding in closo-boranes

Boranes of the general formula $\mathrm{B}_{n} \mathrm{H}_{n}^{2-}$ and isoelectronic carboranes such as $\mathrm{CB}_{n-1} \mathrm{H}_{n}^{-}$and $\mathrm{C}_{2} \mathrm{~B}_{n-2} \mathrm{H}_{n}$ have closo structures, in which $n$ skeletal B and C atoms are located at the vertices of a polyhedron bounded by trianglular faces (deltahedron). For the $\mathrm{B}_{n} \mathrm{H}_{n}^{2-}$ closo-boranes

$$
\begin{equation*}
b=\frac{1}{2}[8 n-(4 n+2)]=2 n-1 \tag{13.4.4}
\end{equation*}
$$

From the geometrical structures of closo-boranes, $s$ and $x$ of the styx code are both equal to 0 . Each $3 c-2 e$ BBB bond has a bond valence value of 2 . Thus,

$$
\begin{equation*}
b=2 t+y \tag{13.4.5}
\end{equation*}
$$

## Structural Chemistry of Selected Elements

Combining expressions (13.4.4) and (13.4.5) leads to

$$
\begin{equation*}
2 t+y=2 n-1 \tag{13.4.6}
\end{equation*}
$$

When the number of electron pairs of the molecular skeleton is counted, one gets

$$
\begin{equation*}
t+y=n+1 \tag{13.4.7}
\end{equation*}
$$

Hence from (13.4.6) and (13.4.7),

$$
\begin{align*}
& t=n-2,  \tag{13.4.8}\\
& y=3, \tag{13.4.9}
\end{align*}
$$

so that each closo-borane $\mathrm{B}_{n} \mathrm{H}_{n}^{2-}$ has exactly three $\mathrm{B}-\mathrm{B}$ bonds in its valence bond structural formula.

Table 13.4.2. Bond valence and other parameters for $\mathrm{B}_{n} \mathrm{H}_{n}^{2-}$

| $n$ in $\mathrm{B}_{n} \mathrm{H}_{n}^{2-}$ | sty $x$ <br> code | Bond valence <br> $b$ | No. of <br> edges $=3 t$ | No. of <br> faces $=2 t$ | $t+y$ (No. of <br> skeletal electron pairs) |
| :--- | :---: | :---: | :---: | :---: | :---: |
| 5 | 0330 | 9 | 9 | 6 | 6 |
| 6 | 0430 | 11 | 12 | 8 | 7 |
| 7 | 0530 | 13 | 15 | 10 | 8 |
| 8 | 0630 | 15 | 18 | 12 | 9 |
| 9 | 0730 | 17 | 21 | 14 | 10 |
| 10 | 0830 | 19 | 24 | 16 | 11 |
| 11 | 0930 | 21 | 27 | 18 | 12 |
| 12 | $0,10,3,0$ | 23 | 30 | 20 | 13 |

Table 13.4.2 lists the bond valence of $\mathrm{B}_{n} \mathrm{H}_{n}^{2-}$ and other parameters; $n$ starts from 5, not from 4, as $\mathrm{B}_{4} \mathrm{H}_{4}{ }^{2-}$ would need $t=2$ and $y=3$, which cannot satisfy rule (d) for a tetrahedron. Figure 13.4 .7 shows the localized bonding

description (in one canonical form) for some closo-boranes. The charge of -2 in $\mathrm{B}_{n} \mathrm{H}_{n}^{2-}$ is required for consolidating the $n \mathrm{BH}$ units into a deltahedron. Except for $\mathrm{B}_{5} \mathrm{H}_{5}^{2-}$, the bond valence $b$ is always smaller than the number of edges of the polyhedron.

In the $\mathrm{B}_{n}$ skeleton of closo-boranes, there are $(n-2) 3 c-2 e$ BBB bonds and three normal $\mathrm{B}-\mathrm{B}$ bonds, which amounts to $(n-2)+3=n+1$ electron pairs.

Some isoelectronic species of $\mathrm{C}_{2} \mathrm{~B}_{10} \mathrm{H}_{12}$, such as $\mathrm{CB}_{11} \mathrm{H}_{12}^{-}$, $\mathrm{NB}_{11} \mathrm{H}_{12}$, and their derivatives, are known. Since they have the same number of skeletal atoms and the same bond valence, these compounds are isostructural.

### 13.4.5 Chemical bonding in nido- and arachno-boranes

Using the styx code and bond valence to describe the structures of nido-boranes or carboranes, the bond valence $b$ is equal to

$$
\begin{align*}
b & =\frac{1}{2}[8 n-(4 n+4)]=2 n-2,  \tag{13.4.10}\\
b & =s+2 t+y \tag{13.4.11}
\end{align*}
$$

Combining expressions (13.4.10) and (13.4.11) leads to

$$
\begin{equation*}
s+2 t+y=2 n-2 \tag{13.4.12}
\end{equation*}
$$

The number of valence electron pairs for nido $\mathrm{B}_{n} \mathrm{H}_{n+4}$ is equal to $\frac{1}{2}(4 n+4)=$ $2 n+2$, in which $n+4$ pairs are used to form $\mathrm{B}-\mathrm{H}$ bonds and the remaining electron pairs used to form $2 c-2 e \mathrm{~B}-\mathrm{B}$ bonds $(y)$ and $3 c-2 e \mathrm{BBB}$ bonds $(t)$. Thus,

$$
\begin{equation*}
t+y=(2 n+2)-(n+4)=n-2 \tag{13.4.13}
\end{equation*}
$$

The number of each bond type in nido $-\mathrm{B}_{n} \mathrm{H}_{n+4}$ are obtained from expressions (13.4.12) and (13.4.13):

$$
\begin{align*}
& t=n-s,  \tag{13.4.14}\\
& y=s-2,  \tag{13.4.15}\\
& x+s=4 . \tag{13.4.16}
\end{align*}
$$

The stability of a molecular species with open skeleton may be strengthened by forming $3 c-2 e$ bond(s). In a stable nido-borane, neighboring $\mathrm{H}-\mathrm{B}-\mathrm{H}$ and B-H groups always tend to be converted into the $\mathrm{H}-\mathrm{BHB}-\mathrm{H}$ system:

## Structural Chemistry of Selected Elements

Table 13.4.3. The styx codes of some nido-boranes

|  | Borane |  |  |  |  |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
|  | $\mathrm{B}_{4} \mathrm{H}_{8}$ | $\mathrm{~B}_{5} \mathrm{H}_{9}$ | $\mathrm{~B}_{6} \mathrm{H}_{10}$ | $\mathrm{~B}_{7} \mathrm{H}_{11}$ | $\mathrm{~B}_{8} \mathrm{H}_{12}$ | $\mathrm{~B}_{9} \mathrm{H}_{13}$ | $\mathrm{~B}_{10} \mathrm{H}_{14}$ |
| $s$ | 4 | 4 | 4 | 4 | 4 | 4 | 4 |
| $t$ | 0 | 1 | 2 | 3 | 4 | 5 | 6 |
| $y$ | 2 | 2 | 2 | 2 | 2 | 2 | 2 |
| $x$ | 0 | 0 | 0 | 0 | 0 | 0 | 0 |
| $b=s+2 t+y$ | 6 | 8 | 10 | 12 | 14 | 16 | 18 |

Thus, in nido-borane, $x=0, s=4$, and

$$
\begin{align*}
t & =n-4  \tag{13.4.17}\\
y & =2 \tag{13.4.18}
\end{align*}
$$

Table 13.4.3 lists the styx code and bond valence of some nido-boranes, and Fig. 13.4.8 shows the chemical bonding in their skeletons.
(a)

(d)

(c)

(e)

For the arachno-boranes, $\mathrm{B}_{n} \mathrm{H}_{n+6}$, the relations between styx code and $n$ are as follows:

$$
\begin{align*}
t & =n-s  \tag{13.4.19}\\
y & =s-3  \tag{13.4.20}\\
x+s & =6 . \tag{13.4.21}
\end{align*}
$$

According to the octet and 18 -electron rules, when one C atom replaces one BH group in a borane, the $g$ value and $b$ value are unchanged, and the structure

(e)

Fig. 13.4.9.
Structures of corresponding boranes, carboranes, and metalloboranes having the same bond valence: (a) $\mathrm{B}_{5} \mathrm{H}_{9}$, (b) $\mathrm{CB}_{4} \mathrm{H}_{8}$, and (c) $\mathrm{B}_{3} \mathrm{H}_{7}\left[\mathrm{Fe}(\mathrm{CO})_{3}\right]_{2}$, $b=8$; (d) $\mathrm{B}_{6} \mathrm{H}_{10}$, (e) $\mathrm{CB}_{5} \mathrm{H}_{9}$, and (f) $\mathrm{B}_{5} \mathrm{H}_{8} \operatorname{Ir}(\mathrm{CO})\left(\mathrm{PPh}_{3}\right)_{2}, b=10$.
of the carborane is the same as that of the borane. Likewise, when one transitionmetal atom replaces one BH group, the bond valence counting of (13.4.3) also remains unchanged. Figure 13.4.9 shows two series of compounds, which have the same $b$ value in each series.

### 13.4.6 Electron-counting scheme for macropolyhedral boranes: mno rule

A generalized electron-counting scheme, known as the mno rule, is applicable to a wide range of polycondensed polyhedral boranes and heteroboranes, metallaboranes, metallocenes, and any of their combinations. According to this mno rule, the number of electron pairs $N$ necessary for a macropolyhedral system to be stable is

$$
N=m+n+o+p-q,
$$

where
$m=$ the number of polyhedra,
$n=$ the number of vertices,
$o=$ the number of single-vertex-sharing connections,
$p=$ the number of missing vertices, and
$q=$ the number of capping vertices.
For a closo macropolyhedral borane cluster, the rule giving the required number of electron pairs is $N=m+n$.

Some examples illustrating the application of the mno rule are given in Table 13.4.4, which makes reference to the structures of compounds shown in Fig. 13.4.10.
$\mathrm{B}_{20} \mathrm{H}_{16}$ is composed of two polyhedra sharing four atoms. The $(m+n)$ electron pair count is $2+20=22$, which is appropriate for a closo structure stabilized by 22 skeletal electron pairs ( 16 from 16 BH groups and 6 from four B

Table 13.4.4. Application of the mno rule for electron counting in some condensed polyhedral boranes and related compounds*

* $\mathrm{BH}=$ number of electron pairs from BH groups, $\mathrm{B}=$ number of electron pairs from B atoms, $\mathrm{CH}=$ number of electron pairs from CH groups, $\alpha=$ number of electron pairs from metal center( s ), $\beta=$ number of electron pairs from main-group hetero atom, $\mathrm{H}_{\mathrm{b}}=$ number of electron pairs from bridging hydrogen atoms, $x=$ number of electron pairs from the charge. Also, BH (or CH) can be replaced by BR (or CR).
atoms). In $\left(\mathrm{C}_{2} \mathrm{~B}_{10} \mathrm{H}_{11}\right)_{2}$, which consists of two icosahedral units connected by a $\mathrm{B}-\mathrm{B}$ single bond, the electron count is simply twice that of a single polyhedron. The 26 skeletal electron pairs are provided by 18 BH groups (18 pairs), 2 B atoms ( 2 pairs, $\mathrm{B}-\mathrm{B}$ bond not involved in cluster bonding), and 4 CH groups ( 6 pairs, 3 electrons from each CH group). The structure of $\left[\left(\mathrm{C}_{2} \mathrm{~B}_{9} \mathrm{H}_{11}\right)_{2} \mathrm{Al}\right]^{-}$is constructed from condensation of two icosahedra through a common vertex. The required skeletal electron pairs are contributed by 18 BH groups ( 18 pairs), 4 CH groups ( 6 pairs), the Al atom ( 1.5 pairs), and the anionic charge ( 0.5 pair). The polyhedral borane anion $\mathrm{B}_{21} \mathrm{H}_{18}{ }^{-}$has a shared triangular face. Its 18 BH groups, 3 B atoms, and the negative charge provide $18+4.5+0.5=23$ skeletal pairs, which fit the $m n o$ rule with $m+n=2+21$. For ferrocene, which has 16 electron pairs ( 15 from 10 CH groups and 1 from Fe ), the $m n o$ rule suggests a molecular skeleton with two open (nido) faces ( $m+n+o+p=2+11+1+2=16$ ). The metalloborane $\left[\mathrm{Cp}^{*} \operatorname{IrB}_{18} \mathrm{H}_{20}\right.$ ] is condensed from three nido units. The mno rule gives 31 electron pairs, and the molecular skeleton is stabilized by electron pairs from 15 BH groups (15), 5 CH groups (7.5), 3 shared B atoms (4.5), 5 bridging H atoms (2.5), and the $\operatorname{Ir}$ atom $\left[\frac{1}{2}(9-6)\right]=1.5 ; 6$ electrons occupying 3 nonbonding metal orbitals]. Addition of a sulfur atom as a vertex to the above cluster leads to $\left[\mathrm{Cp}^{*} \mathrm{IrB}_{18} \mathrm{H}_{19} \mathrm{~S}\right]^{-}$, which requires 32 electron pairs. The electrons are supplied by the S atom (4 electrons, as the other 2 valence electrons occupy an exo-cluster orbital), 16 BH groups, 2 shared B atoms, 3 bridging H atoms, the Ir atom, and the negative charge. The cluster compound $\left[\mathrm{Cp}_{2}^{*} \mathrm{Rh}_{2} \mathrm{~S}_{2} \mathrm{~B}_{15} \mathrm{H}_{14}(\mathrm{OH})\right]$ contains a nido $\left\{\mathrm{RhSB}_{8} \mathrm{H}_{7}\right\}$ unit and an arachno $\left\{\mathrm{RhSB}_{9} \mathrm{H}_{8}(\mathrm{OH})\right\}$ unit conjoined by a common $\mathrm{B}-\mathrm{B}$ edge. The mno rule leads to 40 electron pairs, which are supplied by 13 BH groups (13), 2 B atoms (3), 10 CH groups (15), 4 bridging H atoms (2), 2 Rh atoms (3), and 2 S atoms (4). In the structure of $(\mathrm{CpCo})_{3} \mathrm{~B}_{4} \mathrm{H}_{4}, 1 \mathrm{~B}$ atom caps the $\mathrm{Co}_{3}$ face of a $\mathrm{Co}_{3} \mathrm{~B}_{3}$ octahedron, and the 31 electron pairs are supplied by 4 BH groups (4), 15 CH groups (22.5), and 3 Co atoms (4.5).

(The Me group of $\mathrm{Cp}^{*}$ and H atoms is not shown.)

### 13.4.7 Electronic structure of $\beta$-rhombohedral boron

In Section 13.2 and Fig. 13.2.5, the structure of $\beta$-R105 boron is described in terms of large $\mathrm{B}_{84}\left(\mathrm{~B}_{12 \mathrm{a}} @ \mathrm{~B}_{12} @ \mathrm{~B}_{60}\right)$ clusters and $\mathrm{B}_{10}-\mathrm{B}-\mathrm{B}_{10}$ units. Each $\mathrm{B}_{10}$ unit of $C_{3 \mathrm{v}}$ symmetry is fused with three $\mathrm{B}_{6}$ half-icosahedra from three adjacent $\mathrm{B}_{84}$ clusters, forming a $\mathrm{B}_{28}$ cluster composed of four fused icosahedra, as shown in Fig. 13.4.11(a). A pair of such $\mathrm{B}_{28}$ clusters are connected by a six-coordinate $B$ atom to form a $B_{57}\left(B_{28}-B-B_{28}\right)$ unit.
To understand the subtlety and electronic structure of the complex covalent network of $\beta$ - R 105 boron, it is useful to view the contents of the unit cell [Fig. 13.4.11(b)] as assembled from $B_{12 a}$ (at the center of a $B_{84}$ cluster) and $B_{57}$ (lying on a $C_{3}$ axis) fragments connected by $2 c-2 e$ bonds.

The electronic requirement of the $\mathrm{B}_{57}$ unit can be assessed by saturating the dangling valencies with hydrogen atoms, yielding the molecule $\mathrm{B}_{57} \mathrm{H}_{36}$. According to the mno rule, $8+57+1=66$ electron pairs are required for stability, but the number available is 67.5 [ 36 (from 36 BH$)+(21 \times 3) / 2$ (from 21B)]. Thus the $\mathrm{B}_{57} \mathrm{H}_{36}$ polyhedral skeleton needs to get rid of three electrons to achieve stability, whereas the $\mathrm{B}_{12 \mathrm{a}} \mathrm{H}_{12}$ skeleton requires two additional electrons for sufficiency. As the unit cell contains four $\mathrm{B}_{12 \mathrm{a}}$ and one $\mathrm{B}_{57}$ fragments, the idealized structure of $\beta$-rhombohedral boron has a net deficiency of five electrons.

Fig. 13.4.11.
Structure of $\beta$-R 105 boron. (a) Three half-icosahedra of adjacent $\mathrm{B}_{84}$ clusters fuse with a $\mathrm{B}_{10}$ unit to form a $\mathrm{B}_{28}$ unit. (b) Unit cell depicting the $B_{12}$ units at the vertices and edge centers, leaving the $B_{28}-B-B_{28}$ unit along the main body diagonal. Holes of three different types are also indicated.

X-ray studies have established that $\beta$-R105 boron has a very porous (only $36 \%$ of space is filled in the idealized model) and defective structure with the presence of interstitial atoms and partial occupancies. The $\mathrm{B}_{57}$ fragment can dispose of excess electrons by removal of some vertices to form nido or arachno structures, and individual $B_{12 a}$ units can gain electrons by incorporating capping vertices that are accommodated in interstitial holes (see Fig. 13.4.11(b)).

### 13.4.8 Persubstituted derivatives of icosahedral borane $\mathrm{B}_{12} \mathrm{H}_{12}{ }^{2-}$

The compound $\mathrm{Cs}_{8}\left[\mathrm{~B}_{12}\left(\mathrm{BSe}_{3}\right)_{6}\right]$ is prepared from the solid-state reaction between $\mathrm{Cs}_{2} \mathrm{Se}, \mathrm{Se}$, and B at high temperature. In the anion $\left[\mathrm{B}_{12}\left(\mathrm{BSe}_{3}\right)_{6}\right]^{8-}$, each trigonal planar $\mathrm{BSe}_{3}$ unit is bonded to a pair of neighboring B atom in the $\mathrm{B}_{12}$ skeleton, as shown in Fig. 13.4.12. It is the first example of bonding between a chalcogen and an icosahedral $\mathrm{B}_{12}$ core. The point group of $\left[\mathrm{B}_{12}\left(\mathrm{BSe}_{3}\right)_{6}\right]^{8-}$ is $D_{3 \mathrm{~d}}$.

Icosahedral $\mathrm{B}_{12} \mathrm{H}_{12}{ }^{2-}$ can be converted to $\left[\mathrm{B}_{12}(\mathrm{OH})_{12}\right]^{2-}$, in which the 12 hydroxy groups can be substituted to form carboxylic acid esters $\left[\mathrm{B}_{12}\left(\mathrm{O}_{2}\right.\right.$ $\left.\mathrm{CMe})_{12}\right]^{2-},\left[\mathrm{B}_{12}\left(\mathrm{O}_{2} \mathrm{CPh}\right)_{12}\right]^{2-}$, and $\left[\mathrm{B}_{12}\left(\mathrm{OCH}_{2} \mathrm{Ph}\right)_{12}\right]^{2-}$. The sequential twoelectron oxidation of $\left[\mathrm{B}_{12}\left(\mathrm{OCH}_{2} \mathrm{Ph}\right)_{12}\right]^{2-}$ with $\mathrm{Fe}^{3+}$ in ethanol affords hyper closo- $\mathrm{B}_{12}\left(\mathrm{OCH}_{2} \mathrm{Ph}\right)_{12}$ as a dark-orange crystal. An X-ray diffraction study of hypercloso $-\mathrm{B}_{12}\left(\mathrm{OCH}_{2} \mathrm{Ph}\right)_{12}$ revealed that the molecule has distorted icosahedral

geometry $\left(D_{3 \mathrm{~d}}\right)$. The term hypercloso refers to an $n$-vertex polyhedral structure having fewer skeletal electron pairs than $(n+1)$ as required by Wade's rule.

### 13.4.9 Boranes and carboranes as ligands

Many boranes and carboranes can act as very effective polyhapto ligands to form metallaboranes and metallacarboranes. Metallaboranes are borane cages containing one or more metal atoms in the skeletal framework. Metallacarboranes have both metal and carbon atoms in the cage skeleton. In contrast to the metallaboranes, syntheses of metallacarboranes via low- or room-temperature metal insertion into carborane anions in solution are more controllable, usually occurring at a well-defined $\mathrm{C}_{2} \mathrm{~B}_{n}$ open face to yield a single isomer.

The icosahedral carborane cage $\mathrm{C}_{2} \mathrm{~B}_{10} \mathrm{H}_{12}$ can be converted to the nido$\mathrm{C}_{2} \mathrm{~B}_{9} \mathrm{H}_{11}{ }^{2-}$, nido- $\mathrm{C}_{2} \mathrm{~B}_{10} \mathrm{H}_{12}{ }^{2-}$, or arachno- $\mathrm{C}_{2} \mathrm{~B}_{10} \mathrm{H}_{12}{ }^{4-}$ anions, as shown in Fig. 13.4.13. Nido- $\mathrm{C}_{2} \mathrm{~B}_{9} \mathrm{H}_{11}{ }^{2-}$ has a planar five-membered $\mathrm{C}_{2} \mathrm{~B}_{3}$ ring with delocalized $\pi$ orbitals, which is similar to the cyclopentadienyl ring. Likewise, nido- $\mathrm{C}_{2} \mathrm{~B}_{10} \mathrm{H}_{12}{ }^{2-}$ has a nearly planar $\mathrm{C}_{2} \mathrm{~B}_{4}$ six-membered ring and delocalized $\pi$ orbitals, which is analogous to benzene. Arachno- $\mathrm{C}_{2} \mathrm{~B}_{10} \mathrm{H}_{12}{ }^{4-}$ has a boat-like $\mathrm{C}_{2} \mathrm{~B}_{5}$ bonding face in which the five B atoms are coplanar and the two C atoms lie approximately 60 pm above this plane.

Fig. 13.4.12.
Structure of $\left[\mathrm{B}_{12}\left(\mathrm{BSe}_{3}\right)_{6}\right]^{8-}$.

Fig. 13.4.13.
Conversion of icosahedral carborane $o-\mathrm{C}_{2} \mathrm{~B}_{10} \mathrm{H}_{12}$ to nido- $\mathrm{C}_{2} \mathrm{~B}_{9} \mathrm{H}_{11}{ }^{2-}$, nido- $\mathrm{C}_{2} \mathrm{~B}_{10} \mathrm{H}_{12}{ }^{2-}$, and arachno- $\mathrm{C}_{2} \mathrm{~B}_{10} \mathrm{H}_{12}{ }^{4-}$.

The similarity between the $\mathrm{C}_{2} \mathrm{~B}_{3}$ open face in nido- $\mathrm{C}_{2} \mathrm{~B}_{9} \mathrm{H}_{11}{ }^{2-}$ and the $\mathrm{C}_{5} \mathrm{H}_{5}^{-}$ anion implies that the dicarbollide ion can act as an $\eta^{5}$-coordinated ligand to form sandwich complexes with metal atoms, which are analogous to the metallocenes. Likewise, the $\mathrm{C}_{2} \mathrm{~B}_{4}$ open face in nido $-\mathrm{C}_{2} \mathrm{~B}_{10} \mathrm{H}_{12}{ }^{2-}$ is analogous to benzene and it may be expected to function as an $\eta^{6}$-ligand.

A large number of metallacarboranes and polyhedral metallaboranes of s-, p-, d-, and f-block elements are known. In these compounds, the carboranes and boranes act as polyhapto ligands. The domain of metallaboranes and metallacarboranes has grown enormously and engenders a rich structural chemistry. Some new advances in the chemistry of metallacarboranes of f-block elements are described below.

The full-sandwich lanthanacarborane $\left[\mathrm{Na}(\mathrm{THF})_{2}\right]\left[\left(\eta^{5}-\mathrm{C}_{2} \mathrm{~B}_{9} \mathrm{H}_{11}\right)_{2} \mathrm{La}(\mathrm{THF})_{2}\right]$ has been prepared by direct salt metathesis between $\mathrm{Na}_{2}\left[\mathrm{C}_{2} \mathrm{~B}_{9} \mathrm{H}_{11}\right]$ and $\mathrm{LaCl}_{3}$ in THF. The structure of the anion is shown in Fig. 13.4.14(a). The average Lacage atom distance is 280.4 pm , and the ring centroid-La-ring centroid angle is $132.7^{\circ}$.

The structure of samaracarborane $\left[\eta^{5}: \eta^{6}-\mathrm{Me}_{2} \mathrm{Si}\left(\mathrm{C}_{5} \mathrm{H}_{4}\right)\left(\mathrm{C}_{2} \mathrm{~B}_{10} \mathrm{H}_{11}\right)\right]$ $\mathrm{Sm}(\mathrm{THF})_{2}$ is shown in Fig. 13.4.14(b), in which the $\mathrm{Sm}^{3+}$ ion is surrounded by an $\eta^{5}$-cyclopentadienyl ring, $\eta^{6}$-hexagonal $\mathrm{C}_{2} \mathrm{~B}_{4}$ face of the $\mathrm{C}_{2} \mathrm{~B}_{10} \mathrm{H}_{11}$ cage, and two THF molecules in a distorted tetrahedral manner. The ring centroidSm -ring centroid angle is $125.1^{\circ}$ and the average Sm -cage atom and $\mathrm{Sm}-\mathrm{C}\left(\mathrm{C}_{5}\right.$ ring) distances are 280.3 and 270.6 pm , respectively.

Figure 13.4.14(c) shows the coordination environment of the Er atom in the $\left\{\eta^{7}-\left[\left(\mathrm{C}_{6} \mathrm{H}_{5} \mathrm{CH}_{2}\right)_{2}\left(\mathrm{C}_{2} \mathrm{~B}_{10} \mathrm{H}_{10}\right)\right] \mathrm{Er}(\mathrm{THF})\right\}_{2} \cdot\left\{\mathrm{Na}(\mathrm{THF})_{3}\right\}_{2} \cdot 2 \mathrm{THF}$. The Er atom is coordinated by $\eta^{7}$ - $\left[\text { arachno- }\left(\mathrm{C}_{6} \mathrm{H}_{5} \mathrm{CH}_{2}\right)_{2} \mathrm{C}_{2} \mathrm{~B}_{10} \mathrm{H}_{10}\right]^{4-}$ and $\sigma$-bonded to two

B-H groups from a neighboring [arachno- $\left.\left(\mathrm{C}_{6} \mathrm{H}_{5} \mathrm{CH}_{2}\right)_{2} \mathrm{C}_{2} \mathrm{~B}_{10} \mathrm{H}_{10}\right]^{4-}$ ligand and one THF molecule. The average $\mathrm{Er}-\mathrm{B}$ (cage) distance is 266.5 pm , and that for the $\mathrm{Er}-\mathrm{C}$ (cage) is 236.6 pm .

The compound $\left[\left\{\left(\eta^{7}-\mathrm{C}_{2} \mathrm{~B}_{10} \mathrm{H}_{12}\right)\left(\eta^{6}-\mathrm{C}_{2} \mathrm{~B}_{10} \mathrm{H}_{12}\right) \mathrm{U}\right\}_{2}\left\{\mathrm{~K}_{2}(\mathrm{THF})_{5}\right\}\right]_{2}$ has been prepared from the reaction of $o-\mathrm{C}_{2} \mathrm{~B}_{10} \mathrm{H}_{12}$ with excess K metal in THF, followed by treatment with a THF suspension of $\mathrm{UCl}_{4}$. In this structure each $\mathrm{U}^{4+}$ ion is bonded to $\eta^{6}$-nido- $\mathrm{C}_{2} \mathrm{~B}_{10} \mathrm{H}_{12}{ }^{2-}$ and $\eta^{7}$-arachno- $\mathrm{C}_{2} \mathrm{~B}_{10} \mathrm{H}_{12}{ }^{4-}$, and coordinated by two $\mathrm{B}-\mathrm{H}$ groups from the $\mathrm{C}_{2} \mathrm{~B}_{5}$ bonding face of a neighboring arachno$\mathrm{C}_{2} \mathrm{~B}_{10} \mathrm{H}_{12}{ }^{4-}$ ligand, as shown in Fig. 13.4.14(d). This is the first example of an actinacarborane bearing a $\eta^{6}-\mathrm{C}_{2} \mathrm{~B}_{10} \mathrm{H}_{12}{ }^{2-}$ ligand.

### 13.4.10 Carborane skeletons beyond the icosahedron

Recent synthetic studies have shown that carborane skeletons larger than the icosahedron can be constructed by the insertion of additional BH units. The reaction scheme and structure motifs of these carborane species are shown in Fig. 13.4.15. Treatment of $1,2-\left(\mathrm{CH}_{2}\right)_{3}-1,2-\mathrm{C}_{2} \mathrm{~B}_{10} \mathrm{H}_{10}(\mathbf{1})$ with excess lithium metal in THF at room temperature gave $\left\{\left[\left(\mathrm{CH}_{2}\right)_{3}-1,2-\mathrm{C}_{2} \mathrm{~B}_{10} \mathrm{H}_{10}\right]\left[\mathrm{Li}_{4}(\mathrm{THF})_{5}\right]\right\}_{2}$ (2) in 85\% yield. X-ray analysis showed that, in the crystalline state, both the hexagonal and pentagonal faces of the "carbon-atoms-adjacent" arachno-carborane tetra-anion in $\mathbf{2}$ are capped by lithium ions, which may in principle be substituted by BH groups.

The reaction of $\mathbf{2}$ with 5.0 equivalents of $\mathrm{HBBr}_{2} \cdot \mathrm{SMe}_{2}$ in toluene at $-78^{\circ} \mathrm{C}$ to $25^{\circ} \mathrm{C}$ yielded a mixture of a 13-vertex closo-carborane $\left(\mathrm{CH}_{2}\right)_{3} \mathrm{C}_{2} \mathrm{~B}_{11} \mathrm{H}_{11}$ (3, 32\%), a 14-vertex closo-carborane $\left(\mathrm{CH}_{2}\right)_{3} \mathrm{C}_{2} \mathrm{~B}_{12} \mathrm{H}_{12}(\mathbf{4}, 7 \%) ; \mathbf{1}$ (2\%). Closo-carboranes 3 and 4 can be converted through reduction reaction into their nido-carborane salts $\left\{\left[\left(\mathrm{CH}_{2}\right)_{3} \mathrm{C}_{2} \mathrm{~B}_{11} \mathrm{H}_{11}\right]\left[\mathrm{Na}_{2}(\mathrm{THF})_{4}\right]\right\}_{n}(\mathbf{5})$ and $\left\{\left[\left(\mathrm{CH}_{2}\right)_{3} \mathrm{C}_{2} \mathrm{~B}_{12} \mathrm{H}_{12}\right]\left[\mathrm{Na}_{2}(\mathrm{THF})_{4}\right]\right\}_{n}$ (6), respectively. Compound 4 can also be prepared from the reaction of $\mathbf{5}$ with $\mathrm{HBBr}_{2} \cdot \mathrm{SMe}_{2}$, whose cage skeleton is a bicapped hexagonal antiprism.

Quite different from the planar open faces in nido- $\mathrm{C}_{2} \mathrm{~B}_{9} \mathrm{H}_{11}{ }^{2-}$ and nido$\mathrm{C}_{2} \mathrm{~B}_{10} \mathrm{H}_{12}{ }^{2-}$, the open faces of the 13- and 14-vertex nido cages in $\mathbf{5}$ and $\mathbf{6}$ are

Fig. 13.4.15.
Synthesis of "carbon-atoms-adjacent" 13- and 14-vertex closo-carboranes and nido-carborane anions. From L. Deng, H.-S. Chan and Z. Xie, Angew. Chem. Int. Ed. 44, 2128-31 (2005).

Fig. 13.4.16.
Structure of some metallacarboranes with 14 and 15 vertices:
(a) $\left[\eta^{5}-\left(\mathrm{CH}_{2}\right)_{3} \mathrm{C}_{2} \mathrm{~B}_{11} \mathrm{H}_{11}\right] \mathrm{Ni}($ dppe $)$; (b) $\left[\eta^{6}-\left(\mathrm{CH}_{2}\right)_{3} \mathrm{C}_{2} \mathrm{~B}_{11} \mathrm{H}_{11}\right] \mathrm{Ru}(p$-cymene);
(c) $\left[\eta^{6}-\left(\mathrm{CH}_{2}\right)_{3} \mathrm{C}_{2} \mathrm{~B}_{12} \mathrm{H}_{12}\right] \mathrm{Ru}(p$-cymene). From L. Deng, H.-S. Chan and Z. Xie, J. Am. Chem.

Soc. 128, 5219-30 (2006); and L. Deng, J. Zhang, H.-S. Chan and Z. Xie, Angew. Chem. Int. Ed. 45, 4309-13 (2006).
bent five-membered rings. Despite this, they can be capped by metal atoms to give metallacarboranes with 14 and 15 vertices, respectively. Figure 13.4.16 shows some examples of these novel metallacarboranes.

The complexes $\left[\eta^{5}-\left(\mathrm{CH}_{2}\right)_{3} \mathrm{C}_{2} \mathrm{~B}_{11} \mathrm{H}_{11}\right] \mathrm{Ni}(\mathrm{dppe})$ and $\left[\eta^{6}-\left(\mathrm{CH}_{2}\right)_{3} \mathrm{C}_{2} \mathrm{~B}_{11} \mathrm{H}_{11}\right]$ $\mathrm{Ru}\left(p\right.$-cymene) were prepared by the reactions of 5 with (dppe) $\mathrm{NiCl}_{2}$ and $\left[(p \text {-cymene }) \mathrm{RuCl}_{2}\right]_{2}$, respectively. Although both of them are 14 -vertex metallacarboranes having a similar bicapped hexagonal antiprismatic cage geometry, the coordination modes of their carborane anions are quite different: the carborane anion $\left[\left(\mathrm{CH}_{2}\right)_{3} \mathrm{C}_{2} \mathrm{~B}_{11} \mathrm{H}_{11}\right]^{2-}$ is $\eta^{5}$-bound to the Ni atom in the nickelacarborane [Fig. 13.4.16(a)], whereas an $\eta^{6}$-bonding fashion is observed in the ruthenacarborane with an average Ru-cage atom distance of 226.6 pm [Fig. 13.4.16(b)].

Figure 13.4.16(c) shows the structure of a 15 -vertex ruthenacarborane, $\left[\left(\mathrm{CH}_{2}\right)_{3} \mathrm{C}_{2} \mathrm{~B}_{12} \mathrm{H}_{12}\right] \mathrm{Ru}(p$-cymene), which was synthesized by the reaction of 6 with $\left[(p \text {-cymene }) \mathrm{RuCl}_{2}\right]_{2}$. Similar to that in the above-mentioned 14 -vertex ruthenacarborane, the carborane moiety $\left[\left(\mathrm{CH}_{2}\right)_{3} \mathrm{C}_{2} \mathrm{~B}_{12} \mathrm{H}_{12}\right]^{2-}$ in this 15 -vertex ruthenacarborane is also $\eta^{6}$-bound to the Ru atom, forming a hexacosahedral structure. The distances of $\mathrm{Ru}-$ arene(cent) and $\mathrm{Ru}-\mathrm{CB}_{5}$ (cent) are 178 and 141 pm , respectively. This 15 -vertex ruthenacarborane has the largest vertex number in the metallacarborane family known at present.

### 13.5 Boric acid and borates

### 13.5.1 Boric acid

Boric acid, $\mathrm{B}(\mathrm{OH})_{3}$, is the archetype and primary source of oxo-boron compounds. It is also the normal end product of hydrolysis of most boron compounds. It forms flaky, white and transparent crystals, in which the $\mathrm{BO}_{3}$ units are joined to form planar layers by $\mathrm{O}-\mathrm{H} \cdots \mathrm{O}$ hydrogen bonds, as shown in Fig. 13.5.1.

Boric acid is a very weak monobasic acid ( $\mathrm{p} K_{\mathrm{a}}=9.25$ ). It generally behaves not as a Brønsted acid with the formation of the conjugate-base $\left[\mathrm{BO}(\mathrm{OH})_{2}\right]^{-}$, but rather as a Lewis acid by accepting an electron pair from an $\mathrm{OH}^{-}$anion to
form the tetrahedral species $\left[\mathrm{B}(\mathrm{OH})_{4}\right]^{-}$:

$$
\underset{\left[\mathrm{sp}^{2}+\mathrm{p}(\text { unoccupied })\right]}{(\mathrm{HO})_{3} \mathrm{~B}}+: \mathrm{OH}^{-} \longrightarrow \underset{\mathrm{sp}^{3}}{\mathrm{~B}(\mathrm{OH})_{4}^{-}} .
$$

Thus this reaction is analogous to the acceptor-donor interaction between $\mathrm{BF}_{3}$ and $\mathrm{NH}_{3}$ :

$$
\underset{\left[\mathrm{sp}^{2}+\mathrm{p}(\text { unoccupied })\right]}{\mathrm{F}_{3} \mathrm{~B}}+\underset{\mathrm{sp}^{3}}{\mathrm{NH}_{3}} \longrightarrow \underset{\mathrm{SH}_{3}}{\mathrm{~F}_{3} \mathrm{~B}} \leftarrow \mathrm{NH}_{3} .
$$

In the above two reactions, the hybridization of the B atom changes from $\mathrm{sp}^{2}$ (reactant) to $\mathrm{sp}^{3}$ (product).

Partial dehydration of $\mathrm{B}(\mathrm{OH})_{3}$ above 373 K yields metaboric acid, $\mathrm{HBO}_{2}$, which consists of trimeric units $\mathrm{B}_{3} \mathrm{O}_{3}(\mathrm{OH})_{3}$. Orthorhombic metaboric acid is built of discrete molecules $\mathrm{B}_{3} \mathrm{O}_{3}(\mathrm{OH})_{3}$, which are linked into layers by O $\mathrm{H} \cdots \mathrm{O}$ bonds, as shown in Fig. 13.5.2.

In dilute aqueous solution, there is an equilibrium between $\mathrm{B}(\mathrm{OH})_{3}$ and $\mathrm{B}(\mathrm{OH})_{4}^{-}$:

$$
\mathrm{B}(\mathrm{OH})_{3}+2 \mathrm{H}_{2} \mathrm{O} \rightleftharpoons \mathrm{H}_{3} \mathrm{O}^{+}+\mathrm{B}(\mathrm{OH})_{4}^{-} .
$$

At concentrations above 0.1 M , secondary equilibria involving condensation reactions of the two dominant monomeric species give rise to oligomers such as the triborate monoanion $\left[\mathrm{B}_{3} \mathrm{O}_{3}(\mathrm{OH})_{4}\right]^{-}$, the triborate dianion $\left[\mathrm{B}_{3} \mathrm{O}_{3}(\mathrm{OH})_{5}\right]^{2-}$, the tetraborate $\left[\mathrm{B}_{4} \mathrm{O}_{5}(\mathrm{OH})_{4}\right]^{2-}$, and the pentaborate $\left[\mathrm{B}_{5} \mathrm{O}_{6}(\mathrm{OH})_{4}\right]^{-}$.

In $\left(\mathrm{Et}_{4} \mathrm{~N}\right)_{2}\left[\mathrm{BO}(\mathrm{OH})_{2}\right]_{2} \cdot \mathrm{~B}(\mathrm{OH})_{3} \cdot 5 \mathrm{H}_{2} \mathrm{O}$, the conjugate acid-base pair $\mathrm{B}(\mathrm{OH})_{3}$ and dihydrogen borate $\left[\mathrm{BO}(\mathrm{OH})_{2}\right]^{-}$coexist in the crystalline state. In the crystal structure of the inclusion compound $\mathrm{Me}_{4} \mathrm{~N}^{+}\left[\mathrm{BO}(\mathrm{OH})_{2}\right]^{-} \cdot 2\left(\mathrm{NH}_{2}\right)_{2} \mathrm{CO} \cdot \mathrm{H}_{2} \mathrm{O}$, the $\mathrm{BO}(\mathrm{OH})_{2}{ }^{-},\left(\mathrm{NH}_{2}\right)_{2} \mathrm{CO}$, and $\mathrm{H}_{2} \mathrm{O}$ molecules are linked by $\mathrm{N}-\mathrm{H} \cdots \mathrm{O}$ and $\mathrm{O}-\mathrm{H} \cdots \mathrm{O}$ bonds to form a host lattice featuring a system of parallel channels, which accommodate the guest $\mathrm{Me}_{4} \mathrm{~N}^{+}$cations (see Section 20.4.4 for further details). The measured dimensions of the $\left[\mathrm{BO}(\mathrm{OH})_{2}\right]^{-}$anion, which has crystallographically imposed symmetry $m$, show that the valence tautomeric form I with a formal $\mathrm{B}=\mathrm{O}$ double bond makes a more important contribution than II to its electronic structure (Fig. 13.5.3).

### 13.5.2 Structure of borates

## (1) Structural units in borates

The many structural components that occur in borates consist of planar triangular $\mathrm{BO}_{3}$ units and/or tetrahedral $\mathrm{BO}_{4}$ units with vertex-sharing linkage, and may be divided into three kinds. Some examples are given below:

Fig. 13.5.2.
Structure of layer of orthorhombic metaboric acid.

& \left.\left[\mathrm{~B}_{3} \mathrm{O}_{3}(\mathrm{OH})_{5}\right]^{2-}: \mathrm{Ca}_{2} \mathrm{~B}_{3} \mathrm{O}_{3}(\mathrm{OH})_{5}\right] \cdot \mathrm{H}_{2} \mathrm{O} \\
& {\left[\mathrm{~B}_{4} \mathrm{O}_{5}(\mathrm{OH})_{4}\right)^{2-}: \mathrm{Na}_{2}\left[\mathrm{~B}_{4} \mathrm{O}_{5}(\mathrm{OH})_{4}\right] \cdot 8 \mathrm{H}_{2} \mathrm{O}}
\end{aligned}
$$

(a)

(b)

(c)

## (2) Structure of borax

The main source of boron comes from borax, which is used in the manufacture of borosilicate glass, borate fertilizers, borate-based detergents, and flame-retardants. The crystal structure of borax was determined by Xray diffraction in 1956, and by neutron diffraction in 1978. It consists of $\mathrm{B}_{4} \mathrm{O}_{5}(\mathrm{OH})_{4}^{2-}, \mathrm{Na}^{+}$ions, and water molecules, so that its chemical formula is $\mathrm{Na}_{2}\left[\mathrm{~B}_{4} \mathrm{O}_{5}(\mathrm{OH})_{4}\right] \cdot 8 \mathrm{H}_{2} \mathrm{O}$, not $\mathrm{Na}_{2} \mathrm{~B}_{4} \mathrm{O}_{7} \cdot 10 \mathrm{H}_{2} \mathrm{O}$ as given in many older books. The structure of $\left[\mathrm{B}_{4} \mathrm{O}_{5}(\mathrm{OH})_{4}\right]^{2-}$ is shown in Figs. 13.5.4(a) and (b). In the crystal, the anions are linked by $\mathrm{O}-\mathrm{H} \cdots \mathrm{O}$ hydrogen bonds to form an infinite chain, as shown in Fig. 13.5.4(c). The sodium ions are octahedrally coordinated by water molecules, and the octahedra share edges to form another chain. These two kinds of chains are linked by weaker hydrogen bonds between the OH groups of $\left[\mathrm{B}_{4} \mathrm{O}_{5}(\mathrm{OH})_{4}\right]^{2-}$ anions and the aqua ligands, and this accounts for the softness of borax.

## (3) Structural principles for borates

Several general principles have been formulated in connection with the structural chemistry of borates:
(a) In borates, boron combines with oxygen either in trigonal planar or tetrahedral coordination. In addition to the mononuclear anions $\mathrm{BO}_{3}^{3-}$ and $\mathrm{BO}_{4}^{5-}$ and their partially or fully protonated forms, there exists an extensive series of polynuclear anions formed by corner-sharing of $\mathrm{BO}_{3}$ and $\mathrm{BO}_{4}$ units. The polyanions may form separate boron-oxygen complexes, rings, chains, layers, and frameworks.
(b) In boron-oxygen polynuclear anions, most of the oxygen atoms are linked to one or two boron atoms, and a few can bridge three boron atoms.
(c) In borates, the hydrogen atoms do not attach to boron atoms directly, but always to oxygens not shared by two borons, thereby generating OH groups.
(d) Most boron-oxygen rings are six-membered, comprising three B atoms and three oxygen atoms.
(e) In a borate crystal there may be two or more different boron-oxygen units.

Fig. 13.5.4.
Structure of borax: (a) bond lengths in $\left[\mathrm{B}_{4} \mathrm{O}_{5}(\mathrm{OH})_{4}\right]^{2-}$ (in pm), (b) perspective view of the anion, and (c) $\left[\mathrm{B}_{4} \mathrm{O}_{5}(\mathrm{OH})_{4}^{2-}\right]_{n}$ chain.

## Structural Chemistry of Selected Elements

### 13.6 Organometallic compounds of group 13 elements

### 13.6.1 Compounds with bridged structure

The compounds $\mathrm{Al}_{2}\left(\mathrm{CH}_{3}\right)_{6},\left(\mathrm{CH}_{3}\right)_{2} \mathrm{Al}\left(\mu-\mathrm{C}_{6} \mathrm{H}_{5}\right)_{2} \mathrm{Al}\left(\mathrm{CH}_{3}\right)_{2}$, and $\left(\mathrm{C}_{6} \mathrm{H}_{5}\right)_{2} \mathrm{Al}(\mu-$ $\left.\mathrm{C}_{6} \mathrm{H}_{5}\right)_{2} \mathrm{Al}\left(\mathrm{C}_{6} \mathrm{H}_{5}\right)_{2}$ all have bridged structures, as shown in Figs. 13.6.1 (a), (b) and (c) respectively. The bond distances and angles are listed in Table 13.6.1.

The bonding in the Al-C-Al bridges involves a $3 c-2 e$ molecular orbital formed from essentially $\mathrm{sp}^{3}$ orbitals of the C and Al atoms. This type of $3 c-2 e$ interaction in the bridge necessarily results in an acute Al-C-Al angle ( $75^{\circ}$ to $78^{\circ}$ ), which is consistent with the experimental data. This orientation is sterically favored and places each ipso-carbon atom in an approximately tetrahedral configuration.

In the structure of $\mathrm{Me}_{2} \mathrm{Ga}(\mu-\mathrm{C} \equiv \mathrm{C}-\mathrm{Ph})_{2} \mathrm{GaMe}_{2}$ [Fig. 13.6.1(d)], each alkynyl bridge leans over toward one of the Ga centers. The organic ligand

Table 13.6.1. Structural parameters found in some carbon-bridged organoaluminum compounds

| Compound | Distance (pm) |  |  | Angle ( ${ }^{\circ}$ ) |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: |
|  | $\mathrm{Al}-\mathrm{C}_{\mathrm{b}}$ | Al-C ${ }_{\text {t }}$ | $\mathrm{Al} \cdots \mathrm{Al}$ | Al-C-Al | $\mathrm{C}-\mathrm{Al}-\mathrm{C}$ <br> (internal) | $\mathrm{C}-\mathrm{Al}-\mathrm{C}$ <br> (external) |
| $\mathrm{Al}_{2} \mathrm{Me}_{6}$ | 214 | 197 | 260 | 74.7 | 105.3 | 123.1 |
| $\mathrm{Al}_{2} \mathrm{Me}_{4} \mathrm{Ph}_{2}$ | 214 | 197 | 269 | 77.5 | 101.3 | 115.4 |
| $\mathrm{Al}_{2} \mathrm{Ph}_{6}$ | 218 | 196 | 270 | 76.5 | 103.5 | 121.5 |

forms an $\mathrm{Ga}-\mathrm{C} \sigma$ bond and interacts with the second Ga center by using its $\mathrm{C} \equiv \mathrm{C} \pi$ bond. Thus each alkynyl group is able to provide three electrons for bridge bonding, in contrast to one electron as normally supplied by an alkyl or aryl group.

Compounds $\operatorname{In}(\mathrm{Me})_{3}$ and $\mathrm{Tl}(\mathrm{Me})_{3}$ are monomeric in solution and the gas phase. In the solid state, they also exist as monomers essentially, but close intermolecular contacts become important. In crystalline $\operatorname{In}(\mathrm{Me})_{3}$, significant In $\cdots$ C intermolecular interactions are observed, suggesting that the structure can be described in terms of cyclic tetramers, as shown in Fig. 13.6.1(e), with interatomic distances of In-C 218 pm and In $\cdots$ C 308 pm . The corresponding bond distances in isostructural $\mathrm{Tl}(\mathrm{Me})_{3}$ are $\mathrm{Tl}-\mathrm{C}=230 \mathrm{pm}$ and $\mathrm{Tl} \cdots \mathrm{C}=316 \mathrm{pm}$.

### 13.6.2 Compounds with $\pi$ bonding

Many organometallic compounds of group 13 are formed by $\pi$ bonds. The $\pi$ ligands commonly used are olefins, cyclopentadiene, or their derivatives.

The structure of the dimer $[\mathrm{ClAl}(\mathrm{Me}-\mathrm{C}=\mathrm{C}-\mathrm{Me}) \mathrm{AlCl}]_{2}$ is of interest. There are $3 c-2 e \pi$ bonds between the Al atoms and the $\mathrm{C}=\mathrm{C}$ bonds, as shown in Fig. 13.6.2(a). The Al-C distances in the Al-olefin units are relatively long, approximately 235 pm , but the sum of the four interactions lead to remarkable stability of the dimer. The energy gained through each Al-olefin interaction is calculated to be about 25 to $40 \mathrm{~kJ} \mathrm{~mol}^{-1}$.

The $\left[\mathrm{Al}\left(\eta^{5}-\mathrm{Cp}^{*}\right)_{2}\right]^{+}\left(\mathrm{Cp}^{*}=\mathrm{C}_{5} \mathrm{Me}_{5}\right)$ ion is at present the smallest sandwich metallocene of any main-group element. The Al-C bond length is 215.5 pm . Figure 13.6.2(b) shows the structure of this ion.

The molecular structure of $\mathrm{Al}_{4} \mathrm{Cp}_{4}^{*}$ in the crystal is shown in Fig. 13.6.2(c). The central $\mathrm{Al}_{4}$ tetrahedron has $\mathrm{Al}-\mathrm{Al}$ bond length 276.9 pm , which is shorter

Fig. 13.6.2.

## Structural Chemistry of Selected Elements

than those in Al metal ( 286 pm ). Each $\mathrm{Cp}^{*}$ ring is $\eta^{5}$-coordinated to an Al atom, whereby the planes of the $\mathrm{Cp}^{*}$ rings are parallel to the opposite base of the tetrahedron. The average Al-C distances is 233.4 pm .

The half-sandwich structure of $\mathrm{GaCp}^{*}$ in the gas phase, as determined by electron diffraction, is shown in Fig. 13.6.2(d). This compound has a pentagonal pyramidal structure with an $\eta^{5}-\mathrm{C}_{5}$ ring. The $\mathrm{Ga}-\mathrm{C}$ distance is 240.5 pm .

Both CpIn and CpTl are monomeric in the gas phase, but in the solid they possess a polymeric zigzag chain structure, in which the In (or Tl ) atoms and Cp rings alternate, as shown in Fig. 13.6.2(e).

### 13.6.3 Compounds containing $M-M$ bonds

The compounds $\mathrm{R}_{2} \mathrm{Al}-\mathrm{AlR}_{2}, \mathrm{R}_{2} \mathrm{Ga}-\mathrm{GaR}_{2}$, and $\mathrm{R}_{2} \mathrm{In}-\mathrm{InR}_{2}\left[\mathrm{R}=\mathrm{CH}\left(\mathrm{SiMe}_{3}\right)_{2}\right]$ have been prepared and characterized. The bond lengths in these compounds are Al-Al $266.0 \mathrm{pm}, \mathrm{Ga}-\mathrm{Ga} 254.1 \mathrm{pm}$, and $\mathrm{In}-\mathrm{In} 282.8 \mathrm{pm}$; the $\mathrm{M}_{2} \mathrm{C}_{4}$ frameworks are planar as shown in Fig. 13.6.3(a). In $\mathrm{Al}_{2}\left(\mathrm{C}_{6} \mathrm{H}_{2}{ }^{i} \mathrm{Pr}_{3}\right)_{4}, \mathrm{Ga}_{2}\left(\mathrm{C}_{6} \mathrm{H}_{2}{ }^{i} \mathrm{Pr}_{3}\right)_{4}$, and $\operatorname{In}_{2}\left[\mathrm{C}_{6} \mathrm{H}_{2}\left(\mathrm{CF}_{3}\right)_{3}\right]_{4}$, the bond lengths are $\mathrm{Al}-\mathrm{Al} 265 \mathrm{pm}, \mathrm{Ga}-\mathrm{Ga} 251.5 \mathrm{pm}$, and $\mathrm{In}-\mathrm{In} 274.4 \mathrm{pm}$, and here the $\mathrm{M}_{2} \mathrm{C}_{4}$ framework are nonplanar, as shown in Fig. 13.6.3(b). In these structures the $\mathrm{Ga}-\mathrm{Ga}$ bond lengths are shorter than the Al-Al bond lengths. The anomalous behavior of gallium among Group 13 elements is due to the insertion of electrons into the $d$ orbitals of the preceding 3d elements in the Periodic Table and the associated contraction of the atomic radius.

Fig. 13.6.3.
Structures of some compounds containing $M-M$ bonds: (a) planar $M_{2} R_{4}$ ( $M=A 1, G a$, In), (b) nonplanar $M_{2} R_{4}$ ( $M=A 1, G a, I n$ ), (c) $K_{2} \mathrm{Ga}_{3}$ core of $\mathrm{K}_{2}\left[\mathrm{Ga}_{3}\left(\mathrm{C}_{6} \mathrm{H}_{3} \mathrm{Mes}_{2}\right)_{3}\right]$, (d) $\left[\mathrm{GaC}\left(\mathrm{SiMe}_{3}\right)_{3}\right]_{4}$, (e) $(\mathrm{AlMe})_{8}\left(\mathrm{CCH}_{2} \mathrm{Ph}\right)_{5}(\mathrm{C} \equiv \mathrm{C}-\mathrm{Ph})$, and (f) icosahedral $\mathrm{Al}_{12}$ core in $\mathrm{K}_{2}\left[\mathrm{Al}_{12}{ }^{i} \mathrm{Bu}_{12}\right]$.

The structures of compounds $\mathrm{Na}_{2}\left[\mathrm{Ga}_{3}\left(\mathrm{C}_{6} \mathrm{H}_{3} \mathrm{Mes}_{2}\right)_{3}\right]$ and $\mathrm{K}_{2}\left[\mathrm{Ga}_{3}\left(\mathrm{C}_{6} \mathrm{H}_{3}\right.\right.$ $\left.\left.\mathrm{Mes}_{2}\right)_{3}\right]$ are worthy of note. In these compounds, the $\mathrm{Na}_{2} \mathrm{Ga}_{3}$ and $\mathrm{K}_{2} \mathrm{Ga}_{3}$ cores have trigonal bipyramidal geometry, as shown in Fig. 13.6.3(c). The bond lengths are $\mathrm{Ga}-\mathrm{Ga} 244.1 \mathrm{pm}$ (Na salt), 242.6 pm (K salt), Ga-Na 322.9 pm , and $\mathrm{Ga}-\mathrm{K} 355.4 \mathrm{pm}$. The planarity of the $\mathrm{Ga}_{3}$ ring and the very short $\mathrm{Ga}-\mathrm{Ga}$ bonds implies electron delocalization in the three-membered ring, the requisite two $\pi$ electrons being provided by the two K (or Na ) atoms (one electron each) to the empty $\mathrm{p}_{z}$ orbitals of the three $\mathrm{sp}^{2}$-hybridized Ga atoms.

Figures 13.6.3(d)-(f) show the structures of three compounds which contain metallic polyhedral cores. In $\left[\mathrm{GaC}\left(\mathrm{SiMe}_{3}\right)_{3}\right]_{4}$, the $\mathrm{Ga}-\mathrm{Ga}$ bond length is 268.8 pm , in $(\mathrm{AlMe})_{8}\left(\mathrm{CCH}_{2} \mathrm{Ph}\right)_{5}(\mathrm{C} \equiv \mathrm{C}-\mathrm{Ph})$ the $\mathrm{Al}-\mathrm{Al}$ bond lengths are observed to be close to two average values: 260.9 and 282.9 pm , and in $\mathrm{K}_{2}\left[\mathrm{Al}_{12}{ }^{i} \mathrm{Bu}_{12}\right]$ the $\mathrm{Al}-\mathrm{Al}$ bond length is 268.5 pm .
$\mathrm{Al}_{50} \mathrm{Cp}_{12}^{*}\left(\right.$ or $\left.\mathrm{Al}_{50} \mathrm{C}_{120} \mathrm{H}_{180}\right)$ is a giant molecule, whose crystal structure shows a distorted square-antiprismatic $\mathrm{Al}_{8}$ moiety at its center, as shown in Fig. 13.6.4. $\mathrm{This}_{\mathrm{Al}_{8}}$ core is surrounded by 30 Al atoms that form an icosidodecahedron with 12 pentagonal faces and 20 trigonal faces. Each pentagonal faces is capped by an $\mathrm{AlCp} *$ unit, and the set of 12 Al atoms forms a very regular icosahedron, in which the $\mathrm{Al} \cdots \mathrm{Al}$ average distance is 570.2 pm . Each of the peripheral 12 Al atoms is coordinated by 10 atoms ( 5 Al and 5 C ) in the form of a staggered "mixed sandwich." In the molecule, the average Al-Al bond length is 277.0 pm ( $257.8-287.7 \mathrm{pm}$ ). The $60 \mathrm{CH}_{3}$ groups of the $12 \mathrm{Cp}^{*}$ ligands at the surface exhibits a topology resembling that of the carbon atoms in fullerene- $\mathrm{C}_{60}$. The average distance between a pair of nearest methyl groups of neighboring Cp* ligands ( 386 pm ) is approximately twice the van der Waals radius of a methyl group ( 195 pm ). The entire $\mathrm{Al}_{50} \mathrm{Cp}^{*}{ }_{12}$ molecule has a volume which is about five times large than that of a $\mathrm{C}_{60}$ molecule.

Fig. 13.6.4.
Molecular structure of $\mathrm{Al}_{50} \mathrm{Cp}_{12}^{*}$ ( $\mathrm{Cp}^{*}=$ pentamethylcyclopentadienide). For clarity, the $\mathrm{Cp}^{*}$ units are omitted, and only the bonds from the outer 12 Al atoms toward the ring centers are shown. The shaded atoms represent the central distorted square-antiprismatic $\mathrm{Al}_{8}$ moiety.

Fig. 13.6.5.
Structural formulas of some open-chain homocatenated compounds of heavier group 13 elements.

Fig. 13.6.6.
Molecular structure of a linear homocatenated compound containing six indium centers. The 3,5-dimethylphenyl groups of the $\beta$-diketiminate ligands have been omitted for clarity. Bond lengths (pm): $\operatorname{In}(1)-\operatorname{In}(2)$ 281.2, $\operatorname{In}(2)-\operatorname{In}(3) 283.5, \operatorname{In}(3)-\operatorname{In}(4) 285.4$, $\operatorname{In}(4)-\operatorname{In}(5) 284.1, \operatorname{In}(5)-\operatorname{In}(6) 282.2$; $\operatorname{In}(1)-\mathrm{I}(1) 279.8, \operatorname{In}(6)-\mathrm{I}(2) 278.0$; standard deviation 0.1 pm . Average $\mathrm{In}-\mathrm{In}-\mathrm{In}$ bond angle at $\operatorname{In}(2)$ to $\operatorname{In}(5)$ is $139.4^{\circ}$.

### 13.6.4 Linear catenation in heavier group 13 elements

For the heavier congeners of boron, the occurrence of well-characterized compounds possessing a linear extended skeleton containing two or more unsupported two-electron $\mathrm{E}-\mathrm{E}$ bonds is quite rare. Some discrete molecules exhibiting this feature include the open-chain trigallium subhalide complex $\mathrm{I}_{2}\left(\mathrm{PEt}_{3}\right) \mathrm{Ga}-\mathrm{GaI}\left(\mathrm{PEt}_{3}\right)-\mathrm{GaI}_{2}\left(\mathrm{PEt}_{3}\right)(\mathrm{Fig} .13 .6 .5(\mathrm{a}))$ and the trigonal tetranuclear indium complex $\left\{\operatorname{In}\left[\operatorname{In}\left(2,4,6-{ }^{i} \operatorname{Pr}_{3} \mathrm{C}_{6} \mathrm{H}_{2}\right)_{2}\right]_{3}\right\}$ (Fig. 13.6.5(b)).

Using a chelating ligand of the $\beta$-diketiminate class, a novel linear homocatenated hexanuclear indium compound has been synthesized (Fig. 13.6.5(c)). The four internal indium atoms are in the +1 oxidation state, and the terminal indium atoms, each carrying an iodo ligand, are both divalent. The coordination geometry at each indium center is distorted tetrahedral. As shown in Fig. 13.6.6, the mixed-valent molecule has a pseudo $C_{2}$ axis with a $\beta$-diketiminate ligand chelated to each metal center, and its zigzag backbone is held together by five unsupported In-In single bonds constructed from $\mathrm{sp}^{3}$ hybrid orbitals.

### 13.7 Structure of naked anionic metalloid clusters

The term metalloid cluster is used to describe a multinuclear molecular species in which the metal atoms exhibit closest packing (and hence delocalized intermetallic interactions) like that in bulk metal, and the metal-metal contacts outnumber the peripheral metal-ligand contacts. Most examples are found in the field of precious-metal cluster chemistry. In recent years, an increasing number of cluster species of group 13 elements have been synthesized with cores

consisting of $\mathrm{Al}_{n}(n=7,12,14,50,69)$ and $\mathrm{Ga}_{m}(m=9,10,19,22,24,26,84)$ atoms, for example $\left[\mathrm{Al}_{77}\left\{\mathrm{~N}\left(\mathrm{SiMe}_{3}\right)_{2}\right\}_{20}\right]^{2-}$ and $\left[\mathrm{Ga}_{8}\left\{\mathrm{~N}\left(\mathrm{SiMe}_{3}\right)_{2}\right\}_{20}\right]^{4-}$.

### 13.7.1 Structure of $\mathrm{Ga}_{84}\left[\mathrm{~N}\left(\mathrm{SiMe}_{3}\right)_{2}\right]_{20}{ }^{4-}$

The largest metalloid cluster characterized to date is $\mathrm{Ga}_{84}\left[\mathrm{~N}\left(\mathrm{SiMe}_{3}\right)_{2}\right]_{20}^{4-}$, the structure of which is illustrated in Fig. 13.7.1. It comprises four parts: a $\mathrm{Ga}_{2}$ unit, a $\mathrm{Ga}_{32}$ shell, a $\mathrm{Ga}_{30}$ "belt," and $20 \mathrm{Ga}\left[\mathrm{N}\left(\mathrm{SiMe}_{3}\right)_{2}\right]$ groups. The $\mathrm{Ga}_{2}$ unit [as shown in (a)] is located at the center of the 64 naked Ga atoms; the $\mathrm{Ga}-\mathrm{Ga}$ bond distance is 235 pm , which is almost as short as the "normal" triple $\mathrm{Ga}-\mathrm{Ga}$ bond ( 232 pm ). The $\mathrm{Ga}_{2}$ unit is encapsulated by a $\mathrm{Ga}_{32}$ shell in the form of a football with icosahedral caps, as shown in (b). The $\mathrm{Ga}_{2} @ \mathrm{Ga}_{32}$ aggregate is surrounded by a belt of 30 Ga atoms that are also naked, as shown in (c). Finally the entire $\mathrm{Ga}_{64}$ framework is protected by $20 \mathrm{Ga}\left[\mathrm{N}\left(\mathrm{SiMe}_{3}\right)_{2}\right]$ groups to form $\mathrm{Ga}_{84}\left[\mathrm{~N}\left(\mathrm{SiMe}_{3}\right)_{2}\right]_{20}{ }^{4-}$, as shown in (d). This large anionic cluster has a diameter of nearly 2 nm .

### 13.7.2 Structure of NaTl

The structure of sodium thallide NaTl can be understood as a diamond-like framework of Tl atoms, whose vacant sites are completely filled with Na atoms. Figure 13.7.2(a) shows the structure of NaTl , in which the $\mathrm{Tl}-\mathrm{Tl}$ covalent bonds are represented by solid lines. The Tl atom has three valence electrons, which are insufficient for the construction of a stable diamond framework. The deficit can be partially compensated by the introduction of Na atoms. The effective radius of the Na atom is considerably smaller than that in pure metallic sodium.

Fig. 13.7.1.
Structure of $\mathrm{Ga}_{84}\left[\mathrm{~N}\left(\mathrm{SiMe}_{3}\right)_{2}\right]_{20} 4-[$ the larger circles (shaded and unshaded) represent Ga atom, and the small circles represent N atoms]: (a) central $\mathrm{Ga}_{2}$ unit, (b) $\mathrm{Ga}_{32}$ shell, (c) a "belt" of 30 Ga atoms, and (d) the front of $\mathrm{Ga}_{84}\left[\mathrm{~N}\left(\mathrm{SiMe}_{3}\right)_{2}\right]_{20}{ }^{4-}$. The $\mathrm{Ga}_{2}$ and N atoms at the back are not shown, the $\mathrm{Ga}_{32}$ shell is emphasized by the broken lines, the "belt" of 30 Ga atoms are shaded, and for the ligands $\mathrm{N}\left(\mathrm{SiMe}_{3}\right)_{2}$ only the N atoms directly bonded to the Ga atoms are shown.

Fig. 13.7.2.
Structure of (a) NaTl and (b) $\mathrm{Li}_{2} \mathrm{AlSi}$.

(a)

(b)

Therefore, the chemical bonding in NaTl is expected to be a mixture of covalent, ionic, and metallic interactions.

The NaTl-type structure is the prototype for Zintl phases, which are intermetallic compounds which crystallize in typical "non-metal" crystal structures. Binary AB compounds LiAl, LiGa, LiIn and NaIn are both isoelectronic (isovalent) and isostructural with NaTl . In the $\mathrm{Li}_{2} \mathrm{AlSi}$ ternary compound, Al and Si form a diamond-like framework, in which the octahedral vacant sites of the Al sublattice are filled by Li atoms, as shown in Fig. 13.7.2(b).

From the crystal structure, physical measurements, and theoretical calculations, the nature of the chemical bond in the NaTl-type compound AB can be understood in the following terms:
(a) Strong covalent bonds exist between the B atoms ( $\mathrm{Al}, \mathrm{Ga}, \mathrm{In}, \mathrm{Tl}, \mathrm{Si}$ ).
(b) The alkali atoms (A) are not in bonding contact.
(c) The chemical bond between the A and B framework is metallic with a small ionic component.
(d) For the upper valence/conduction electron states a partial metal-like charge distribution can be identified.

### 13.7.3 Naked TIn ${ }_{n}^{m-}$ anion clusters

The heavier elements of Group 13, in particular thallium, are able to form discrete naked clusters with alkali metals. Table 13.7.1 lists some examples of $\mathrm{Tl}_{n}^{m-}$ naked anion clusters, and Fig. 13.7.3 shows their structures.

The bonding in these $\mathrm{Tl}_{n}{ }^{m-}$ anion clusters is similar to that in boranes. For example, the bond valences $(b)$ of $\mathrm{Tl}_{5}{ }^{7-}$ and centered $\mathrm{Tl}_{13}{ }^{11-}$ clusters are equal to those of $\mathrm{B}_{5} \mathrm{H}_{5}{ }^{2-}$ and $\mathrm{B}_{12} \mathrm{H}_{12}{ }^{2-}$, respectively. Note that, in $\mathrm{Tl}_{13}{ }^{11-}$, the central Tl atom contributes all three valence electrons to cluster bonding, so that the total number of bonding electrons is $(3+12 \times 1+11)=26$. This cluster is thus consolidated by ten $\mathrm{Tl}-\mathrm{Tl}-\mathrm{Tl} 3 c-2 e$ and three $\mathrm{Tl}-\mathrm{Tl} 2 c-2 e$ bonds. The $\mathrm{Tl}_{9}^{9-}$ cluster has 36 valence electrons, and its bond valence $b$ is 18 . The cluster is stabilized by three $\mathrm{Tl}-\mathrm{Tl}-\mathrm{Tl} 3 c-2 e$ bonds, as labeled by the three shaded faces in Fig. 13.7.3(e), and the remaining twelve edges represent $12 \mathrm{Tl}-\mathrm{Tl} 2 c-2 e$ bonds.

Table 13.7.1. Some examples of $\mathrm{Tl}_{n}^{m-}$ anion clusters

| Composition | Anion | Structure in Fig. 13.7.3 | Cluster symmetry | Bond valence (b) | Bonding |
| :---: | :---: | :---: | :---: | :---: | :---: |
| $\mathrm{Na}_{2} \mathrm{Tl}$ | $\mathrm{Tl}_{4}{ }^{\text {- }}$ | (a) | $T_{\text {d }}$ | 6 | $6 \mathrm{Tl}-\mathrm{Tl} 2 c-2 e$ bonds |
| $\mathrm{Na}_{2} \mathrm{~K}_{21} \mathrm{Tl}_{19}$ | $2 \mathrm{Tl}_{5}{ }^{7-}$ | (b) | $D_{3 \mathrm{~h}}$ | 9 | $\left\{\begin{array}{l} 3 \mathrm{Tl}-\mathrm{Tl}-\mathrm{Tl} 3 c-2 e \text { bonds } \\ 3 \mathrm{Tl}-\mathrm{Tl} 2 c-2 e \text { bonds } \end{array}\right.$ |
|  | $\mathrm{Tl}_{9}{ }^{9-}$ | (e) | defective $I_{\mathrm{h}}$ | 18 | $\left\{\begin{array}{l} 3 \mathrm{Tl}-\mathrm{Tl}-\mathrm{Tl} 3 c-2 e \text { bonds } \\ 12 \mathrm{Tl}-\mathrm{Tl} 2 c-2 e \text { bonds } \end{array}\right.$ |
| KTl | $\mathrm{Tl}_{6}{ }^{\text {- }}$ | (c) | $D_{4 \mathrm{~h}}$ | 12 | $12 \mathrm{Tl}-\mathrm{Tl} 2 \mathrm{c}-2 \mathrm{e}$ bonds |
| $\mathrm{K}_{10} \mathrm{Tl}_{7}$ | $\mathrm{Tl}_{7}^{7-}, 3 \mathrm{e}^{-}$ | (d) | $\sim D_{5 \mathrm{~h}}$ | 14 | $\left\{\begin{array}{l} 5 \mathrm{Tl}-\mathrm{Tl}-\mathrm{Tl} 3 c-2 e \text { bonds } \\ 4 \mathrm{Tl}-\mathrm{Tl} 2 c-2 e \text { bonds } \end{array}\right.$ |
| $\mathrm{K}_{8} \mathrm{Tl}_{11}$ | $\mathrm{Tl}_{11}{ }^{7-}, \mathrm{e}^{-}$ | (f) | $\sim D_{3 \mathrm{~h}}$ | 24 | $\left\{\begin{array}{l} 3 \mathrm{Tl}-\mathrm{Tl}-\mathrm{Tl} 3 c-2 e \text { bonds } \\ 18 \mathrm{Tl}-\mathrm{Tl} 2 c-2 e \text { bonds } \end{array}\right.$ |
| $\mathrm{Na}_{3} \mathrm{~K}_{8} \mathrm{Tl}_{13}$ | Tl ${ }_{13}{ }^{11-}$ | (g) | Centered $\sim I_{\text {h }}$ | 23 | $\left\{\begin{array}{l} 10 \mathrm{Tl}-\mathrm{Tl}-\mathrm{Tl} 3 c-2 e \text { bonds } \\ 3 \mathrm{Tl}-\mathrm{Tl} 2 c-2 e \text { bonds } \end{array}\right.$ |

The compound $\mathrm{K}_{10} \mathrm{Tl}_{7}$ is composed of ten $\mathrm{K}^{+}, \mathrm{arl}_{7}^{7-}$ and three delocalized electrons per formula unit and exhibits metallic properties. The $\mathrm{Tl}_{7}^{7-}$ cluster is an axially compressed pentagonal bipyramid conforming closely to $D_{5 \mathrm{~h}}$ symmetry [Fig. 13.7.3(d)]. The apex-apex bond distance of 346.2 pm is slightly longer than the bonds in the pentagonal waist ( $318.3-324.7 \mathrm{pm}$ ). Comparison between the structures of $\mathrm{Tl}_{7}^{7-}$ and $\mathrm{B}_{7} \mathrm{H}_{7}^{2-}$ [Fig. 13.4.6(a)] shows that both are pentagonal bipyramidal but $\mathrm{Tl}_{7}^{7-}$ is compressed along the $C_{5}$ axis for the formation of a coaxial $2 c-2 e \mathrm{Tl}-\mathrm{Tl}$ bond, so the bond valences of $\mathrm{Tl}_{7}^{7-}$ and $\mathrm{B}_{7} \mathrm{H}_{7}{ }^{2-}$ are 14 and 13 , respectively.

## Structural Chemistry of Group 14 Elements

### 14.1 Allotropic modifications of carbon

With the exception of the gaseous low-carbon molecules: $\mathrm{C}_{1}, \mathrm{C}_{2}, \mathrm{C}_{3}, \mathrm{C}_{4}, \mathrm{C}_{5}, \ldots$, the carbon element exists in the diamond, graphite, fullerene, and amorphous allotropic forms.

### 14.1.1 Diamond

Diamond forms beautiful, transparent, and highly refractive crystals, and has been used as a noble gem since antiquity. It consists of a three-dimensional network of carbon atoms, each of which is bonded tetrahedrally by covalent $\mathrm{C}-\mathrm{C}$ single bonds to four others, so that the whole diamond crystal is essentially a "giant molecule." Nearly all naturally occurring diamonds exist in the cubic form, space group $F d \overline{3} m$ (no. 227), with $a=356.688 \mathrm{pm}$ and $Z=8$. The $\mathrm{C}-\mathrm{C}$ bond length is 154.45 pm , and the $\mathrm{C}-\mathrm{C}-\mathrm{C}$ bond angle is $109.47^{\circ}$. In the crystal structure, the carbon atoms form six-membered rings that take the all-chair conformation [Fig. 14.1.1(a)]. The mid-point of every C-C bond is located at an inversion center, so that the six nearest carbon atoms about it are in a staggered arrangement, which is the most stable conformation.

In addition to cubic diamond, there is a metastable hexagonal form, which has been found in aerorite and can be prepared from graphite at 13 GPa above 1300 K. Hexagonal diamond crystallizes in space group $P 6_{3} / \mathrm{mmc}$ (no. 194) with $a=251 \mathrm{pm}, c=412 \mathrm{pm}$ and $Z=4$, as shown in Fig. 14.1.1(b). The bond type and the $\mathrm{C}-\mathrm{C}$ bond length are the same as in cubic diamond. The difference between the two forms is the orientation of two sets of tetrahedral bonds about neighboring carbon atoms: cubic diamond has the staggered arrangement

about each $\mathrm{C}-\mathrm{C}$ bond at an inversion center, but in hexagonal diamond some bonds take the eclipsed arrangement related by mirror symmetry. As repulsion between nonbonded atoms in the eclipsed arrangement is greater than that in the staggered arrangement, hexagonal diamond is much rarer than cubic diamond.

Diamond is the hardest natural solid known and has the highest melting point, $4400 \pm 100 \mathrm{~K}(12.4 \mathrm{GPa})$. It is an insulator in its pure form. Since the density of diamond ( $3.51 \mathrm{~g} \mathrm{~cm}^{-3}$ ) far exceeds that of graphite ( $2.27 \mathrm{~g} \mathrm{~cm}^{-3}$ ), high pressures can be used to convert graphite into diamond even though graphite is thermodynamically more stable by $2.9 \mathrm{~kJ} \mathrm{~mol}^{-1}$. To attain commercially viable rates for the pressure-induced conversion of graphite to diamond, a transitionmetal catalyst such as iron, nickel, or chromium is generally used. Recently, the method has been employed to deposit thin films of diamond onto a metallic or other material surface. The extreme hardness and high thermal conductivity of diamond find applications in numerous areas, notably the hardening of surfaces of electronic devices and as cutting and/or grinding materials.

Elemental silicon, germanium, and tin have the cubic diamond structure with unit-cell edge $a=543.072,565.754$, and $649.12 \mathrm{pm}(\alpha-\mathrm{Sn})$, respectively.

### 14.1.2 Graphite

Graphite is the common modification of carbon that is stable under normal conditions. Its crystal structure consists of planar layers of hexagonal carbon rings. Within the layer each carbon atom is bonded covalently to three neighboring carbon atoms at 141.8 pm . The $\sigma$ bonds between neighbors within a layer are formed from the overlap of $\mathrm{sp}^{2}$ hybrids, and overlap involving the remaining electron and perpendicular $p_{z}$ orbital on every atom generates a network of $\pi$ bonds that are delocalized over the entire layer. The relatively free movement of $\pi$ electrons in the layers leads to abnormally high electrical conductivity for a non-metallic substance.

The layers are stacked in a staggered manner with half of the atoms of one layer situated exactly above atoms of the layer below, and the other half over the rings centers. There are two crystalline forms that differ in the sequence of layer stacking.
(1) Hexagonal graphite or $\alpha$-graphite: The layers are arranged in the sequence ...ABAB..., as shown in Fig. 14.1.2(a). The space group is $P 6_{3} / \mathrm{mmc}$
(a)

Fig. 14.1.2.
Structure of graphite: (a) $\alpha$-graphite and (b) $\beta$-graphite.
(no. 194), and the unit cell has dimensions of $a=245.6 \mathrm{pm}$ and $c=669.4$ pm , so that the interlayer distance is $c / 2=334.7 \mathrm{pm}$.
(2) Rhombohedral graphite or $\beta$-graphite: The layers are arranged in the sequence ...ABCABC..., as shown in Fig. 14.1.2(b). The space group is $R \overline{3} m$ (no. 166), and the unit cell has dimensions of $a=246.1 \mathrm{pm}$ and $c=1006.4 \mathrm{pm}$. The interlayer separation $c / 3=335.5 \mathrm{pm}$ is similar to that of $\alpha$-graphite.

The enthalpy difference between hexagonal and rhombohedral graphite is only $0.59 \pm 0.17 \mathrm{~kJ} \mathrm{~mol}^{-1}$. The two forms are interconvertible by grinding (hexagonal $\rightarrow$ rhombohedral) or heating above $1025^{\circ} \mathrm{C}$ (rhombohedral $\rightarrow$ hexagonal). Partial conversion leads to an increase in the average spacing between layers; this reaches a maximum of 344 pm for turbostratic graphite in which the stacking sequence of the parallel layers is completely random.

In graphite the layers are held together by van der Waals forces. The relative weak binding between layers is consistent with its softness and lubricity, as adjacent layers are able to easily slide by each other. Graphite mixed with clay constitutes pencil "lead," which should not be confused with metallic lead or dark-gray lead sulfide.

### 14.1.3 Fullerenes

The third allotropic modification of carbon, the fullerenes, consists of a series of discrete molecules of closed cage structure bounded by planar faces, whose vertices are made up of carbon atoms. If the molecular cage consists of pentagons and hexagons only, the number of pentagons must always be equal to 12, while the number of hexagons may vary. Fullerenes are discrete globular molecules that are soluble in organic solvents, and their structure and properties are different from those of diamond and graphite.
Fullerenes can be obtained by passing an electric arc between two graphite electrodes in a controlled atmosphere of helium, or by controlling the helium/oxygen ratio in the incomplete combustion of benzene, followed by evaporation of the carbon vapor and re-crystallization from benzene. The main product of the preparation is fullerene- $\mathrm{C}_{60}$, and the next abundant product is fullerene- $\mathrm{C}_{70}$.

The structure of $\mathrm{C}_{60}$ has been determined by single-crystal neutron diffraction and electron diffraction in the gas phase. It has icosahedral $\left(I_{\mathrm{h}}\right)$ symmetry with 60 vertices, 90 edges, 12 pentagons, and 20 hexagons. The $\mathrm{C}-\mathrm{C}$ bond lengths are 139 pm for $6 / 6$ bonds (fusion of two six-membered rings) and 144 pm for $6 / 5$ bonds (fusion between five- and six-membered rings). The 60 carbon atoms all lie within a shell of mean diameter 700 pm . Figure 14.1.3(a) shows the soccerball shape of the $\mathrm{C}_{60}$ molecule. Each carbon atom forms three $\sigma$ bonds with three neighbors, and the remaining orbitals and electrons of the 60 C atoms form delocalized $\pi$ bonds. This structure may be formulated by the valencebond formula shown in Fig. 14.1.3(b). The $\mathrm{C}_{60}$ molecule can be chemically functionalized, and an unambiguous atom-numbering scheme is required for systematic nomenclature of its derivatives. Figure 14.1.3(c) shows the planar formula with carbon atom-numbering scheme of the $\mathrm{C}_{60}$ molecule.

In the $\mathrm{C}_{60}$ molecule, the sum of the $\sigma$ bond angles at each C atom is $348^{\circ}(=$ $120^{\circ}+120^{\circ}+108^{\circ}$ ), and the mean $\mathrm{C}-\mathrm{C}-\mathrm{C}$ angle is $116^{\circ}$. The $\pi$ atomic orbital

Fig. 14.1.3.
Structure of fullerene- $\mathrm{C}_{60}$ : (a) molecular shape, (b) valence-bond formula, and (c) planar formula with carbon atom-numbering scheme.
lies normal to the convex surface, the angle between the $\sigma$ and $\pi$ orbitals being $101.64^{\circ}$. It may be approximately calculated that each $\sigma$ orbital has s component $30.5 \%$ and p $69.5 \%$, and each $\pi$ orbital has s $8.5 \%$ and p $91.5 \%$.

Table 14.1.1. Some physical properties of fullerene- $\mathrm{C}_{60}$

| Density $\left(\mathrm{g} \mathrm{cm}^{-3}\right)$ | 1.65 |
| :--- | :---: |
| Bulk modulus $(\mathrm{GPa})$ | 18 |
| Refractive index $(630 \mathrm{~nm})$ | 2.2 |
| Heat of combustion (crystalline $\left.\mathrm{C}_{60}\right)\left(\mathrm{kJ} \mathrm{mol}^{-1}\right)$ | 2280 |
| Electron affinity $(\mathrm{eV})$ | $2.6-2.8$ |
| First ionization energy (eV) | 7.6 |
| Band gap $(\mathrm{eV})$ | 1.9 |
| Solubility $(303 \mathrm{~K})\left(\mathrm{g} \mathrm{dm}^{-3}\right)$ |  |
| $\mathrm{CS}_{2}$ | 5.16 |
| Toluene $^{\text {Benzene }}$ | 2.15 |
| $\mathrm{CCl}_{4}$ | 1.44 |
| Hexane | 0.45 |

Fullerene- $\mathrm{C}_{60}$ is a brown-black crystal, in which the nearly spherical molecules rotate continuously at room temperature. The structure of the crystal can be considered as a stacking of spheres of diameter 1000 pm in cubic closest packing ( $a=1420 \mathrm{pm}$ ) or hexagonal closest packing ( $a=1002 \mathrm{pm}$, $c=1639 \mathrm{pm})$. Figure 14.1.4 shows the crystal structure of fullerene- $\mathrm{C}_{60}$.

Below 249 K , the molecules are orientated in an ordered fashion, and the symmetry of the crystal is reduced from a face-centered cubic lattice to a primitive cubic lattice. At 5 K , the crystal structure determined by neutron diffraction yielded the following data: space group $P a \overline{3}$ (no. 205), $a=1404.08$ (1) pm; C-C bond lengths: ( $6 / 6$ ) $139.1 \mathrm{pm},(6 / 5) 144.4 \mathrm{pm}$, and 146.6 pm (mean 145.5 pm ).

In the $\mathrm{C}_{60}$ molecule, the mean distance from the center to every C vertex is 350 pm , so the molecule has a spherical skeleton with diameter 700 pm . Allowing for the van der Waals radius of the C atom ( 170 pm ), the $\mathrm{C}_{60}$ molecule has a central cavity of diameter 360 pm , which can accommodate a foreign atom. Some physical properties of $\mathrm{C}_{60}$ are summarized in Table 14.1.1.

Fig. 14.1.4.
The cubic face-centered structure of fullerene- $\mathrm{C}_{60}$.

In addition to $\mathrm{C}_{60}$, many other higher homologs have been prepared and characterized. Several synthetic routes to fullerenes have yielded gram quantities of pure $\mathrm{C}_{60}$ and $\mathrm{C}_{70}$, whereas $\mathrm{C}_{76}, \mathrm{C}_{78}, \mathrm{C}_{80}, \mathrm{C}_{82}, \mathrm{C}_{84}$ and other fullerenes have been isolated as minor products. Figure 14.1 .5 shows the structures of the following fullerenes: $\mathrm{C}_{20}, \mathrm{C}_{50}, \mathrm{C}_{70}$, and two $\mathrm{C}_{78}$-isomers.

In general, the polyhedral closed cages of fullerenes are made up entirely of $n$ three-coordinate carbon atoms that constitute 12 pentagonal and $(n / 2-10)$ hexagonal faces. The larger fullerenes synthesized so far do faithfully satisfy the isolated pentagon rule (IPR), which governs the stability of fullerenes comprising hexagons and exactly 12 pentagons. On the other hand, smaller fullerenes do not obey the IPR, and are so labile that their properties and reactivity have only been studied in the gas phase. The smallest fullerene that can exist theoretically is $\mathrm{C}_{20}$. It has been synthesized from dodecahedrane $\mathrm{C}_{20} \mathrm{H}_{20}$ by replacing the hydrogen atoms with relatively weakly bound bromine atoms to form a triene precursor of average composition $\left[\mathrm{C}_{20} \mathrm{HBr}_{13}\right]$, which was then subjected to debromination in the gas phase. The bowl isomer of $\mathrm{C}_{20}$ is likewise generated by gas-phase debromination of a $\left[\mathrm{C}_{20} \mathrm{HBr}_{9}\right]$ precursor prepared from bromination of corannulene $\mathrm{C}_{20} \mathrm{H}_{10}$. Identification of the two $\mathrm{C}_{20}$ isomers was achieved by mass-selective anion-photoelectron spectroscopy. Figure 14.1.5(a) shows the molecular structure of fullerene $\mathrm{C}_{20}$.

Fullerene- $\mathrm{C}_{50}$ has been trapped as its perchloro adduct $\mathrm{C}_{50} \mathrm{Cl}_{10}$, which was obtained in milligram quantity from the addition of $\mathrm{CCl}_{4}$ to the usual graphite arc-discharge process for the synthesis of $\mathrm{C}_{60}$ and larger fullerenes. The $D_{5 \mathrm{~h}}$ structure of $\mathrm{C}_{50} \mathrm{Cl}_{10}$, with all chlorine atoms lying in the equatorial plane and attached to $\mathrm{sp}^{3}$ carbon atoms, was established by mass spectrometry, ${ }^{13} \mathrm{C} \mathrm{NMR}$, and other spectroscopic methods. The idealized structure of $\mathrm{C}_{50}$ is displayed in Fig. 14.1.5(b).

The fullerene-C ${ }_{70}$ molecule has $D_{5 \mathrm{~h}}$ symmetry and an approximately ellipsoidal shape, as shown in Fig. 14.1.5(c). As in $\mathrm{C}_{60}$, the 12 five-membered rings in $\mathrm{C}_{70}$ are not adjacent to one another. In contrast to $\mathrm{C}_{60}, \mathrm{C}_{70}$ has an equatorial phenylene belt comprising 15 fused hexagons and two polar caps, each assembled from a pentagon that shares its edges with 5 hexagons. The curvature at the polar region is very similar to that of $\mathrm{C}_{60}$. There are five sets of geometrically distinct carbon atoms, and the observed ${ }^{13} \mathrm{C}$ NMR signals have the intensity ratios of 1:1:2:2:1. The measured carbon-carbon bond lengths (Fig. 14.1.6) in the crystal structure of the complex $\left(\eta^{2}-\mathrm{C}_{70}\right) \operatorname{Ir}(\mathrm{CO}) \mathrm{Cl}\left(\mathrm{PPh}_{3}\right)_{2}$ suggest that two equivalent lowest-energy Kekulé structures per equatorial hexagon are required to describe the structure and reactivity properties of $\mathrm{C}_{70}$.

The structures of two geometric isomers of fullerene- $\mathrm{C}_{78}$ have been elucidated by ${ }^{13} \mathrm{C}$ NMR spectroscopy: one has $C_{2 \mathrm{v}}$ symmetry, as shown in Fig. 14.1.5(d); the other has $D_{3}$ symmetry, as shown in Fig. 14.1.5(e). Structural assignments with qualities ranging from reliable to absolutely certain have also been made for $\mathrm{C}_{74}\left(D_{3 \mathrm{~h}}\right), \mathrm{C}_{76}\left(D_{2}\right), \mathrm{C}_{78}$ [a new isomer of $C_{2 \mathrm{v}}$ symmetry, which has a more spherical shape compared to the $\mathrm{C}_{78}\left(C_{2 \mathrm{v}}\right)$ isomer shown in Fig. 14.1.5(d)], $\mathrm{C}_{80}\left(D_{2}\right), \mathrm{C}_{82}\left(C_{2}\right), \mathrm{C}_{84}\left(D_{2}\right)$, and $\mathrm{C}_{84}\left(D_{2 \mathrm{~d}}\right)$.

In addition to the single globular species, fullerenes can be formed by joining two or more carbon cages, as found for the dimer $\mathrm{C}_{120}$ shown in Fig. 14.1.7. Xray diffraction showed that the dimer is connected by a pair of $\mathrm{C}-\mathrm{C}$ bonds linking the edges of hexagonal faces ( $6 / 6$ bonds) in two $\mathrm{C}_{60}$ units to form a central fourmembered ring, in which the bond lengths are 157.5 pm (connecting the two cages) and 158.1 pm ( $6 / 6$ bonds).

Fig. 14.1.6.
Two equivalent valence bond structures of $\mathrm{C}_{70}$ and measured bond lengths of the polyhedral cage in
$\left(\eta^{2}-\mathrm{C}_{70}\right) \operatorname{Ir}(\mathrm{CO}) \mathrm{Cl}\left(\mathrm{PPh}_{3}\right)_{2}$.

## Structural Chemistry of Selected Elements

Fullerene-C 60 was selected as 'Molecule of the Year 1991' by the journal Science (Washington). Discovery of this modification of carbon in the mid-1980s created a great excitement in the scientific community and popular press. Some of this interest undoubtedly stemmed from the fact that carbon is a common element that had been studied since ancient times, but still an entirely new field of fullerene chemistry suddenly emerged with great potential for exciting research and practical applications.

### 14.1.4 Amorphous carbon

Amorphous carbon is a general term that covers non-crystalline forms of carbon such as coal, coke, charcoal, carbon black (soot), activated carbon, vitreous carbon, glassy carbon, carbon fiber, carbon nanotubes, and carbon onions, which are important materials and widely used in industry. The arrangements of the carbon atoms in amorphous carbon are different from those in diamond, graphite, and fullerenes, but the bond types of carbon atoms are the same as in these three crystalline allotropes. Most forms of amorphous carbon consist of graphite scraps in irregularly packing.
Coal is by far the world's most abundant fossil fuel, with a total recoverable resource of about 1000 billion ( $10^{12}$ ) tons. It is a complex mixture of many compounds that contain a high percentage of carbon and hydrogen, but many other elements are also present as impurities. The composition of coal varies considerably depending on its age and location. A typical bituminous coal has the approximate composition $80 \% \mathrm{C}, 5 \% \mathrm{H}, 8 \% \mathrm{O}, 3 \% \mathrm{~S}$, and $2 \% \mathrm{~N}$. The manifold structures of coal are very complex and not clearly defined.

The high-temperature carbonization of coal yields coke, which is a soft, poorly graphitized form of carbon, most of which is used in steel manufacture.

Activated carbon is a finely divided form of amorphous carbon manufactured from the carbonization of an organic precursor, which possesses a microporous structure with a large internal surface area. The ability of the hydrophobic surface to adsorb small molecules accounts for the widespread applications of activated carbon as gas filters, decoloring agents in the sugar industry, water purification agents, and heterogeneous catalysts.

Carbon black (soot) is made by the incomplete combustion of liquid hydrocarbons or natural gas. The particle size of carbon black is exceedingly small, only 0.02 to $0.3 \mu \mathrm{~m}$, and its principal application is in the rubber industry where it is used to strengthen and reinforce natural rubber.

Carbon fibers are filaments consisting of non-graphitic carbon obtained by carbonization of natural or synthetic organic fibers, or fibers drawn from organic precursors such as resins or pitches, and subsequently heat-treated up to temperatures of about $300^{\circ} \mathrm{C}$. Carbon fibers are light and exceeding strong, so that they are now important industrial materials that have gained increasing applications ranging from sport equipment to aerospace strategic uses.

From observations in transmission electron micrography (TEM), carbon soot particles are found to have an idealized onion-like shelled structure, as shown in Fig. 14.1.8. Carbon onions varying from 3 to 1000 nm in diameter have been observed experimentally. In an idealized model of a carbon onion, the first shell is a $\mathrm{C}_{60}$ core of $I_{\mathrm{h}}$ symmetry, the second shell is $\mathrm{C}_{240}$ (comprising $2^{2} \times 60$

atoms), and in general the number of carbon atom in the $n$th shell is $n^{2} \times 60$. The molecular formula of a carbon onion is $\mathrm{C}_{60} @ \mathrm{C}_{240} @ \mathrm{C}_{540} @ \mathrm{C}_{960} @ .$. , and the intershell distance is always $\sim 350 \mathrm{pm}$.

Recent work based on HRTEM (high-resolution transmission electron microscopy) and simulations has established that carbon onions are spherical rather than polyhedral, and the intershell spacing increases gradually from a value well below that of graphite at the center to the expected value at the outermost pair. The individual shells are not aligned in any regular fashion and do not rotate relative to each other. The innermost core can be a smaller fullerene (e.g. $\mathrm{C}_{28}$ ) or a diamond fragment varying in size from 2 to 4.5 nm , and the internal cavity can be as large as 2 nm in diameter.

### 14.1.5 Carbon nanotubes

Carbon nanotubes were discovered in 1991 and consist of elongated cages bounded by cylindrical walls constructed from rolled graphene (graphite-like) sheets. In contrast to the fullerenes, nanotubes possess a network of fused six-membered rings, and each terminal of the long tube is closed by a halffullerene cap. Single-walled carbon nanotubes (SWNTs) with diameters in the range 0.4 to 3.0 nm have been observed experimentally; most of them lie within the range 0.6 to 2.0 nm , and those with diameter $0.7,0.5$ and 0.4 nm correspond to the fullerenes $\mathrm{C}_{60}, \mathrm{C}_{36}$ and $\mathrm{C}_{20}$, respectively. Electron micrographs of the smallest 0.4 nm nanotubes prepared by the arc-discharge method showed that each is capped by half of a $\mathrm{C}_{20}$ dodecahedron and has an antichiral structure.

A carbon SWNT can be visualized as a hollow cylinder formed by rolling a planar sheet of hexagonal graphite (unit-cell parameters $a=0.246$, $c=0.669 \mathrm{~nm}$ ). It can be uniquely described by a vector $\mathbf{C}=n \mathbf{a}_{1}+m \mathbf{a}_{2}$, where $\mathbf{a}_{1}$ and $\mathbf{a}_{2}$ are reference unit vectors as defined in Fig. 14.1.9. The SWNT is generated by rolling up the sheet such that the two end-points of the vector $\boldsymbol{C}$ are superimposed. The tube is denoted as $(n, m)$ with $n \geq m$, and its diameter $D$

Fig. 14.1.8.
Section of a carbon onion.

Fig. 14.1.9.
Generation of the chiral $(8,4)$ carbon nanotube by rolling a graphite sheet along the vector $\mathbf{C}=n \mathbf{a}_{1}+m \mathbf{a}_{2}$, and definition of the chiral angle $\theta$. The reference unit vectors $\mathbf{a}_{1}$ and $\mathbf{a}_{2}$ are shown, and the broken lines indicate the directions for generating achiral zigzag and armchair nanotubes.

Fig. 14.1.10.
Lateral view of three kinds of carbon nanotubes with end caps: (a) armchair $(5,5)$ capped by one-half of $\mathrm{C}_{60}$, (b) zigzag ( 9,0 ) capped by one-half of $\mathrm{C}_{60}$, and (c) an enantiomorphic pair of chiral SWNTs each capped by a hemisphere of icosahedral fullerene $\mathrm{C}_{140}$.
is given by

$$
D=|\mathbf{C}| / \pi=a\left(n^{2}+n m+m^{2}\right)^{\frac{1}{2}} / \pi
$$

The tubes with $m=n$ are called "armchair" and those with $m=0$ are referred to as "zigzag." All others are chiral with the chiral angle $\theta$ defined as that between the vectors $\mathbf{C}$ and $\mathbf{a}_{1} ; \theta$ can be calculated from the equation

$$
\theta=\tan ^{-1}\left[3^{\frac{1}{2}} m /(m+2 n)\right] .
$$

armchair $(5,5)$
-
zigzag $(9,0)$

chiral $(15,-5)$

chiral $(10,5)$

The values of $\theta$ lies between $0^{\circ}$ (for a zigzag tube) and $30^{\circ}$ (for an armchair tube). Note that the mirror image of a chiral $(n, m)$ nanotube is specified by $(n+m,-m)$. The three types of SWNTs are illustrated in Fig. 14.1.10.

There are multiwalled carbon nanotubes (MWNTs), each consisting of ten inner tubes or more. In a carbon MWNT, the spacing between two adjacent coaxial zigzag tubes $\left(n_{1}, 0\right)$ and $\left(n_{2}, 0\right)$ is $\Delta d / 2=(0.123 / \pi)\left(n_{2}-n_{1}\right)$. However, this cannot be made to be close to $c / 2=0.335 \mathrm{~nm}$ (the interlayer separation

in graphite) by any reasonable combination of $n_{2}$ and $n_{1}$, and hence no zigzag nanotube can exist as a component of a MWNT. On the other hand, a MWNT can be constructed for all armchair tubes $(5 m, 5 m)$ with $m=1,2,3$, etc., for which the intertube spacing is $(0.123 / \pi) 3^{1 / 2}(5)=0.339 \mathrm{~nm}$, which satisfies the requirement.

In practice, defect-free coaxial nanotubes rarely occur in experimental preparations. The observed structures include the capped, bent, and toroidal SWNTs, as well as the capped and bent, branched, and helical MWNTs. Figure 14.1.11 shows the HRTEM micrograph of a helical multiwalled carbon nanotube which incorporates a small number of five- and seven-membered rings into the graphene sheets of the nanotube surfaces.

### 14.2 Compounds of carbon

More than twenty million compounds containing carbon atoms are now known, the majority of which are organic compounds that contain carbon-carbon bonds.

From the perspective of structural chemistry, the modes of bonding, coordination, and the bond parameters of a particular element in its allotropic modifications may be further extended to its compounds. Thus organic compounds can be conveniently divided into three families that originate from their prototypes: aliphatic compounds from diamond, aromatic compounds from graphite, and fullerenic compounds from fullerenes.

### 14.2.1 Aliphatic compounds

Aliphatic compounds comprise hydrocarbons and their derivatives in which the molecular skeletons consist of tetrahedral carbon atoms connected by $\mathrm{C}-\mathrm{C}$ single bonds. These tetrahedral carbon atoms can be arranged as chains, rings, or finite frameworks, and often with an array of functional groups as substituents on various sites. The alkanes $\mathrm{C}_{n} \mathrm{H}_{2 n+2}$ and their derivatives are typical examples of aliphatic compounds.

Some frameworks of alicyclic compounds are derived from fragments of diamond, as shown in Fig. 14.2.1. In these molecules, all six-membered carbon rings have the chair conformation. Diamantane $\mathrm{C}_{14} \mathrm{H}_{20}$ is also named

Isotetramantane, $C_{\mathrm{s}}$
congressane as it was chosen as the logo of the XIXth Conference of IUPAC in London in 1963 as a challenging target for the participants; the successful synthesis was accomplished two years later. There are three structural isomers of tetramantane $\mathrm{C}_{22} \mathrm{H}_{28}$. X-ray analysis of anti-tetramantane has revealed an interesting bond-length progression: $\mathrm{CH}-\mathrm{CH}_{2}=152.4 \mathrm{pm}, \mathrm{C}-\mathrm{CH}_{2}=152.8 \mathrm{pm}$, $\mathrm{CH}-\mathrm{CH}=153.7 \mathrm{pm}$, and $\mathrm{C}-\mathrm{CH}=154.2 \mathrm{pm}$, approaching the limit of 154.45 pm in diamond as the number of bonded H atoms decreases.

### 14.2.2 Aromatic compounds

Graphite typifies the basic structural unit present in aromatic compounds, in which the planar carbon skeletons of these molecules and their derivatives can be considered as fragments of graphite, each consisting of carbon atoms which use their $\mathrm{sp}^{2}$ hybrids to form $\sigma$ bonds to one another, and overlap between the remaining parallel $\mathrm{p}_{z}$ orbitals gives rise to delocalized $\pi$ bonding. The aromatic compounds may be divided into the following four classes.

## (1) Benzene and benzene derivatives

Up to six hydrogen atoms in benzene can be mono- or poly-substituted by other atoms or groups to give a wide variety of derivatives. Up to six sterically bulky groups such as $\mathrm{SiMe}_{3}$ and ferrocenyl $\left(\mathrm{C}_{5} \mathrm{H}_{5} \mathrm{FeC}_{5} \mathrm{H}_{4}\right.$, Fc ) groups can be substituted into a benzene ring. Hexaferrocenylbenzene, $\mathrm{C}_{6} \mathrm{Fc}_{6}$, is of structural interest as a supercrowded arene, a metalated hexakis(cyclopentadienylidene)radialene, and the core for the construction of "Ferris wheel" supermolecules. In the crystalline solvate $\mathrm{C}_{6} \mathrm{Fc}_{6} \cdot \mathrm{C}_{6} \mathrm{H}_{6}$, the $\mathrm{C}_{6} \mathrm{Fc}_{6}$ molecule adopts a propeller-like configuration with alternating up and down Fc groups around the central benzene ring. Perferrocenylation causes the benzene ring to take a chair conformation with alternating $\mathrm{C}-\mathrm{C}-\mathrm{C}-\mathrm{C}$ dihedral angles of $\pm 14^{\circ}$, and the elongated $\mathrm{C}-\mathrm{C}$ bonds exhibit noticeable bond alternation averaging $142.7 / 141.1 \mathrm{pm}$. The $\mathrm{C}_{\mathrm{ar}}-\mathrm{C}_{\mathrm{Fc}}$ bonds average $146.9(5) \mathrm{pm}$.

(b)

Acenaphthylene

Fig. 14.2.2.
Carbon skeletons of some polycyclic aromatic compounds of the (a) benzenoid type and (b) non-benzenoid type.

## (2) Polycyclic benzenoid aromatic compounds

These compounds consist of two or more benzene rings fused together, and the number of delocalized $\pi$ electrons conforms to the Hückel $(4 n+2)$ rule for aromaticity. Figure 14.2.2(a) shows the carbon skeletons of some typical examples.

## (3) Non-benzenoid aromatic compounds

Many aromatic compounds have considerable resonance stabilization but do not possess a benzene nucleus, or in the case of a fused polycyclic system, the molecular skeleton contains at least one ring that is not a benzene ring. The cyclopentadienyl anion $\mathrm{C}_{5} \mathrm{H}_{5}^{-}$, the cycloheptatrienyl cation $\mathrm{C}_{7} \mathrm{H}_{7}^{+}$, the aromatic annulenes (except for [6]annulene, which is benzene), azulene, biphenylene and acenaphthylene (see Fig. 14.2.2(b)) are common examples of non-benzenoid aromatic hydrocarbons. The cyclic oxocarbon dianions $\mathrm{C}_{n} \mathrm{O}_{n}^{2-}(n=3,4,5,6)$ constitute a class of non-benzenoid aromatic compounds stabilized by two delocalized $\pi$ electrons. Further details are given in Section 20.4.4.

## (4) Heterocyclic aromatic compounds

In many cyclic aromatic compounds an element other than carbon (commonly $\mathrm{N}, \mathrm{O}$, or S ) is also present in the ring. These compounds are called heterocycles. Figure 14.2 .3 shows some nitrogen heterocycles commonly used as ligands, as well as planar, sunflower-like octathio[8]circulene, $\mathrm{C}_{16} \mathrm{~S}_{8}$, which can be regarded as a novel form of carbon sulfide.

### 14.2.3 Fullerenic compounds

The derivatives of fullerenes are called fullerenic compounds, which are now mainly prepared from $\mathrm{C}_{60}$ and, to a lesser extent, from $\mathrm{C}_{70}$ and $\mathrm{C}_{84}$.

Since efficient methods for the synthesis and purification of gram quantities of $\mathrm{C}_{60}$ and $\mathrm{C}_{70}$ became available in the early 1990s, fullerene chemistry has developed at a phenomenal pace. There are many reactions which can generate

Fig. 14.2.3.

fullerenic compounds, as shown in Fig. 14.2.4. Unlike the aromatics, fullerenes have no hydrogen atoms or other groups attached, and so are unable to undergo substitution reactions. However, the globular fullerene carbon skeleton gives rise to an unprecedented diversity of derivatives. This unique feature leads to a vast number of products that may arise from addition of just one reagent. Substitution reactions can take place on derivatives, once these have been formed by addition. Some fullerenic compounds are briefly described below.
(a)
(b)
(c)

## (1) Fullerenes bonded to non-metallic elements

This class of compounds consists of fullerene adducts with covalent bonds formed between the fullerene carbon atoms and non-metallic elements. Since all carbon atoms lie on the globular fullerene surface, the number of sites, as well as their positions, where additions take place vary from case to case. Examples of these compounds include $\mathrm{C}_{60} \mathrm{O}, \mathrm{C}_{60}\left(\mathrm{CH}_{2}\right), \mathrm{C}_{60}\left(\mathrm{CMe}_{3}\right), \mathrm{C}_{60} \mathrm{Br}_{6}$, $\mathrm{C}_{60} \mathrm{Br}_{8}, \mathrm{C}_{60} \mathrm{Br}_{24}, \mathrm{C}_{50} \mathrm{Cl}_{10}$, and $\mathrm{C}_{60}\left[\mathrm{OsO}_{4}(\mathrm{pyBu})_{2}\right]$. In the first two examples, the oxygen atom and the methylene carbon atom are each bonded to two carbon atoms on a (6/6) edge in the fullerene skeleton. The structure of $\mathrm{C}_{60} \mathrm{O}$ is shown in Fig. 14.2.5(a). In the next five examples, the C atom of $\mathrm{CMe}_{3}$, as well as Br and Cl , is each bonded to only one carbon atom of fullerene. The structure of $\mathrm{C}_{60} \mathrm{Br}_{6}$ is displayed in Fig. 14.2.5(b). In the final example, the six-coordinate osmium(VI) moiety $\mathrm{OsO}_{4}(\mathrm{pyBu})_{2}$ is linked to $\mathrm{C}_{60}$ through the formation of a pair of $\mathrm{O}-\mathrm{C}$ single bonds with two neighboring carbon atoms in the fullerene skeleton, as shown in Fig. 14.2.5(c).

## (2) Coordination compounds of fullerene

This class of coordination compounds features direct covalent bonds between complexed metal groups and the carbon atoms of fullerene systems. Monoadducts such as $\mathrm{C}_{60} \mathrm{Pt}\left(\mathrm{PPh}_{3}\right)_{2}$ each have only one group bonded to a fullerene, as shown in Fig. 14.2.6(a). Multiple adducts are formed when several groups are attached to the same fullerene nucleus. Typical examples are $\mathrm{C}_{60}\left[\mathrm{Pt}\left(\mathrm{PPh}_{3}\right)_{2}\right]_{6}$ and $\mathrm{C}_{70}\left[\mathrm{Pt}\left(\mathrm{PPh}_{3}\right)_{2}\right]_{4}$, whose structures are displayed in Figs. 14.2.6(b) and 14.2.6(c), respectively.

## (3) Fullerenes as $\pi$-ligands

In this class of metal complexes, there is delocalized $\pi$ bonding between fullerene and the metal atom. The structures of $\left(\eta^{5}-\mathrm{C}_{5} \mathrm{H}_{5}\right) \mathrm{Fe}\left(\eta^{5}-\mathrm{C}_{60} \mathrm{Me}_{5}\right)$ and $\left(\eta^{5}-\mathrm{C}_{5} \mathrm{H}_{5}\right) \mathrm{Fe}\left(\eta^{5}-\mathrm{C}_{70} \mathrm{Me}_{3}\right)$, each containing a fused ferrocene moiety, are shown in Fig. 14.2.7. The shared pentagonal carbon ring of the $\mathrm{C}_{60}$ (or $\mathrm{C}_{70}$ ) skeleton acts as a $6 \pi$-electron donor ligand to the $\mathrm{Fe}(\mathrm{II})$ atom of the $\mathrm{Fe}\left(\mathrm{C}_{5} \mathrm{H}_{5}\right)$ fragment. In $\left(\eta^{5}-\mathrm{C}_{5} \mathrm{H}_{5}\right) \mathrm{Fe}\left(\eta^{5}-\mathrm{C}_{60} \mathrm{Me}_{5}\right)$, the five methyl groups attached to five $\mathrm{sp}^{3}$ carbon atoms protrude outward at an angle of $42^{\circ}$ relative to the symmetry axis of the molecule. The $\mathrm{C}_{5} \mathrm{H}_{5}$ group and cyclopentadienide in $\mathrm{Fe}\left(\mathrm{C}_{60} \mathrm{Me}_{5}\right)$ are arranged in a staggered manner; the $\mathrm{C}-\mathrm{C}$ bond lengths are 141.1 pm (averaged

Fig. 14.2.5.
Fullerenes bonded to non-metallic elements: (a) $\mathrm{C}_{60} \mathrm{O}$, (b) $\mathrm{C}_{60} \mathrm{Br}_{6}$, and (c) $\mathrm{C}_{60}\left[\mathrm{OsO}_{4}(\mathrm{pyBu})_{2}\right]$.

## Structural Chemistry of Selected Elements

for $\mathrm{C}_{5} \mathrm{H}_{5}$ ) and 142.5 pm (averaged for $\mathrm{C}_{60} \mathrm{Me}_{5}$ ). The $\mathrm{Fe}-\mathrm{C}$ distances are 203.3 pm for $\mathrm{C}_{5} \mathrm{H}_{5}$ and 208.9 pm for $\mathrm{C}_{60} \mathrm{Me}_{5}$, which are comparable to those in known ferrocene derivatives. The structural features of $\left(\eta^{5}-\mathrm{C}_{5} \mathrm{H}_{5}\right) \mathrm{Fe}\left(\eta^{5}-\right.$ $\left.\mathrm{C}_{70} \mathrm{Me}_{3}\right)$ are similar to those of $\left(\eta^{5}-\mathrm{C}_{5} \mathrm{H}_{5}\right) \mathrm{Fe}\left(\eta^{5}-\mathrm{C}_{60} \mathrm{Me}_{5}\right)$. The $\mathrm{C}-\mathrm{C}$ bond lengths in the shared pentagon are $141-3 \mathrm{pm}$. The $\mathrm{Fe}-\mathrm{C}$ bond distances are 205.4 pm (averaged for $\mathrm{C}_{5} \mathrm{H}_{5}$ ) and 208.3 pm (averaged for $\mathrm{C}_{70} \mathrm{Me}_{3}$ ).

## (4) Metal fullerides

Fullerenes exhibit an electron-accepting nature and react with strong reducing agents, such as the alkali metals, to yield metal fulleride salts. The compounds $\mathrm{Li}_{12} \mathrm{C}_{60}, \mathrm{Na}_{11} \mathrm{C}_{60}, \mathrm{M}_{6} \mathrm{C}_{60}(\mathrm{M}=\mathrm{K}, \mathrm{Rb}, \mathrm{Cs}), \mathrm{K}_{4} \mathrm{C}_{60}$ and $\mathrm{M}_{3} \mathrm{C}_{60}\left(\mathrm{M}_{3}=\mathrm{K}_{3}\right.$, $\mathrm{Rb}_{3}, \mathrm{RbCs}_{2}$ ) have been prepared.

The $\mathrm{M}_{3} \mathrm{C}_{60}$ compounds are particularly interesting as they become superconducting materials at low temperature, with transition temperatures ( $T_{\mathrm{c}}$ ) of 19 K for $\mathrm{K}_{3} \mathrm{C}_{60}, 28 \mathrm{~K}$ for $\mathrm{Rb}_{3} \mathrm{C}_{60}$, and 33 K for $\mathrm{RbCs}_{2} \mathrm{C}_{60}$.

Fulleride $\mathrm{K}_{3} \mathrm{C}_{60}$ is a face-centered cubic crystal, space group $F m \overline{3} m$, with $a=1424(1) \mathrm{pm}$ and $Z=4$. The $\mathrm{C}_{60}{ }^{3-}$ ions form a ccp structure with $\mathrm{K}^{+}$ions filling all the tetrahedral interstices (radius 112 pm ) and octahedral interstices (radius 206 pm ), as shown in Fig. 14.2.8.

Both $\mathrm{K}_{4} \mathrm{C}_{60}$ and $\mathrm{Rb}_{4} \mathrm{C}_{60}$ are tetragonal, and the structure of $\mathrm{M}_{6} \mathrm{C}_{60}$ at room temperature is body-centered cubic. These metal fullerides are all insulators.

## (5) Fullerenic supramolecular adducts

Fullerenes $\mathrm{C}_{60}$ and $\mathrm{C}_{70}$ form supramolecular adducts with a variety of molecules, such as crown ethers, ferrocene, calixarene, and hydroquinone. In the solid state, the intermolecular interactions may involve ionic interaction, hydrogen bonding, and van der Waals forces. Figure 14.2.9 shows a part of the structure of $[\mathrm{K}(18 \mathrm{C} 6)]_{3} \cdot \mathrm{C}_{60} \cdot\left(\mathrm{C}_{6} \mathrm{H}_{5} \mathrm{CH}_{3}\right)_{3}$, in which $\mathrm{C}_{60}^{3-}$ is surrounded by a pair of $\left[\mathrm{K}^{+}(18 \mathrm{C} 6)\right]$ complexed cations.

## (6) Fullerene oligomers and polymers

This class of compounds contain two or more fullerenes and they may be further divided into the following three categories.
(a) Dimers and polymers containing two or more fullerenes are linked together through $\mathrm{C}-\mathrm{C}$ covalent bonds formed by the carbon atoms on the globular surface. Figure 14.2.10(a) shows the structure of dimeric $\left[\mathrm{C}_{60}\left({ }^{t} \mathrm{Bu}\right)\right]_{2}$. In addition, chain-like polymeric fullerenes with the following structure have been proposed, although none has yet been prepared:

$$
\left\lceil\mathrm{C}_{60} \mathrm{H}_{2}-\mathrm{C}_{60} \mathrm{H}_{2}-\mathrm{C}_{60} \mathrm{H}_{2} \dashv_{n}\right.
$$

(b) Two or more fullerenes are linked together through the formation of $\mathrm{C}-\mathrm{C}$ covalent bonds with an organic functional group. Figure 14.2.10(b) shows the structure of $\left[\mathrm{C}_{60}\right]_{3}\left(\mathrm{C}_{14} \mathrm{H}_{14}\right)$, in which three fullerenes form an adduct through C-C linkage with the central $\mathrm{C}_{14} \mathrm{H}_{14}$ unit.

Fig. 14.2.8.

## Structural Chemistry of Selected Elements

(c) Fullerenes are linked as pendants at regular intervals to a skeleton of a polymeric chain, such as:

## (7) Heterofullerenes

Heterofullerenes are fullerenes in which one or more carbon atoms in the cage are replaced by other main-group atoms. Compounds containing boron, such as $\mathrm{C}_{59} \mathrm{~B}, \mathrm{C}_{58} \mathrm{~B}_{2}, \mathrm{C}_{69} \mathrm{~B}$, and $\mathrm{C}_{68} \mathrm{~B}_{2}$, have been detected in the mass spectra of the products obtained using boron/graphite rods in arc discharge synthesis. Since nitrogen has one more electron than carbon, the azafullerenes are radicals $\left(\mathrm{C}_{59} \mathrm{~N} \cdot, \mathrm{C}_{69} \mathrm{~N} \cdot\right)$, which can either dimerise to give $\left(\mathrm{C}_{59} \mathrm{~N}\right)_{2}$ and $\left(\mathrm{C}_{69} \mathrm{~N}\right)_{2}$, or take up hydrogen to give $\mathrm{C}_{59} \mathrm{NH}$.

## (8) Endohedral fullerenes (incar-fullerenes)

Fullerenes can encapsulate various atoms within the cages, and these compounds have been referred to as endohedral fullerenes. For example, the symbolic representations $\mathrm{La} @ \mathrm{C}_{60}$ and $\mathrm{La}_{2} @ \mathrm{C}_{80}$ indicate that the fullerene cage encapsulates one and two lanthanum atom(s), respectively. The IUPAC description refers to these fullerenes species as incar-fullerenes, and the formulas are written as $i \mathrm{LaC}_{60}$ and $i \mathrm{La}_{2} \mathrm{C}_{80}$, ( $i$ is derived from incarcerane). Some metal endohedral fullerenes are listed in Table 14.2.1. The endohedral fullerenes are expected to have interesting and potentially very useful bulk properties as well as a fascinating chemistry. Some non-metallic elements, such as $\mathrm{N}, \mathrm{P}$, and noble gases, can be incarcerated into fullerenes to form $\mathrm{N} @ \mathrm{C}_{60}, \mathrm{P} @ \mathrm{C}_{60}$, $\mathrm{N} @ \mathrm{C}_{70}, \mathrm{Sc}_{3} \mathrm{~N} @ \mathrm{C}_{80}, \operatorname{Ar} @ \mathrm{C}_{60}$, etc.

Table 14.2.1. Endohedral fullerenes

| Fullerene | Metallic atom | Fullerene | Metallic atom |
| :--- | :--- | :--- | :--- |
| $\mathrm{C}_{36}$ | U | $\mathrm{C}_{56}$ | $\mathrm{U}_{2}$ |
| $\mathrm{C}_{44}$ | $\mathrm{~K}, \mathrm{La}, \mathrm{U}$ | $\mathrm{C}_{60}$ | $\mathrm{Y}_{2}, \mathrm{La}_{2}, \mathrm{U} \mathrm{C}_{2}$ |
| $\mathrm{C}_{48}$ | Cs | $\mathrm{C}_{66}$ | $\mathrm{Sc}_{2}$ |
| $\mathrm{C}_{50}$ | $\mathrm{U}, \mathrm{La}$ | $\mathrm{C}_{74}$ | $\mathrm{Sc}_{2}$ |
| $\mathrm{C}_{60}$ | $\mathrm{Li}, \mathrm{Na}, \mathrm{K}, \mathrm{Rb}, \mathrm{Cs}, \mathrm{Ca}, \mathrm{Ba}, \mathrm{Co}$, | $\mathrm{C}_{76}$ | $\mathrm{La}_{2}$ |
|  | $\mathrm{Y}, \mathrm{La}, \mathrm{Ce}, \mathrm{Pr}, \mathrm{Nd}, \mathrm{Sm}, \mathrm{Eu}, \mathrm{Gd}$, | $\mathrm{C}_{79} \mathrm{~N}$ | $\mathrm{La}_{2}$ |
|  | $\mathrm{~Tb}, \mathrm{Dy}, \mathrm{Ho}, \mathrm{Lu}, \mathrm{U}$ | $\mathrm{C}, \mathrm{C}, \mathrm{C}_{80}$ | $\mathrm{La}_{2}, \mathrm{Ce}_{2}, \mathrm{Pr}_{2}$ |
| $\mathrm{C}_{70}$ | $\mathrm{Li}, \mathrm{Ca}, \mathrm{Y}, \mathrm{Ba}, \mathrm{La}, \mathrm{Ce}, \mathrm{Gd}, \mathrm{Lu}, \mathrm{U}$ | $\mathrm{C}_{82}$ | $\mathrm{Er}_{2}, \mathrm{Sc}_{2}, \mathrm{Y}_{2}, \mathrm{La}_{2}, \mathrm{Lu}_{2}$, |
| $\mathrm{C}_{72}$ | U |  | $\mathrm{Sc}_{2} \mathrm{C}_{2}$ |
| $\mathrm{C}_{74}$ | $\mathrm{Ca}, \mathrm{Sc}, \mathrm{La}, \mathrm{Gd}, \mathrm{Lu}$ | $\mathrm{C}_{84}$ | $\mathrm{Sc}_{2}, \mathrm{La}_{2}, \mathrm{Sc}_{2} \mathrm{C}_{2}$ |
| $\mathrm{C}_{76}$ | La | $\mathrm{C}_{68}$ | $\mathrm{Sc}_{3} \mathrm{~N}$ |
| $\mathrm{C}_{80}$ | $\mathrm{Ca}, \mathrm{Sr}, \mathrm{Ba}$ | $\mathrm{C}_{78}$ | $\mathrm{Sc}_{3} \mathrm{~N}$ |
| $\mathrm{C}_{81} \mathrm{~N}$ | La | $\mathrm{C}_{80}$ | $\mathrm{Sc}_{3} \mathrm{~N}, \mathrm{ErSc}_{2} \mathrm{~N}, \mathrm{Sc} 2 \mathrm{LaN}$, |
| $\mathrm{C}_{82}$ | $\mathrm{Ca}, \mathrm{Sr}, \mathrm{Ba}, \mathrm{Sc}, \mathrm{Y}, \mathrm{La}, \mathrm{Ce}, \mathrm{Pr}$, |  | $\mathrm{ScLa}_{2} \mathrm{~N}, \mathrm{La}_{3} \mathrm{~N}$ |
|  | $\mathrm{Nd}, \mathrm{Sm}, \mathrm{Eu}, \mathrm{Gd}, \mathrm{Tb}, \mathrm{Dy}, \mathrm{Ho}$, | $\mathrm{C}_{82}$ | $\mathrm{Sc}_{3}$ |
|  | $\mathrm{Er}, \mathrm{Tm}, \mathrm{Yb}, \mathrm{Lu}$ | $\mathrm{C}_{84}$ | $\mathrm{Sc}_{3}$ |
| $\mathrm{C}_{84}$ | $\mathrm{Ca}, \mathrm{Sr}, \mathrm{Ba}, \mathrm{Sc}, \mathrm{La}$ | $\mathrm{C}_{82}$ | $\mathrm{Sc}_{4}$ |

Theoretical and experimental studies of the structures and electronic properties of endohedral fullerenes have yielded many interesting results. The enclosed N and P atoms of $\mathrm{N} @ \mathrm{C}_{60}$ and $\mathrm{P} @ \mathrm{C}_{60}$ retain their atomic ground state configuration and are localized at the center of the fullerenes, as shown in Fig. 14.2.11(a). The atoms are almost freely suspended inside the respective molecular cages and exhibit properties resembling those of ions in electromagnetic traps. In $\mathrm{Ca} @ \mathrm{C}_{60}$, the Ca atom lies at an off-center position by 70 pm , as shown in Fig. 14.2.11(b). The symmetry of $\mathrm{Ca}^{@} \mathrm{C}_{60}$ is predicted to be $C_{5 \mathrm{v}}$, implying that the Ca atom lies on a fivefold rotation axis of the $\mathrm{C}_{60}$ cage. The predicted distances between the Ca atom and the first and second set of nearest C atoms are 279 and 293 pm , respectively.

A single-crystal X-ray diffraction study of $\left[\mathrm{Sc}_{3} \mathrm{~N} @ \mathrm{C}_{78}\right] \cdot[\mathrm{Co}(\mathrm{OEP})]$ $\cdot 1.5\left(\mathrm{C}_{6} \mathrm{H}_{6}\right) \cdot 0.3\left(\mathrm{CHCl}_{3}\right)$ (OEP is the dianion of octaethylporphyrin) showed that the fullerene is embraced by the eight ethyl groups of the porphyrin macrocycle. The structure of $\left[\mathrm{Sc}_{3} \mathrm{~N} @ \mathrm{C}_{78}\right]$ is shown in Fig. 14.2.11(c). The N-Sc distances range from 198 to 212 pm , and the shortest C -Sc distances fall within a narrow range of $202-11 \mathrm{pm}$. The flat $\mathrm{Sc}_{3} \mathrm{~N}$ unit is oriented so that it lies near the equatorial mirror plane of the $\mathrm{C}_{78}$ cage.

A synchrotron X-ray powder diffraction study of $\left(\mathrm{Sc}_{2} \mathrm{C}_{2}\right) @ \mathrm{C}_{84}$ showed that the lozenge-shaped $\mathrm{Sc}_{2} \mathrm{C}_{2}$ unit is encapsulated by the $D_{2 \mathrm{~d}}-\mathrm{C}_{84}$ fullerene, as shown in Fig. 14.2.11(d). The $\mathrm{Sc}-\mathrm{Sc}, \mathrm{Sc}-\mathrm{C}$ and $\mathrm{C}-\mathrm{C}$ distances in the $\mathrm{Sc}_{2} \mathrm{C}_{2}$ unit are 429,226 and 142 pm , respectively.

### 14.3 Bonding in carbon compounds

### 14.3.1 Types of bonds formed by the carbon atom

The capacity of the carbon atom to form various types of covalent bonds is attributable to its unique characteristics as an element in the Periodic Table.

Fig. 14.2.11.
Structures of some endofullerenes: (a) $\mathrm{N} @ \mathrm{C}_{60}$, (b) $\mathrm{Ca} @ \mathrm{C}_{60}$, (c) $\mathrm{Sc}_{3} \mathrm{~N} @ \mathrm{C}_{78}$ and (d) $\mathrm{Sc}_{2} \mathrm{C}_{2} @ \mathrm{C}_{84}$.

Table 14.3.1. Hybridization schemes of carbon atom

|  | sp | $\mathrm{sp}^{2}$ | $\mathrm{sp}^{3}$ |
| :--- | :--- | :--- | :--- |
| Number of orbitals | 2 | 3 | 4 |
| Interorbital angle | $180^{\circ}$ | $120^{\circ}$ | $109.47^{\circ}$ |
| Geometry | Linear | Trigonal | Tetrahedral |
| \% s character | 50 | 33 | 25 |
| \% p character | 50 | 67 | 75 |
| Electronegativity of carbon | 3.29 | 2.75 | 2.48 |
| Remaining p orbitals | 2 | 1 | 0 |

The electronegativity of the carbon atom is 2.5 , which means that the carbon atom cannot easily gain or lose electrons to form an anion or cation. As the number of valence orbitals is exactly equal to the number of valence electrons, the carbon atom cannot easily form a lone pair or electron-deficient bonds. Carbon has a small atomic radius, so its orbitals can overlap effectively with the orbitals of neighbor atoms in a molecule.

For simplicity, we use the conventional concept of hybridization to describe the bond types, but bonding is frequently more subtle and more extended than implied by this localized description. The parameters of typical hybridization schemes of the carbon atom are listed in Table 14.3.1.

The hybrid orbitals of carbon always overlap with orbitals of other atoms in a molecule to form $\sigma$ bonds. The remaining p orbitals can then be used to form $\pi$ bonds, which can be classified into two categories: localized and delocalized. The localized $\pi$ bonds of carbon form double and triple bonds as illustrated below:

$\pi=$

$\pi_{y} \pi_{z}$

$\pi_{y}$
$\pi$

The carbon atom can also form $\sigma$ and $\pi$ bonds to metal atoms in various fashions. For example:
(a)

single bond
(b)

(c)

double bond
(d)

triple bond

A particularly interesting example is the tungsten complex

which contains $\mathrm{C} \equiv \mathrm{W}, \mathrm{C}=\mathrm{W}$, and $\mathrm{C}-\mathrm{W}$ bonds with lengths 179 , 194, and 226 pm , respectively.

The delocalized $\pi$ bonds involve three or more carbon atoms or heteroatoms. For instance:

$\begin{array}{rr}\pi_{3}{ }^{4} & \pi_{4}^{4} \\ \mathrm{C}_{3} \mathrm{H}_{5} & \mathrm{CH}_{5}\end{array}$
$\pi_{5}{ }^{6}$
$\mathrm{C}_{5} \mathrm{H}_{5}^{-}$

$\pi_{6}{ }^{6}$
$\mathrm{C}_{6} \mathrm{H}_{6}$
$\mathrm{C}_{5} \mathrm{H}_{5} \mathrm{~N}$

An enormous variety of $\pi$-bonded systems, whether they be neutral or ionic, cyclic or linear, odd or even in the number of carbon atoms, serve as ligands that coordinate to transition metals. Figure 14.3 .1 shows some representatives of the innumerable organometallic coordination compounds stabilized by metal- $\pi$ bonding.

Larger aromatic rings and polycyclic aromatic hydrocarbons can also function as $\pi$ ligands in forming sandwich-type metal complexes. For example, the planar cyclooctatetraenyl dianion $\mathrm{C}_{8} \mathrm{H}_{8}{ }^{2-}$ functions as a $\eta^{8}$-ligand to form the sandwich compound uranocene, $\mathrm{U}\left(\mathrm{C}_{8} \mathrm{H}_{8}\right)_{2}$, which takes the eclipsed configuration.

Recently the "sandwich" motif has been extended to the case of two cyclic aromatic ligands flanking a small planar aggregate of metal atoms. In $\left[\operatorname{Pd}_{3}\left(\eta^{7}-\right.\right.$ $\left.\left.\mathrm{C}_{7} \mathrm{H}_{7}\right)_{2} \mathrm{Cl}_{3}\right]\left(\mathrm{PPh}_{4}\right)$, a triangular unit of palladium( 0 ) atoms each coordinated by

(c)

Fig. 14.3.2.
(a) Molecular geometry and (b) structural formula of the $\left[\mathrm{Pd}_{3}\left(\eta^{7}-\mathrm{C}_{7} \mathrm{H}_{7}\right)_{2} \mathrm{Cl}_{3}\right]^{-}$ion; the $\mathrm{Pd}-\mathrm{C}$ and $\mathrm{Pd} \cdots \mathrm{C}$ bond lengths are in the ranges 215-47 and 253-61 pm, respectively. (c) Structure of the $\left[\mathrm{Pd}_{5}\left(\mathrm{C}_{18} \mathrm{H}_{12}\right)_{2}\left(\mathrm{C}_{7} \mathrm{H}_{8}\right)\right]^{2+}$ ion; coordination of an electronically delocalized $\mathrm{C}_{3}$ fragment to a Pd center is represented by a broken line.
a terminal chloride ligand is sandwiched between two planar cycloheptatrienyl $\mathrm{C}_{7} \mathrm{H}_{7}{ }^{+}$rings, as shown in Figs. 14.3.2(a, b). The measured $\mathrm{Pd}-\mathrm{Pd}$ (274.5 to $278.9 \mathrm{pm})$ and $\mathrm{Pd}-\mathrm{Cl}(244.2$ to 247.1 pm ) bonds are within the normal ranges.

In $\left[\mathrm{Pd}_{5}(\text { naphthacene })_{2}\right.$ (toluene $\left.)\right]\left[\mathrm{B}\left(\mathrm{Ar}_{f}\right)_{4}\right]_{2} \cdot 3$ toluene, where $\mathrm{Ar}_{\mathrm{f}}=3,5-$ $\left(\mathrm{CF}_{3}\right)_{2} \mathrm{C}_{6} \mathrm{H}_{3}$, the sheet-like pentapalladium $(0)$ core is composed of a triangle sharing an edge with a trapezoid; the innermost Pd-Pd distance ( 291.6 pm ) is relatively long. This metal monolayer is sandwiched between two naphthacene radical cations, each of which coordinates to the $\mathrm{Pd}_{5}$ sheet through 12 carbons via the $\mu_{5}-\eta^{2}: \eta^{2}: \eta^{2}: \eta^{3}: \eta^{3}$ mode, as illustrated in Fig. 14.3.2(c). One of the four independent toluene molecules in the unit cell is located near the apex Pd atom at a closest contact of 252 pm , but its coordination mode (either $\eta^{2}$ or $\eta^{1}$ ) cannot be definitively assigned owing to disorder.

### 14.3.2 Coordination numbers of carbon

Carbon is known with all coordination numbers from 0 to 8 . Some typical examples are given in Table 14.3.2, and their structures are shown in Fig. 14.3.3. In these examples, the compounds with the high coordination numbers, such as $\geq 5$, do not belong to the class of hypervalent compounds, but rather to electron-deficient systems. Hypervalent molecules usually have a central atom which requires the presence of more than an octet of electrons to form more than four $2 c-2 e$ bonds, such as the S atom in $\mathrm{SF}_{6}$.

### 14.3.3 Bond lengths of $\mathrm{C}-\mathrm{C}$ and $\mathrm{C}-\mathrm{X}$ bonds

The bond lengths of carbon-carbon bonds are listed in Table 14.3.3. The bond lengths of some important bond types of carbon-heteroatom bonds are given in Table 14.3.4. The values given here are average values from experimental determinations and do not necessarily exactly apply to a particular compound.

### 14.3.4 Factors influencing bond lengths

The measured bond lengths in a molecule provide valuable information on its structure and properties. Some factors that influence the bond lengths are discussed below.

Table 14.3.2. Coordination numbers of carbon

| Coordination number | Examples | Structure in Fig. 14.3.2 |
| :---: | :---: | :---: |
| 0 | C atoms, gas phase |  |
| 1 | CO, stable gas | (a) |
| 2 | $\mathrm{CO}_{2}$, stable gas | (b) Linear |
| 2 | HCN, stable gas | (c) Linear |
| 2 | : $\mathrm{CX}_{2}$ (carbene), $\mathrm{X}=\mathrm{H}, \mathrm{F}, \mathrm{OH}$ | (d) Bent |
| 3 | $\mathrm{C}=$ OXY (oxohalides, ketones) | (e) Planar |
| 3 | $\mathrm{CH}_{3}{ }^{-}, \mathrm{CPh}_{3}{ }^{-}$ | (f) Pyramidal |
| 3 | $\mathrm{Ta}\left(=\mathrm{CHCMe}_{3}\right)_{2}\left(\mathrm{Me}_{3} \mathrm{C}_{6} \mathrm{H}_{2}\right)\left(\mathrm{PMe}_{3}\right)_{2}$ | (g) T-shaped* |
| 4 | $\mathrm{CX}_{4}(\mathrm{X}=\mathrm{H}, \mathrm{F}, \mathrm{Cl})$ | (h) Tetrahedral |
| 4 | $\mathrm{Fe}_{4} \mathrm{C}(\mathrm{CO})_{13}$ | (i) C capping $\mathrm{Fe}_{4}$ |
| 5 | $\mathrm{Al}_{2} \mathrm{Me}_{6}$ | (j) Bridged dimer |
| 5 | $\left(\mathrm{Ph}_{3} \mathrm{PAu}\right)_{5} \mathrm{C}^{+} \cdot \mathrm{BF}_{4}{ }^{-}$ | (k) Trigonal bipyramidal |
| 6 | $\left[\mathrm{Ph}_{3} \mathrm{PAu}\right]_{6} \mathrm{C}^{2+}$ | (1) Octahedral |
| 6 | $\mathrm{C}_{2} \mathrm{~B}_{10} \mathrm{H}_{12}$ | (m) Pentagonal pyramidal |
| 7 | $\left[\mathrm{LiMe}_{4}\right.$ crystal | (n) $\dagger$ |
| 8 | $\left[\left(\mathrm{Co}_{8} \mathrm{C}(\mathrm{CO})_{18}\right]^{2-}\right.$ | (o) Cubic |

* The unique H is equatorial and angle $\mathrm{Ta}=\mathrm{C}-\mathrm{CMe}_{3}$ is $169^{\circ}$.
${ }^{\dagger}$ The distance of intramolecular $\mathrm{C}-\mathrm{Li}$ is 231 pm , (a C atom caps 3 Li atoms in each face of the $\mathrm{Li}_{4}$ tetrahedron), $\mathrm{C}-\mathrm{H}$ is 96 pm , and intermolecular $\mathrm{C}-\mathrm{Li}$ is 236 pm .

## (1) Bonds between atoms of different electronegativities

It is generally found that the greater the difference in electronegativity between the bonding atoms, the greater the deviation from the predicted bond distance based on covalent radii or the mean values given in Tables 14.3.3 and 14.3.4. Empirical methods for the adjustment of covalent bond lengths by a factor dependent on the electronegativity differences between the atoms have been proposed.

Fig. 14.3.3.
Coordination numbers of carbon in its compounds.

Table 14.3.3. Bond lengths (in pm) of carbon-carbon bonds

| Bond | Bond length | Example |
| :--- | :--- | :--- |
| $\mathrm{C}-\mathrm{C}$ |  |  |
| $\mathrm{sp}^{3}-\mathrm{sp}^{3}$ | 153 | Ethane $\left(\mathrm{H}_{3} \mathrm{C}-\mathrm{CH}_{3}\right)$ |
| $\mathrm{sp}^{3}-\mathrm{sp}^{2}$ | 151 | Propene $\left(\mathrm{H}_{3} \mathrm{C}-\mathrm{CH}=\mathrm{CH}_{2}\right)$ |
| $\mathrm{sp}^{3}-\mathrm{sp}^{2}$ | 147 | Propyne $\left(\mathrm{H}_{3} \mathrm{C}-\mathrm{C} \equiv \mathrm{CH}\right)$ |
| $\mathrm{sp}^{2}-\mathrm{sp}^{2}$ | 148 | Butadiene $\left(\mathrm{H}_{2} \mathrm{C}=\mathrm{CH}-\mathrm{CH}=\mathrm{CH}_{2}\right)$ |
| $\mathrm{sp}^{2}-\mathrm{sp}$ | 143 | Vinylacetylene $(\mathrm{H} 2 \mathrm{C}=\mathrm{CH}-\mathrm{C} \equiv \mathrm{CH})$ |
| $\mathrm{sp}-\mathrm{sp}$ | 138 | Butadiyne $(\mathrm{HC} \equiv \mathrm{C}-\mathrm{C} \equiv \mathrm{CH})$ |
| $\mathrm{C}=\mathrm{C}$ |  |  |
| $\mathrm{sp}^{2}-\mathrm{sp}^{2}$ | 132 | Ethylene $\left(\mathrm{H}_{2} \mathrm{C}=\mathrm{CH}_{2}\right)$ |
| $\mathrm{sp} \mathrm{s}^{2}-\mathrm{sp}$ | 131 | Allene $\left(\mathrm{H}_{2} \mathrm{C}=\mathrm{C}=\mathrm{CH}_{2}\right)$ |
| $\mathrm{sp}-\mathrm{sp}$ | 128 | Butatriene $\left(\mathrm{H}_{2} \mathrm{C}=\mathrm{C}=\mathrm{C}=\mathrm{CH}_{2}\right)$ |
| $\mathrm{C} \equiv \mathrm{C}$ |  |  |
| $\mathrm{sp}-\mathrm{sp}$ | 118 | Acetylene $(\mathrm{HC} \equiv \mathrm{CH})$ |

Table 14.3.4. Bond lengths (in pm ) of $\mathrm{C}-\mathrm{X}$ bonds

|  | $s p-\mathrm{X}$ |  | 127 | 163 |  | 179 | 199 |  |

## (2) Steric strain

Steric strain exists in a molecule when bonds are forced to make abnormal angles. There are in general two kinds of structural features that result in sterically-caused abnormal bond angles. One of these is common to small ring compounds, where the bond angles must be less than those resulting from normal orbital overlap. Such strain is called small-angle strain. The other arises when nonbonded atoms are forced into close proximity by the geometry of the molecule. This effect is known as steric overcrowding.

Steric strain generally leads to elongated bond lengths as compared to the expected values given in Tables 14.3.3 and 14.3.4.

## (3) Conjugation

A hybrid atomic orbital of higher s content has a smaller size and lies closer to the nucleus. Accordingly, carbon-carbon bonds are shortened by increasing s character of the overlapping hybrid orbitals. The $\mathrm{C}\left(\mathrm{sp}^{3}\right)-\mathrm{C}\left(\mathrm{sp}^{3}\right)$ single bond is generally longer than other single bonds involving $\mathrm{sp}^{2}$ and sp carbon atoms. This general rule arises mainly from conjugation between the bonded atoms. When mean values are used to estimate bond lengths, the conjugation factor must be taken into account. For example, the $\mathrm{C}-\mathrm{C}$ bond length in benzene is 139.8 pm , which is virtually equal to the mean value of the $\mathrm{C}\left(\mathrm{sp}^{2}\right)-\mathrm{C}\left(\mathrm{sp}^{2}\right)$ and $\mathrm{C}=\mathrm{C}$ bond lengths: $\frac{1}{2}(148+132)=140 \mathrm{pm}$. Hence the conjugation of alternating single and double bonds in benzene can be expressed as resonance between two limiting valence bond (canonical) structures:

## (4) Hyperconjugation

The overlap of a C-H $\sigma$ orbital with the $\pi$ (or p ) orbital on a directly bonded carbon atom is termed hyperconjugation. This interaction has a shortening effect on the $\mathrm{C}-\mathrm{C}$ bond length, a good example being the structure of the tert-butyl cation $\left[\mathrm{C}\left(\mathrm{CH}_{3}\right)_{3}\right]^{+}$.

(b)

The structure of $\left[\mathrm{C}\left(\mathrm{CH}_{3}\right)_{3}\right]^{+}$in the crystalline salt $\left[\mathrm{C}\left(\mathrm{CH}_{3}\right)_{3}\right] \mathrm{Sb}_{2} \mathrm{~F}_{11}$ is shown in Fig. 14.3.4(a). The carbon skeleton is planar with an average $\mathrm{C}-\mathrm{C}$ bond length of 144.2 pm and approximate $D_{3 \mathrm{~h}}$ molecular symmetry. The experimental C-C bond length is shorter by 6.8 pm than the normal $\mathrm{C}\left(\mathrm{sp}^{3}\right)-\mathrm{C}\left(\mathrm{sp}^{2}\right)$ bond length of 151 pm . This is due to hyperconjugative interaction between three filled $\mathrm{C}-\mathrm{H}$ $\sigma$ bond orbitals and the empty p orbital on the central carbon atom that leads to partial $\mathrm{C}-\mathrm{C} \pi$ bonding, as shown in Fig. 14.3.4 (b).

## (5) Surroundings of bonding atoms

The geometry and connected groups of bonding atoms usually influence the bond lengths. For example, an analysis of $\mathrm{C}-\mathrm{OR}$ bond distances in more than 2000 ethers and carboxylic esters (all with $\mathrm{sp}^{3}$ carbon) showed that this distance increases with increasing electron-withdrawing power of the R group, and also when the C atom changes from primary through secondary to tertiary. For such compounds mean $\mathrm{C}-\mathrm{O}$ bond lengths range from 141.8 to 147.5 pm .

As an illustrative example taken from the current literature, consider the variation of $\mathrm{C}-\mathrm{C}$ and $\mathrm{C}-\mathrm{O}$ bond lengths in the deltate species $\mathrm{C}_{3} \mathrm{O}_{3}^{2-}$ held within a dinuclear organometallic uranium(IV) complex. In a remarkable synthesis, this cyclic aromatic oxocarbon dianion is generated by the metal-mediated reductive cyclotrimerization of carbon monoxide, as indicated in the reaction scheme

A strongly reducing organouranium(III) complex stabilized by $\eta^{5}$ cyclopentadienide and $\eta^{8}$-cyclooctatetraenediide ligands, together with tetrahydrofuran, is used to crack the robust $\mathrm{C} \equiv \mathrm{O}$ triple bond at room temperature and ambient pressure. Low-temperature X-ray analysis revealed the presence of a reductively homologated CO trimer, $\mathrm{C}_{3} \mathrm{O}_{3}{ }^{2-}$, as a $\eta^{1}: \eta^{2}$ bridging ligand between two organouranium(IV) centers. The measured dimensions of the central molecular skeleton are shown below:

The noticeable distortion of the $\mathrm{C}_{3}$ ring and measured $\mathrm{C}-\mathrm{C}, \mathrm{C}-\mathrm{O}$ and $\mathrm{U}-$ $O$ bond lengths reflect the conjugation effect, the chemical environment of individual atoms, steric congestion around the respective uranium centers, and variation caused by experimental errors.

### 14.3.5 Abnormal carbon-carbon single bonds

## (1) Unusually long C-C bonds

Figure 14.3 .5 shows some organic molecules which have abnormally long $\mathrm{C}-\mathrm{C}$ bonds. Rationalization of these unusual structures is discussed below.
(a) Oxalic acid, $\mathrm{HOOC}-\mathrm{COOH}$

In the oxalic acid molecule, there is a $\mathrm{O}=\stackrel{\mid}{\mathrm{C}}-\mathrm{C}=\mathrm{O}$ system which satisfies the condition for conjugation, and the existence of delocalized $\pi$ bonding has been

(d)

(b)

(c)

(e)

substantiated by deformation density studies. The central $\mathrm{C}\left(\mathrm{sp}^{2}\right)-\mathrm{C}\left(\mathrm{sp}^{2}\right)$ bond has a length of 156.8 pm . A MNDO computation showed that the four fully occupied $\pi$ MOs are alternately bonding and antibonding orbitals between the two C atoms. Thus the $\pi$ MOs contribute little to bonding. The $\sigma$ bond order is less than unity mainly because each carbon atom is bonded to two highly electronegative oxygen atoms, leading to a reduction of charge density on the carbon atom. The bond order in the $\mathrm{C}-\mathrm{C}$ bond is made up of a $\sigma$ component of 0.815 and a $\pi$ component of only 0.015 . The strongly reducing properties of oxalic acid are associated with its relatively weak $\mathrm{C}-\mathrm{C}$ bond which easily cleaves during a reaction, and the resulting fragments are then oxidized to carbon dioxide.
(b) Cubane, $\mathrm{C}_{8} \mathrm{H}_{8}$

Several cubane structures have been determined. The mean $\mathrm{C}-\mathrm{C}$ bond length is 155.6 pm from 42 independent measurements of the edges. This long bond length can be understood by considering the lesser overlap of endocyclic orbitals that are richer in p character than the typical $\mathrm{sp}^{3}$ hybrid.

## (c) Dewar benzene derivatives

In derivatives of Dewar benzene, the bond length of the bridging $\mathrm{C}-\mathrm{C}$ bond is found to lie in the range $156-159 \mathrm{pm}$. The elongation of bond length is mainly due to the strain caused by the fusion of two four-membered rings.
(d) 1-Cyano-tetracyclodecane, $\mathrm{C}_{10} \mathrm{H}_{13} \mathrm{CN}$

In this molecule, the pair of bridgehead atoms each has all four bonds directed to the same side as its partner atom, and the central bond length is 164.3 pm . Thus the bridgehead atoms have an "inverted" bond configuration and serious $\mathrm{C}-\mathrm{C}$ bond strain.
(e) [2.2]Paracyclophane, $\mathrm{C}_{16} \mathrm{H}_{16}$

In the cyclophanes, the bridging bond lengths are generally the longest and in some instances have been found to be near or greater than 160 pm . The

(d)

(e)

IIa

IIb

elongation of the $\mathrm{C}-\mathrm{C}$ single bond in the bridging $-\mathrm{CH}_{2}-\mathrm{CH}_{2}-$ group of [2.2]paracyclophane is attributable to the inherent steric strain.

Further examples of organic molecules containing very long carbon-carbon single bonds have been reported in recent years. The extended $\mathrm{C}\left(\mathrm{sp}^{3}\right)-\mathrm{C}\left(\mathrm{sp}^{3}\right)$ bond in the hexaarylethane shown in Fig. 14.3.6(a) is caused by severe steric repulsion between the bulky substituted phenyl groups. In the bi(anthracene-9,10-dimethylene) photodimer shown in Fig. 14.3.6(b), the bridge bond of the cyclobutane ring has a length longer than the rest. Extremely long C(sp $\left.{ }^{3}\right)$ $\mathrm{C}\left(\mathrm{sp}^{3}\right)$ bonds have been shown to exist in the naphthocyclobutenes shown in Fig. 14.3.6(c).

The bond length variation in the substituted benzodicyclobutadiene shown in Fig. 14.3.6(d), as determined from X-ray analysis, can be fairly well accounted for by resonance between the canonical formulas Ia and Ib . The central sixmembered ring contains a pair of extremely long $\mathrm{C}\left(\mathrm{sp}^{2}\right)-\mathrm{C}\left(\mathrm{sp}^{2}\right)$ bonds at $154.0(5) \mathrm{pm}$, which significantly exceed the reference bond distance of 149.0(3) pm observed for tris(benzocyclobutadieno)benzene [Fig. 14.3.6(e)]. The bond length pattern in the latter compound indicates that its structure is better described by the radiallene formula IIa in preference to formula IIb, which contains anti-aromatic cyclobutadiene moieties.

## (2) Unusually short bonds between tetracoordinate carbon atoms

Figure 14.3.7 shows some organic molecules containing abnormally short single bonds between two four-coordinate carbon atoms.
(a)
140.8(2) $(\mathrm{R}=\mathrm{Me})$
144.4(3) $(\mathrm{R}=\mathrm{Ph})$

(b)

$144.5(n=3)$
(e)
(d)

(c)

The bond between two bridgehead carbon atoms in bicyclo[1.1.0]butane exhibits the properties of a carbon-carbon multiple bond, although it is formally a single bond. The dihedral angle $\delta$ between the three-membered rings in 1,5-dimethyltricyclo[2.1.0.0]pentan-3-one is made small by the short span of the carbonyl linkage, as shown in Fig. 14.3.7(a). The bridgehead bond has a pronounced $\pi$ character with a length of $140.8(2) \mathrm{pm}$. In the 1,5 -diphenyl analog, the two aromatic rings are oriented almost perpendicular (at $93.6^{\circ}$ and $93.6^{\circ}$ ) to the plane bisecting the angle $\delta$. There is optimal conjugation between the phenyl groups via the $\pi$-population of the bridge bond, and the conjugation effect leads to its lengthening of the latter to $144.4(3) \mathrm{pm}$. The central exocyclic $\mathrm{C}\left(\mathrm{sp}^{3}\right)-\mathrm{C}\left(\mathrm{sp}^{3}\right)$ bond connecting two bicyclobutane moieties is quite short [Fig. 14.3.7(b)], as are the related linkages in bicubyl [Fig. 14.3.7(c)] and hexakis(trimethylsilyl)bitetrahedryl [Fig. 14.3.7(d)]. The calculated s character of the linking $\mathrm{C}-\mathrm{C}$ bond in the bitetrahedryl molecule is $\mathrm{sp}^{1.53}$, which is consistent with its significant shortening.

In the crystal structure of the in-isomer of the methylcyclophane shown in Fig. 14.3.7(e), there are two independent molecules with measured $\mathrm{C}-\mathrm{Me}$ bond distances of $147.5(6)$ and $149.5(6) \mathrm{pm}$. The inward-pointing methyl group is forced into close contact with the basal aromatic ring, and the steric congestion accounts for compression of the $\mathrm{C}-\mathrm{Me}$ bond.

### 14.3.6 Complexes containing a naked carbon atom

In the realm of all-carbon ligands in the formation of transition-metal complexes, the naked carbon atom holds a special position. Based on the geometry of metal-carbon interaction, these compounds can be divided into four classes: terminal carbide (I), 1,3-dimetallaallene (II), C-metalated carbyne (III), and carbido cluster (IV):
:C 三M
(I)
$\mathrm{M}=\mathrm{C}=\mathrm{M}$
(II)

(III)

(IV)

Fig. 14.3.7.
Molecules containing very short C-C single bonds. The bond lengths are shown in pm. Values are given for two independent molecules of compound (e).

Fig. 14.3.8.
Complexes containing a metal-terminal carbon triple bond.

There are two well-characterized examples of a naked carbon atom bound by a triple bond to a metal center ( Fig 14.3.8). The molybdenum carbide anion $\left[\mathrm{CMo}\{\mathrm{N}(\mathrm{R}) \mathrm{Ar}\}_{3}\right]^{-}\left(\mathrm{R}=\mathrm{C}\left(\mathrm{CD}_{3}\right)_{2}\left(\mathrm{CH}_{3}\right), \mathrm{Ar}=\mathrm{C}_{6} \mathrm{H}_{3} \mathrm{Me}_{2}-3,5\right)$, an isoelectronic analog of $\operatorname{NMo}\{\mathrm{N}(\mathrm{R}) \mathrm{Ar}\}_{3}$, can be prepared in a multistep procedure via deprotonation of the $\mathrm{d}^{0}$ methylidyne complex $\mathrm{HCMo}\left\{\mathrm{N}(\mathrm{R}) \mathrm{Ar}_{3}\right.$. The $\mathrm{Mo} \equiv \mathrm{C}$ distance of $171.3(9) \mathrm{pm}$ is at the low end of the known range for molybdenum-carbon multiple bonds. In the diamagnetic, air-stable terminal ruthenium carbide complex $\mathrm{Ru}(\equiv \mathrm{C}$ : $) \mathrm{Cl}_{2}\left(\mathrm{LL}^{\prime}\right)\left(\mathrm{L}=\mathrm{L}^{\prime}=\mathrm{PCy}_{3}\right.$, or $\mathrm{L}=\mathrm{PCy}_{3}$ and $\mathrm{L}^{\prime}=1,3$-dimesityl-4,5-dihydroimidazol-2-ylidene), the measured $\mathrm{Ru}-\mathrm{C}$ distance of $165.0(2) \mathrm{pm}$ is consistent with the existence of a very short $\mathrm{Ru} \equiv \mathrm{C}$ triple bond.

Many complexes containing a $\mathrm{M}-\mathrm{C}-\mathrm{M}^{\prime}$ bridge have been reported. The earliest know example of a 1,3-dimetallallene complex, $\{\mathrm{Fe}(\mathrm{tpp})\}_{2} \mathrm{C}(\mathrm{tpp}=$ tetraphenylporphyrin), was synthesized by the reaction of $\mathrm{Fe}(\mathrm{tpp})$ with $\mathrm{CI}_{4}$, $\mathrm{CCl}_{3} \mathrm{SiMe}_{3}, \mathrm{CH}_{2} \mathrm{Cl}_{2}$ and BuLi. The single carbon atom bridges the two $\mathrm{Fe}(\mathrm{tpp})$ moieties with $\mathrm{Fe}-\mathrm{C} 167.5(1) \mathrm{pm}$ in the linear $\mathrm{Fe}-\mathrm{C}-\mathrm{Fe}$ unit. Thermal decomposition of the olefin metathesis catalyst $\left(\mathrm{IMesH}_{2}\right)\left(\mathrm{PCy}_{3}\right)(\mathrm{Cl})_{2} \mathrm{Ru}=\mathrm{CH}_{2}$ (IMesH ${ }_{2}=1,3$-dimesityl-4,5-dihydroimidazol-2-ylidene) results in the formation of a C-bridged dinuclear ruthenium complex, as shown in the following scheme. The $\mathrm{Ru} \equiv \mathrm{C}-\mathrm{Ru}$ bond angle is $160.3(2)^{\circ}$. The measured $\mathrm{Ru} \equiv \mathrm{C}$ bond distance of $169.8(4) \mathrm{pm}$ is slightly longer than those in reported $\mu$-carbide ruthenium complexes such as $\left(\mathrm{PCy}_{3}\right)_{2}(\mathrm{Cl})_{2} \mathrm{Ru} \equiv \mathrm{C}-\mathrm{Pd}(\mathrm{Cl})_{2}\left(\mathrm{SMe}_{2}\right)$ (166.2(2) pm ), and the $\mathrm{Ru}-\mathrm{C}$ distance of $187.5(4) \mathrm{pm}$ is much shorter than the usual $\mathrm{R}-\mathrm{C}$ single bonds in ruthenium complexes such as $\left(\mathrm{Me}_{3} \mathrm{CO}\right)_{3} \mathrm{~W} \equiv \mathrm{C}-\mathrm{Ru}(\mathrm{CO})_{2}(\mathrm{Cp})$ (209(2) pm).

The carbide-centered polynuclear transition-metal carbonyl clusters exhibit a rich variety of structures. A common feature to this class of carbide complexes is that the naked carbon is wholly or partially enclosed in a metal cage composed of homo/hetero metal atoms, and there is also a subclass that can be considered as tetra-metal-substituted methanes. The earliest known compound of this kind is $\mathrm{Fe}_{5} \mathrm{C}(\mathrm{CO})_{15}$, in which the carbon atom is located at the center

(c)

Fig. 14.3.9.
Molecular structures of some transition-metal clusters containing a naked carbon atom.
of the base of a square pyramid with $\mathrm{Fe}(\mathrm{CO})_{3}$ groups occupying its five vertices. Carbido carbonyl clusters of Ru and Os are well documented. Octahedral $\mathrm{Ru}_{6} \mathrm{C}(\mathrm{CO})_{17}$ is composed of four $\mathrm{Ru}(\mathrm{CO})_{3}$ and two cis- $\mathrm{Ru}(\mathrm{CO})_{2}$ fragments, the latter being bridged by a carbonyl group [Fig. 14.3.9(a)]. $\mathrm{Os}_{10} \mathrm{C}(\mathrm{CO})_{24}$ is built of an octahedral arrangement of $\mathrm{Os}(\mathrm{CO})_{2}$ groups with four of its eight faces each capped by an $\mathrm{Os}(\mathrm{CO})_{3}$ group, as shown in Fig. 14.3.9(b). The exposed carbon atom in $\mathrm{Fe}_{4} \mathrm{C}(\mathrm{CO})_{13}$ shows the greatest chemical activity, and the $\mathrm{Fe}_{4} \mathrm{C}$ system serves as a plausible model for a surface carbon atom in heterogeneous catalytic processes [Fig. 14.3.9(c)]. Addition of $\mathrm{Co}_{3}\left(\mu_{3}-\mathrm{CCl}\right)(\mathrm{CO})_{9}$ to a solution of $\left(\mathrm{PPh}_{4}\right)_{2}\left[\mathrm{Fe}_{3}(\mu-\mathrm{CCO})(\mathrm{CO})_{9}\right](\mathrm{CCO}$ is the ketenylidene group $\mathrm{C}=\mathrm{C}=\mathrm{O})$ in $\mathrm{CH}_{2} \mathrm{Cl}_{2}$, in the presence of thallium salt, generates the species $\left[\left\{\mathrm{Co}_{3}(\mathrm{CO})_{9}\right\} \mathrm{C}\left\{\mathrm{Fe}_{3}(\mathrm{CO})_{9}(\mu-\mathrm{CCO})\right\}\right]^{-}$containing a single carbon atom linking two different trimetallic clusters; subsequent addition of ethanol yielded the complex $\left[\left\{\mathrm{Co}_{3}(\mathrm{CO})_{9}\right\} \mathrm{C}\left\{\mathrm{Fe}_{3}(\mathrm{CO})_{9}\left(\mu-\mathrm{C}-\mathrm{CO}_{2} \mathrm{Et}\right)\right\}\right]^{2-}$. The structures of these two hexanuclear hetereometallic anions are shown in Fig. 14.3.9(d).

The reaction of $\mathrm{AlMe}_{3}$ with $\left(t-\mathrm{Bu}_{3} \mathrm{PN}\right)_{2} \mathrm{TiMe}_{2}$ leads to the formation of two Ti complexes, of which $\left[\left(\mu^{2}-t-\mathrm{Bu} 3 \mathrm{PN}\right) \mathrm{Ti}(\mu-\mathrm{Me})\left(\mu^{4}-\mathrm{C}\right)\left(\mathrm{AlMe}_{2}\right)_{2}\right]_{2}$ is the major product. Single-crystal X-ray analysis revealed that it has a saddle-like structure, with two phosphinimide ligands lying on one side and four $\mathrm{AlMe}_{2}$ groups on the other [Fig. 14.3.9(e)]. The Ti and carbide C atoms in the central $\mathrm{Ti}_{2} \mathrm{C}_{2}$ ring both exhibit distorted tetrahedral coordination geometry.

### 14.3.7 Complexes containing naked dicarbon ligands

There is an interesting series of heterobinuclear complexes in which the Ru and Zr centers are connected by three different types of $\mathrm{C}_{2}$ bridges: $\mathrm{C}-\mathrm{C}, \mathrm{C}=\mathrm{C}$, and $\mathrm{C} \equiv \mathrm{C}$.

In polynuclear metal complexes bearing a naked $\mathrm{C}_{2}$ species, multiple metalcarbon interactions generally occur, and the measured carbon-carbon bond distances indicate that the $\mathrm{C}_{2}$ ligand may be considered to originate from fully deprotonated ethane, ethylene, or acetylene, which is stabilized in a "permetallated" coordination environment. Singly and doubly bonded dicarbon moieties are found in some polynuclear transition-metal carbonyl complexes (carboncarbon bond length in pm): $\mathrm{Rh}_{12}\left(\mathrm{C}_{2}\right)(\mathrm{CO})_{25}, 148(2)$; $\left[\mathrm{Co}_{6} \mathrm{Ni}_{2}\left(\mathrm{C}_{2}\right)_{2}(\mathrm{CO})_{16}\right]^{2-}$, 149(1); $\mathrm{Fe}_{2} \mathrm{Ru}_{6}\left(\mu_{6}-\mathrm{C}_{2}\right)_{2}(\mu-\mathrm{CO})_{3}(\mathrm{CO})_{14} \mathrm{Cp}_{2}, 133.4(8)$ and 135.4(7); $\mathrm{Ru}_{6}\left(\mu_{6}{ }^{-}\right.$ $\left.\mathrm{C}_{2}\right)\left(\mu-\mathrm{SMe}_{2}\right)_{2}\left(\mu-\mathrm{PPh}_{2}\right)_{2}(\mathrm{CO})_{14}, 138.1(8)$. The following discussion is concerned only with anionic species derived from acetylene.

Acetylene is a Brønsted acid ( $\mathrm{p} K_{a} \sim 25$ ). Its chemistry is associated with its triple-bond character and the labile hydrogen atoms. It can easily lose one proton to form the acetylide monoanion $\mathrm{HC} \equiv \mathrm{C}^{-}$(IUPAC name acetylenide) or release two to give the acetylide dianion ${ }^{-} \mathrm{C} \equiv \mathrm{C}^{-}\left(\mathrm{C}_{2}{ }^{2-}\right.$, IUPAC name acetylenediide). The acetylenide $\mathrm{H}-\mathrm{C} \equiv \mathrm{C}^{-}$and substituted derivatives $\mathrm{R}-\mathrm{C} \equiv \mathrm{C}^{-}$form organometallic compounds with the alkali metals. In these compounds, the interactions of the $\pi$ orbitals of the $\mathrm{C} \equiv \mathrm{C}$ fragment with metal orbitals may lead to many structural types, e.g.,

The acetylenediide $\mathrm{C}_{2}^{2-}$ can combine with alkali and alkaline-earth metals to form ionic salts, which are readily decomposed by water. Four modifications of $\mathrm{CaC}_{2}$ (commonly known as calcium carbide) are known: room-temperature tetragonal $\mathrm{CaC}_{2} \mathbf{I}$, high-temperature cubic $\mathrm{CaC}_{2} \mathbf{I V}$ (in which the $\mathrm{C}_{2}^{2-}$ dianion exhibits orientational disorder), low-temperature $\mathrm{CaC}_{2}$ II, and a fourth modification $\mathrm{CaC}_{2}$ III (Fig. 14.3.10). $\mathrm{MgC}_{2}, \mathrm{SrC}_{2}$, and $\mathrm{BaC}_{2}$ adopt the tetragonal $\mathrm{CaC}_{2} \mathbf{I}$ structure, which consists of a packing of $\mathrm{Ca}^{2+}$ and discrete $\mathrm{C}_{2}^{2-}$ ions in a distorted NaCl lattice, with the $\mathrm{C}_{2}^{2-}$ dumbbell (bond length 119.1 pm from neutron powder diffraction) aligned parallel to the $c$ axis.
Ternary metal acetylenediides of composition $\mathrm{AM}^{\mathrm{I}} \mathrm{C}_{2}(\mathrm{~A}=\mathrm{Li}$ to Cs and $M^{I}=\operatorname{Ag}(\mathrm{I}), \mathrm{Au}(\mathrm{I})$; or $\mathrm{A}=\mathrm{Na}$ to Cs and $\mathrm{M}^{\mathrm{I}}=\mathrm{Cu}(\mathrm{I})$ ) have been prepared; $\mathrm{NaAgC}_{2}, \mathrm{KAgC}_{2}$, and $\mathrm{RbAgC}_{2}$ are isomorphous [Fig. 14.3.11(a)], but $\mathrm{LiAgC}_{2}$ [Fig. 14.3.11(b)] and $\mathrm{CsAgC}_{2}$ [Fig. 14.3.11(c)] belong to different structural types. The ternary acetylenediides $\mathrm{A}_{2} \mathrm{MC}_{2}(\mathrm{~A}=\mathrm{Na}$ to $\mathrm{Cs}, \mathrm{M}=\mathrm{Pd}, \mathrm{Pt})$ crystallize in the same structure type, which is characterized by $\left[\mathrm{M}\left(\mathrm{C}_{2}\right)_{2 / 2}{ }^{2-}\right]_{\infty}$ chains

separated by alkali metal ions [Fig. 14.3.11(d)]. The ternary alkaline-earth acetylenediide $\mathrm{Ba}_{3} \mathrm{Ge}_{4} \mathrm{C}_{2}$ can be synthesized from the elements or by the reaction of $\mathrm{BaC}_{2}$ with $\mathrm{BaGe}_{2}$ at 1530 K ; it consists of slightly compressed tetrahedral [ $\left.\mathrm{Ge}_{4}\right]^{4-}$ anions inserted into a twisted octahedral $\mathrm{Ba}_{6 / 2}$ three-dimensional framework. The $\mathrm{Ba}_{6}$ octahedra are centered by $\mathrm{C}_{2}{ }^{2-}$ dumbbells ( $\mathrm{C}-\mathrm{C}$ bond length $120(6) \mathrm{pm})$, which are statistically oriented in two directions.
(a)

(b)

(d)

The group $11\left(\mathrm{Cu}_{2} \mathrm{C}_{2}, \mathrm{Ag}_{2} \mathrm{C}_{2}\right.$, and $\left.\mathrm{Au}_{2} \mathrm{C}_{2}\right)$ and group $12\left(\mathrm{ZnC}_{2}, \mathrm{CdC}_{2}\right.$ and $\mathrm{Hg}_{2} \mathrm{C}_{2} \cdot \mathrm{H}_{2} \mathrm{O}$, and $\mathrm{Hg}_{2} \mathrm{C}_{2}$ ) acetylenediides exhibit properties characteristic of covalent polymeric solids, but their tendency to detonate upon mechanical shock and insolubility in common solvents present serious difficulties in structural characterization. The earliest known and most studied non-ionic acetylenediide is $\mathrm{Ag}_{2} \mathrm{C}_{2}$ (commonly known as silver acetylide or silver carbide), which forms a series of double salts of the general formula $\mathrm{Ag}_{2} \mathrm{C}_{2} \cdot m \mathrm{AgX}$, where $\mathrm{X}^{-}=\mathrm{Cl}^{-}, \mathrm{I}^{-}, \mathrm{NO}_{3}^{-}, \mathrm{H}_{2} \mathrm{AsO}_{4}^{-}$, or $\frac{1}{2} \mathrm{EO}_{4}^{2-}(\mathrm{E}=\mathrm{S}, \mathrm{Se}, \mathrm{Cr}$, or W$)$, and $m$ is the molar ratio. From 1998 onward, systematic studies have yielded a wide range of double, triple, and quadruple salts of silver(I) containing silver acetylenediide as a component, e.g., $\mathrm{Ag}_{2} \mathrm{C}_{2} \cdot m \mathrm{AgNO}_{3}(m=1,5,5.5$, and 6), $\mathrm{Ag}_{2} \mathrm{C}_{2} \cdot 8 \mathrm{AgF}, \mathrm{Ag}_{2} \mathrm{C}_{2} \cdot 2 \mathrm{AgClO}_{4} \cdot 2 \mathrm{H}_{2} \mathrm{O}, \mathrm{Ag}_{2} \mathrm{C}_{2} \cdot \mathrm{AgF} \cdot 4 \mathrm{AgCF}_{3} \mathrm{SO}_{3} \cdot \mathrm{RCN}$ $\left(\mathrm{R}=\mathrm{CH}_{3}, \mathrm{C}_{2} \mathrm{H}_{5}\right)$ and $2 \mathrm{Ag}_{2} \mathrm{C}_{2} \cdot 3 \mathrm{AgCN} \cdot 15 \mathrm{AgCF}_{3} \mathrm{CO}_{2} \cdot 2 \mathrm{AgBF}_{4} \cdot 9 \mathrm{H}_{2} \mathrm{O}$. A structural feature common to these compounds is that the $\mathrm{C}_{2}{ }^{2-}$ species is fully encapsulated inside a polyhedron with $\operatorname{Ag}(\mathrm{I})$ at each vertex, which may be represented as $C_{2} @ \mathrm{Ag}_{n}$. Note that each $\mathrm{C}_{2} @ \mathrm{Ag}_{n}$ cage carries a charge of $(n-2)+$, and such cages are linked by anionic (and co-existing neutral) ligands to form a two- or three-dimensional coordination network. Some polyhedral $\mathrm{Ag}_{n}$ cages with encapsulated $\mathrm{C}_{2}{ }^{2-}$ species found in various silver(I) double salts are shown in Fig. 14.3.12. In $\mathrm{Ag}_{2} \mathrm{C}_{2} \cdot 6 \mathrm{AgNO}_{3}$, the dumbbell-like $\mathrm{C}_{2}{ }^{2-}$ moiety is located inside a rhombohedral silver cage whose edges lie

in the range of 295-305 pm, but it exhibits orientational disorder about a crystallographic threefold axis [Fig. 14.3.12(e)]. The utilization of $\mathrm{C}_{2} @ \mathrm{Ag}_{n}$ polyhedra as building blocks for the supramolecular assembly of new coordination frameworks has resulted in a series of discrete, 1-D, 2-D, and 3-D complexes bearing interesting structural motifs; further details are presented in Section 20.4.5.

(b)

To date, there are only two well-characterized copper(I) acetylenediide complexes. In $\left[\mathrm{Cu}_{4}\left(\mu-\eta^{1}: \eta^{2}-\mathrm{C} \equiv \mathrm{C}\right)(\mu-\mathrm{dppm})_{4}\right]\left(\mathrm{BF}_{4}\right)_{2}\left(\mathrm{dppm}=\mathrm{Ph}_{2} \mathrm{PCH}_{2} \mathrm{PPh}_{2}\right)$, the cation contains a saddle-like $\mathrm{Cu}_{4}(\mu-\mathrm{dppm})_{4}$ system, with the $\mathrm{C}_{2}$ unit surrounded by a distorted rectangular $\mathrm{Cu}_{4}$ array and interacting with the Cu atoms in $\eta^{1}$ and $\eta^{2}$ modes [Fig. 14.3.13(a)]. In comparison, the tetranuclear, $C_{2}{ }^{-}$ symmetric cation of $\left[\mathrm{Cu}_{4}\left(\mu-\mathrm{Ph}_{2} \mathrm{Ppypz}\right)_{4}\left(\mu-\eta^{1}: \eta^{2}-\mathrm{C} \equiv \mathrm{C}\right)\right]\left(\mathrm{ClO}_{4}\right)_{2} \cdot 3 \mathrm{CH}_{2} \mathrm{Cl}_{2}$ [ $\mathrm{Ph}_{2} \mathrm{Ppypz}=2$-(diphenylphosphino-6-pyrazolyl)pyridine] consists of a butterfly-shaped $\mathrm{Cu}_{4} \mathrm{C}_{2}$ core in which the acetylenediide anion bridges a pair of $\mathrm{Cu}_{2}$ subunits in both $\eta^{1}$ and $\eta^{2}$ bonding modes; the $\mathrm{C} \equiv \mathrm{C}$ bond length is 126(1) pm [Fig. 14.3.13(b)].

### 14.4 Structural chemistry of silicon

After oxygen (approx $45.5 \mathrm{wt} \%$ ), silicon is the next most abundant element in the earth's crust (approx $27 \mathrm{wt} \%$ ). Elemental Si does not occur naturally, but it combines with oxygen to form a large number of silicate minerals.

### 14.4.1 Comparison of silicon and carbon

Silicon and carbon command dominant positions in inorganic chemistry (silicates) and organic chemistry (hydrocarbons and their derivatives), respectively. Although they have similar valence electronic configurations, $[\mathrm{He}] 2 \mathrm{~s}^{2} 2 \mathrm{p}^{2}$ for C and $[\mathrm{Ne}] 3 \mathrm{~s}^{2} 3 \mathrm{p}^{2}$ for Si , their properties are not similar. The reasons for the difference between the chemistry of the two elements are elaborated below.

## (1) Electronegativity

The electronegativity of C is 2.54 , as compared with 1.92 for Si . Carbon is strictly nonmetallic whereas Si is essentially a non-metallic element with some metalloid properties.

## (2) Configuration of valence shell and multiplicity of bonding

Unlike carbon, the valence shell of the silicon atom has available d orbitals. In many silicon compounds, the d orbitals of Si contribute to the hybrid orbitals and Si forms more than four $2 c-2 e$ covalent bonds. For example, $\mathrm{SiF}_{5}{ }^{-}$uses $\mathrm{sp}^{3} \mathrm{~d}$ hybrid orbitals to form five Si-F bonds, and $\mathrm{SiF}_{6}{ }^{2-}$ uses $\mathrm{sp}^{3} \mathrm{~d}^{2}$ hydrid orbitals to form six $\mathrm{Si}-\mathrm{F}$ bonds.

Furthermore, silicon can use its d orbitals to form $d \pi-p \pi$ multiple bonds, whereas carbon only uses its p orbitals to form $\mathrm{p} \pi-\mathrm{p} \pi$ multiple bonds. Trisilylamines such as $\mathrm{N}\left(\mathrm{SiH}_{3}\right)_{3}$ is a planar molecule, as shown in Fig. 14.4.1(a), which differs from the pyramidal $\mathrm{N}\left(\mathrm{CH}_{3}\right)_{3}$ molecule as shown in Fig. 14.4.1(b). In the planar configuration of $\mathrm{N}\left(\mathrm{SiH}_{3}\right)_{3}$, the central N atom uses trigonal planar $\mathrm{sp}_{x} \mathrm{p}_{y}$ hybrid orbitals to form $\mathrm{N}-\mathrm{Si}$ bonds, with the nonbonding electron pair of N residing in the $2 \mathrm{p}_{z}$ orbital. Silicon has empty, relatively low-lying 3d orbitals able to interact appreciably with the $2 \mathrm{p}_{z}$ orbital of the N atom. This additional delocalized $\mathrm{p} \pi-\mathrm{d} \pi$ interaction shown in Fig 14.4.1(c) enhances the strength of the bonding that causes the $\mathrm{NSi}_{3}$ skeleton to adopt a planar configuration.

Fig. 14.4.1.
(a) Structure of planar $\mathrm{N}\left(\mathrm{SiH}_{3}\right)_{3}$, (b) pyramidal $\mathrm{N}\left(\mathrm{CH}_{3}\right)_{3}$, and (c) the $\mathrm{d} \pi-$ p $\pi$ bonding in $\mathrm{N}\left(\mathrm{SiH}_{3}\right)_{3}$. The occupied $2 \mathrm{p}_{z}$ orbital of the N atom is shaded, and only one $\mathrm{Si} 3 \mathrm{~d}_{x z}$ orbital is shown for clarity.

Structural Chemistry of Selected Elements

Table 14.4.1. Comparison of chemical bonds formed by C and Si

| Bond | Bond length $(\mathrm{pm})$ | Bond energy $\left(\mathrm{kJ} \mathrm{mol}^{-1}\right)$ |
| :--- | :---: | :---: |
| $\mathrm{C}-\mathrm{C}$ | 154 | 356 |
| $\mathrm{C}-\mathrm{H}$ | 109 | 413 |
| $\mathrm{C}-\mathrm{O}$ | 143 | 336 |
| $\mathrm{Si}-\mathrm{Si}$ | 235 | 226 |
| Si-H | 148 | 318 |
| Si-O | 166 | 452 |

## (3) Catenation and silanes

The term catenation is used to describe the tendency for covalent bond formation between atoms of a given element to form chains, cycles, layers, or 3D frameworks. Catenation is common in carbon compounds, but it only occurs to a limited extent in silicon chemistry. The reason can be deduced from the data listed in Table 14.4.1.

Inspection of Table 14.4 .1 shows that $E(\mathrm{C}-\mathrm{C})>E(\mathrm{Si}-\mathrm{Si}), E(\mathrm{C}-\mathrm{H})>E(\mathrm{Si}-$ $\mathrm{H})$ and $E(\mathrm{C}-\mathrm{C})>E(\mathrm{C}-\mathrm{O})$, but $E(\mathrm{Si}-\mathrm{Si}) \ll E(\mathrm{Si}-\mathrm{O})$. Thus alkanes are much more stable than silanes, and silanes react readily with oxygen to convert the $\mathrm{Si}-\mathrm{Si}$ bonds to stronger $\mathrm{Si}-\mathrm{O}$ bonds. Although silanes do not exist in nature, some compounds with $\mathrm{Si}-\mathrm{Si}$ and $\mathrm{Si}=\mathrm{Si}$ bonds have been synthesized in the absence of air and in non-aqueous solvents. The silanes $\mathrm{Si}_{n} \mathrm{H}_{2 n+2}(n=1-8)$, cyclic silanes $\mathrm{Si}_{n} \mathrm{H}_{2 n}(n=5,6)$, and some polyhedral silanes are known. The structures of tetrahedral $\mathrm{Si}_{4}\left(\mathrm{Sit}^{t} \mathrm{Bu}_{3}\right)_{4}$, trigonal-prismatic $\mathrm{Si}_{6}\left(2,6-{ }^{i} \mathrm{PrC}_{6} \mathrm{H}_{3}\right)_{6}$, and cubane-like $\mathrm{Si}_{8}\left(2,6-\mathrm{Et}_{2} \mathrm{C}_{6} \mathrm{H}_{3}\right)_{8}$ are shown below:

$\mathrm{Si}_{4}\left(\mathrm{Si}^{t} \mathrm{Bu}_{3}\right)_{4}$
endocyclic Si-Si 232-4 pm exocyclic $\mathrm{Si}-\mathrm{Si} 236-7 \mathrm{pm}$

$\mathrm{Si}_{6}\left(2,6-{ }^{i} \mathrm{Pr}_{2} \mathrm{C}_{6} \mathrm{H}_{3}\right)_{6}$
Si-Si 237-9 pm Si-C 190-2 pm

$\mathrm{Si}_{8}\left(2,6-\mathrm{Et}_{2} \mathrm{C}_{6} \mathrm{H}_{3}\right)_{8}$
Si-Si 238-41 pm Si-C 190-2 pm

The structures of other examples of oligocyclosilanes are shown in Fig. 14.4.2. The adamantane-like cluster $\left(\mathrm{SiMe}_{2}\right)_{6}\left(\mathrm{Si}-\mathrm{SiMe}_{3}\right)_{4}$ with pendant methyl and trimethylsilyl groups was prepared in 2005.

### 14.4.2 Metal silicides

There exist a number of metal silicides, in which silicon anions formally occur. The structural types of the silicides in the solid state are diverse:
(1) Isolated units
(a) $\mathrm{Si}^{4-}$ : Examples are found in $\mathrm{Mg}_{2} \mathrm{Si}_{\mathrm{C}}, \mathrm{Ca}_{2} \mathrm{Si}_{\mathrm{i}}, \mathrm{Sr}_{2} \mathrm{Si}, \mathrm{Ba}_{2} \mathrm{Si}$.
(a)

(c)

(g)

(h)

(b) $\mathrm{Si}_{2}$ units: $\mathrm{The}_{\mathrm{Si}_{2}}{ }^{6-}$ ion occurs in $\mathrm{U}_{3} \mathrm{Si}_{2}$ ( $\mathrm{Si-Si}$ distance is 230 pm ) and in the series $\mathrm{Ca}_{5} \mathrm{Si}_{3}, \mathrm{Sr}_{5} \mathrm{Si}_{3}$ and $\mathrm{Ba}_{5} \mathrm{Si}_{3}\left[\right.$ as $\left(\mathrm{M}^{2+}\right)_{5}\left(\mathrm{Si}_{2}\right)^{6-}\left(\mathrm{Si}^{4-}\right]$.
(c) $\mathrm{Si}_{4}$ units: The $\mathrm{Si}_{4}{ }^{6-}$ ion has a butterfly structure; examples are found in $\mathrm{Ba}_{3} \mathrm{Si}_{4}$, as shown in Fig. 14.4.3(a). On the other hand, $\mathrm{Si}_{4}{ }^{4-}$ is tetrahedral and examples are found in $\mathrm{NaSi}, \mathrm{KSi}, \mathrm{CsSi}, \mathrm{BaSi}_{2}$, as shown in Fig. 14.4.3(b). Finally, in $\mathrm{K}_{7} \mathrm{LiSi}_{8}$, pairs of $\mathrm{Si}_{4}$ units are connected by $\mathrm{Li}^{+}$, as shown in Fig. 14.4.3(c), with additional interactions involving $\mathrm{K}^{+}$ions.
(a)

(d)
(e)

(2) $\mathrm{Si}_{n}$ chains: Polymeric unit $\left[\mathrm{Si}^{2-}\right]_{n}$ has a planar zigzag shape. Examples are found in USi and CaSi , as shown in Fig. 14.4.3(d). The $\mathrm{Si}-\mathrm{Si}$ distances are 236 (USi) and $247 \mathrm{pm}(\mathrm{CaSi})$.
(3) $\mathrm{Si}_{n}$ layers: Polymeric unit $\left[\mathrm{Si}^{-}\right]_{n}$ in $\mathrm{CaSi}_{2}$ consists of corrugated layers of six-membered rings, as shown in Fig. 14.4.3(e). In $\beta-\mathrm{ThSi}_{2}$, the $\left[\mathrm{Si}^{-}\right]_{n}$ units form planar hexagonal nets, which are similar to the $\mathrm{B}_{n}$ layers in $\mathrm{AlB}_{2}$ [Fig. 13.3.1(f)].
(4) $\mathrm{Si}_{n}$ three-dimensional networks: Examples are $\mathrm{SrSi}_{2}, \alpha-\mathrm{USi}_{2}$, in which $\left[\mathrm{Si}^{-}\right]_{n}$ constitutes a network with metal cations occupying the interstitial sites.

### 14.4.3 Stereochemistry of silicon

## (1) Silicon molecular compounds with coordination numbers from three to six

The compounds formed by one Si atom and one to two other non-metallic atoms, such as SiX or $\mathrm{SiX}_{2}(\mathrm{X}=\mathrm{H}, \mathrm{F}, \mathrm{O}$, and Cl$)$, are not stable species.

Fig. 14.4.2.
The structures of the molecular skeletons of some oligocyclosilanes:
(a) $\mathrm{Si}_{4}{ }^{t} \mathrm{Bu}_{2}\left(2,6-\mathrm{Et}_{2} \mathrm{C}_{6} \mathrm{H}_{3}\right)_{4}$,
(b) $\mathrm{Si}_{5} \mathrm{H}_{2}{ }^{t} \mathrm{Bu}_{4}\left(2,4,6-{ }^{t} \mathrm{Bu}^{i} \mathrm{Pr}_{2} \mathrm{C}_{6} \mathrm{H}_{2}\right)$,
(c) $\mathrm{Si}_{6}{ }^{i} \mathrm{Pr}_{10}$, (d) $\mathrm{Si}_{7} \mathrm{Me}_{12}$, (e) $\mathrm{Si}_{8} \mathrm{Me}_{14}$,
(f) $\mathrm{Si}_{10} \mathrm{Me}_{18}$, (g) $\mathrm{Si}_{8}{ }^{i} \operatorname{Pr}_{12}$,
(h) $\mathrm{Si}_{10} \mathrm{Me}_{16}$.

Fig. 14.4.3.
Structure of silicon anions in metal silicides: (a) $\mathrm{Si}_{4}{ }^{6-}$, (b) $\mathrm{Si}_{4}{ }^{4-}$,
(c) $\left[\mathrm{LiSi}_{8}\right]^{7-}$, (d) $\left[\mathrm{Si}^{2-}\right]_{n}$, (e) $\left[\mathrm{Si}^{-}\right]_{n}$.

Fig. 14.4.4.
Structure of silylium ion (mes) $)_{3} \mathrm{Si}^{+}$.

A number of silenes $\left(\mathrm{R}_{2} \mathrm{Si}=\mathrm{CR}_{2}\right)$ and disilenes $\left(\mathrm{R}_{2} \mathrm{Si}=\mathrm{SiR}_{2}\right)$ containing double bonds, where each Si atom is three-coordinated, are known.

The structure of the free silylium ion (mes) $)_{3} \mathrm{Si}^{+}$has been characterized by X ray analysis of $\left[(\mathrm{mes})_{3} \mathrm{Si}\right]\left[\mathrm{HCB}_{11} \mathrm{Me}_{5} \mathrm{Br}_{6}\right] \cdot \mathrm{C}_{6} \mathrm{H}_{6}$. The (mes) $)_{3} \mathrm{Si}^{+}$cation is well separated from the carborane anion and benzene solvate molecule. As shown in Fig. 14.4.4, the Si atom has trigonal planar coordination geometry expected of a $\mathrm{sp}^{2}$ silylium center, with $\mathrm{Si}-\mathrm{C}$ bond length 181.7 pm (av.), and the mesityl groups have a propeller-like arrangement around the Si center with an averaged twist angle $\tau=49.2^{\circ}$.

In the vast majority of its compounds, Si is tetrahedrally coordinated, which include $\mathrm{SiH}_{4}, \mathrm{SiX}_{4}, \mathrm{SiR}_{4}, \mathrm{SiO}_{2}$, and silicates. Five-coordinate Si can be either trigonal bipyramidal or square pyramidal, the former being more stable than the latter. $\mathrm{In}\left[\mathrm{Et}_{4} \mathrm{~N}\right]\left[\mathrm{SiF}_{5}\right]$ the anion $\mathrm{SiF}_{5}^{-}$is trigonal bipyramidal with $\mathrm{Si}-\mathrm{F}_{(\mathrm{ax})} 165$ pm and $\mathrm{Si}-\mathrm{F}_{(\mathrm{eq})} 159 \mathrm{pm}$ (av). Among the stable compounds of penta-coordinate silicon, the most studied are the silatranes, an example of which is shown below:

In this molecule, the axial nitrogen atom is linked through three $\left(\mathrm{CH}_{2}\right)_{2}$ tethers to oxygen atoms at the triangular base. The tetradentate tripodal ligand occupies four coordination positions around the central Si atom, forming an intramolecular transannular dative bond of the type $\mathrm{N} \rightarrow$ Si. The observed $\mathrm{N} \rightarrow \mathrm{Si}$ bond distances in about 50 silatranes containing three condensed rings vary within the range $200-40 \mathrm{pm}$. The longer the $\mathrm{N} \rightarrow$ Si bond, the more planar the configuration of the $\mathrm{NC}_{3}$ moiety, and the structure of the $\mathrm{RSiO}_{3}$ fragment approaches tetrahedral.

Numerous compounds of octahedral hexa-coordinate Si are known. Some examples are shown below.

In the salt $\left[\mathrm{C}\left(\mathrm{NH}_{2}\right)_{3}\right]_{2}\left[\mathrm{SiF}_{6}\right]$, the $\mathrm{Si}-\mathrm{F}$ bond length in octahedral $\mathrm{SiF}_{6}{ }^{2-}$ is 168 pm , which is longer than the $\mathrm{Si}-\mathrm{F}$ bonds in $\mathrm{SiF}_{5}{ }^{-}$.

## (2) Structure of $\mathrm{Si}(\mathrm{IV})$ compounds with $\mathrm{SiO}_{5}$ and $\mathrm{SiO}_{6}$ skeletons

The chemistry of silicon oxygen compounds with $\mathrm{SiO}_{5}$ and $\mathrm{SiO}_{6}$ skeletons in aqueous solution is of special interest. It has been speculated that such $\mathrm{Si}(\mathrm{IV})$ complexes with ligands derived from organic hydroxy compounds (such as pyrocatechol derivatives, hydroxycarboxylic acids, and carbohydrates) may play a significant role in silicon biochemistry by controlling the transport of silicon.

Several zwitterionic neutral compounds and anionic species with the $\mathrm{SiO}_{5}$ skeleton have been synthesized and characterized by X-ray diffraction. The Si coordination polyhedra of these compounds are typically distorted trigonal bipyramids, with the carboxylate oxygen atoms of the two bidentate ligands in the axial positions. Figure 14.4 .5 shows the structures of (a) $\left.\mathrm{Si}^{[ } \mathrm{C}_{2} \mathrm{O}_{3}(\mathrm{Me})_{2}\right]_{2}\left[\mathrm{O}\left(\mathrm{CH}_{2}\right)_{2} \mathrm{NHMe}_{2}\right]$ with $\mathrm{Si}-\mathrm{O}_{(\mathrm{ax})} 177.3$ and 179.8 pm , and $\mathrm{Si}-\mathrm{O}_{(\mathrm{eq})} 164.3$ to 165.9 pm , and (b) the anion in crystalline $\left[\mathrm{Si}\left(\mathrm{C}_{2} \mathrm{O}_{3} \mathrm{Ph}_{2}\right)_{2}(\mathrm{OH})\right]^{-}\left[\mathrm{H}_{3} \mathrm{NPh}\right]^{+}$, where $\mathrm{Si}-\mathrm{O}_{(\mathrm{ax})} 179.8 \mathrm{pm}$ and $\mathrm{Si}-\mathrm{O}_{(\text {eq })} 165.0$ to 166.0 pm .

Some neutral compounds, cationic species, and anionic species with distorted octahedral $\mathrm{SiO}_{6}$ skeletons have been established. Figure 14.4.6 shows the structures of (a) $\mathrm{Si}_{1}\left[\mathrm{C}_{2} \mathrm{O}_{3} \mathrm{Ph}_{2}\right]\left[\mathrm{C}_{3} \mathrm{HO}_{2} \mathrm{Ph}_{2}\right]_{2}$ in which the $\mathrm{Si}-\mathrm{O}$ bond lengths are 169.3 to 182.1 pm , and (b) the dianion in $\left[\mathrm{Si}\left(\mathrm{C}_{2} \mathrm{O}_{4}\right)_{3}\right]^{2-}\left[\mathrm{HO}\left(\mathrm{CH}_{2}\right)_{2} \mathrm{NH}\left(\mathrm{CH}_{2}\right)_{4}{ }^{+}\right]_{2}$, in which the $\mathrm{Si}-\mathrm{O}$ bond lengths vary from 176.7 to 178.8 pm .

## (3) Structural features of $\mathbf{S i}=\mathbf{S i}$ double bond in disilenes

The first reported disilene is $(\mathrm{mes})_{2} \mathrm{Si}=\mathrm{Si}(\mathrm{mes})_{2}$, which was isolated and characterized in 1981. The characteristic structural features of disilenes are the

Fig. 14.4.5.

Fig. 14.4.7.
Double-bond formation from two triplet carbenes and singlet silylenes.

length of the $\mathrm{Si}=\mathrm{Si}$ double bond $d$, the twist angle $\tau$, and the trans-bent angle $\theta$, as shown below.

In contrast to the $\mathrm{C}=\mathrm{C}$ double bond of sterically crowded alkenes, in which variations of the bond lengths are small, the $\mathrm{Si}=\mathrm{Si}$ bond lengths of disilenes vary between 214 and 229 pm . The twist angle $\tau$ of the two $\mathrm{SiR}_{2}$ planes varies between $0^{\circ}$ and $25^{\circ}$. A further peculiarity of the disilenes, not observed in alkenes, is the possibility of trans-bending of the substituents, which is described by the trans-bent angle $\theta$ between the $\mathrm{SiR}_{2}$ planes and the $\mathrm{Si}=\mathrm{Si}$ vector. The $\theta$ values can reach up to $34^{\circ}$. These differences can be
(c)

(d)

(e)

rationalized as follows: carbenes have either a triplet ground state (T), as shown in Fig. 14.4.7(a), or a singlet ground state (S), as shown in Fig. 14.4.7(b), with relatively low $\mathrm{S} \rightarrow \mathrm{T}$ transition energies. The familiar picture of a $\mathrm{C}=\mathrm{C}$
double-bond results from the approach of two triplet carbenes [Fig. 14.4.7(c)]. In contrast, silylenes have singlet ground states with a relative large $S \rightarrow T$ excitation energy. Approach of two singlet silylenes should usually result in repulsion rather than bond formation [Fig. 14.4.7(d)]. However, if the two silylene molecules are tilted with respect to each other, interaction between the doubly occupied $\mathrm{sp}^{2}$-type orbitals and the vacant p orbitals can form a double donor-acceptor bond. This is accompanied by a trans-bending of the substituents about the $\mathrm{Si}=\mathrm{Si}$ vector, as illustrated in Fig. 14.4.7(e).

## (4) Stable silyl radicals

Silyl radicals stabilized with bulky trialkylsilyl groups can be isolated in crystalline form. X-ray analysis showed that the $\left({ }^{t} \mathrm{Bu}_{2} \mathrm{MeSi}_{3}\right)_{3} \mathrm{Si}^{\cdot}$ radical has trigonal planar geometry about the central $\mathrm{sp}^{2} \mathrm{Si}$ atom, with an averaged $\mathrm{Si}-\mathrm{Si}$ bond length of 242(1) pm. Interestingly, all the methyl substituents at the $\alpha-\mathrm{Si}$ atoms lie in the plane of the polysilane skeleton so that steric hindrance is minimized. Reaction of this radical with lithium metal in hexane at room temperature afforded $\left[\left({ }^{t} \mathrm{Bu}_{2} \mathrm{MeSi}\right)_{3} \mathrm{Si}\right] \mathrm{Li}$, the crystal structure of which showed a planar configuration (sum of $\mathrm{Si}-\mathrm{Si}-\mathrm{Si}$ angles $=119.7^{\circ}$ for the central anionic Si atom) and an averaged $\mathrm{Si}-\mathrm{Si}$ bond length of 236(1) pm.

Crystal structure analysis of the disilene $\left({ }^{t} \mathrm{Bu}_{2} \mathrm{MeSi}\right)_{2} \mathrm{Si}=\mathrm{Si}\left(\mathrm{SiMe}^{t} \mathrm{Bu}_{2}\right)_{2}$ has revealed a highly twisted configuration about the central $\mathrm{Si}=\mathrm{Si}$ double bond, as shown in Fig. 14.4.8(a). The $\operatorname{Si}(1)$ and $\operatorname{Si}(2)$ atoms forming the double bond are both $\mathrm{sp}^{2}$ hybridized, and the twist angle $\tau$ has an exceptionally large value of $54.5^{\circ}$ (see Fig. 14.4.8(b)). The disilene reacts with ${ }^{t} \mathrm{BuLi}$ to produce the $\left[\mathrm{Li}(\mathrm{THF})_{4}\right]^{+}$salt of the silyl anion radical $\left({ }^{t} \mathrm{Bu}_{2} \mathrm{MeSi}_{2} \mathrm{Si}^{-}-\mathrm{Si}^{\cdot}\left(\mathrm{SiMe}^{t} \mathrm{Bu}_{2}\right)_{2}\right.$, in which the anionic $\mathrm{Si}(1)^{-}$atom has flattened pyramidal geometry (sum of bond angles $=352.7^{\circ}$ ) whereas the radical $\operatorname{Si}(2)$ atom retains its $\mathrm{sp}^{2}$ configuration. The mean planes of the $\operatorname{Si}(3)-\operatorname{Si}(1)-\operatorname{Si}(4)$ and $\operatorname{Si}(5)-\operatorname{Si}(2)-\operatorname{Si}(6)$ fragments are nearly orthogonal, with a $\tau$ angle of $88^{\circ}$ about the central $\mathrm{Si}-\mathrm{Si}$ single bond, as illustrated in Fig. 14.4.8(c).
(a)

(b)

(c)

Fig. 14.4.8.
(a) Molecular structure of disilene $\left({ }^{t} \mathrm{Bu}_{2} \mathrm{MeSi}\right)_{2} \mathrm{Si}=\mathrm{Si}\left(\mathrm{SiMe}^{t} \mathrm{Bu}_{2}\right)_{2} . \mathrm{Si}(m)-\mathrm{Si}(n)$ bond lengths (in pm): $1-2,226.0(1) ; 1-3,241.6(2) ; 1-4,241.9(2) ; 2-5,241.3(2) ; 2-6,242.3(2)$. (b) Twisted configuration of the $\mathrm{Si}_{2} \mathrm{Si}=\mathrm{SiSi}_{2}$ skeleton. (c) Nearly orthogonal configuration of the silyl anion radical $\left({ }^{t} \mathrm{Bu}_{2} \mathrm{MeSi}_{2} \mathrm{Si}^{-}-\mathrm{Si}\left(\mathrm{SiMe}^{t} \mathrm{Bu}_{2}\right)_{2}\right.$. Bond lengths $\mathrm{Si}(m)-\mathrm{Si}(n)$ (in pm$): 1-2,234.1(5) ; 1-3$, 239.0(5);1-4, 239.2(5); 2-5, 241.2(1); 2-6, 240.1(1).

## Structural Chemistry of Selected Elements

### 14.4.4 Silicates

## (1) Classification of silicates

Silicates constitute the largest part of the earth's crust and mantle. They play a dominant role as raw materials as well as products in technological processes, such as building materials, cements, glasses, ceramics, and refractory materials.

In the silicates, the tetrahedral $\mathrm{SiO}_{4}$ units are either isolated or share corners with other tetrahedra, giving rise to an enormous variety of structures. In many silicates, silicon may be replaced to a certain extent by other elements, such as aluminium, so the structures of silicates are further extended to cover cases where such partial substitution occurs.

Table 14.4.2. Classification of natural silicates

| Number of shared O atoms <br> in $\mathrm{SiO}_{4}$ unit | Structure | Name |
| :--- | :--- | :--- |
| 0 (no O atom shared) | Discrete $\mathrm{SiO}_{4}$ unit | Neso-silicates |
| 1 | Discrete $\mathrm{Si}_{2} \mathrm{O}_{7}$ unit | Soro-silicates |
| 2 | Cyclic $\left(\mathrm{SiO}_{3}\right)_{n}$ structures | Cyclo-silicates |
| 2 | Infinite chains or ribbons | Ino-silicates |
| 3 | Infinite layers | Phyllo-silicates |
| 4 | Infinite 3D frameworks | Tecto-silicates |

The kind and the degree of linkage of $\mathrm{SiO}_{4}$ tetrahedra constitute a basis for the classification of natural silicates, as shown in Table 14.4.2.
(a) Silicates containing discrete $\mathrm{SiO}_{4}{ }^{4-}$ or $\mathrm{Si}_{2} \mathrm{O}_{7}{ }^{6-}$

The discrete $\mathrm{SiO}_{4}{ }^{4-}$ anion [as shown in Fig. 14.4.9(a)] occurs in the orthosilicates, such as phenacite $\mathrm{Be}_{2} \mathrm{SiO}_{4}$, olivine $(\mathrm{Mg}, \mathrm{Fe}, \mathrm{Mn})_{2} \mathrm{SiO}_{4}$, and zircon $\mathrm{ZrSiO}_{4}$. Another important group of orthosilicates is the garnets,

(b)

(c)

(d)

(e)

(f)

(g)

$\mathrm{M}_{3}^{\mathrm{II}} \mathrm{M}_{2}^{\mathrm{III}}\left(\mathrm{SiO}_{4}\right)_{3}$, in which $\mathrm{M}^{\mathrm{II}}$ are eight-coordinate (e.g. $\mathrm{Ca}, \mathrm{Mg}, \mathrm{Fe}$ ) and $\mathrm{M}^{\mathrm{III}}$ are six-coordinate (e.g., $\mathrm{Al}, \mathrm{Cr}, \mathrm{Fe}$ ). Orthosilicates are also vital components of Portland cements: $\beta-\mathrm{Ca}_{2} \mathrm{SiO}_{4}$ has a discrete $\left[\mathrm{SiO}_{4}\right]$ group with Ca in six- or eight-coordination.

An example of a disilicate containing the discrete $\mathrm{Si}_{2} \mathrm{O}_{7}{ }^{6-}$ ion [as shown in Fig. 14.4.9(b)] is the mineral thortveitite $\mathrm{Sc}_{2} \mathrm{Si}_{2} \mathrm{O}_{7}$, in which $\mathrm{Sc}^{\mathrm{III}}$ is octahedral and $\mathrm{Si}-\mathrm{O}-\mathrm{Si}$ is linear with staggered conformation. There is also a series of lanthanoid disilicates $\mathrm{Ln}_{2} \mathrm{Si}_{2} \mathrm{O}_{7}$, in which the $\mathrm{Si}-\mathrm{O}-\mathrm{Si}$ angle decreases progressively from $180^{\circ}$ to $133^{\circ}$, and the coordination number of Ln increases from 6 through 7 to 8 as the size of Ln increases from six-coordinated $\mathrm{Lu}^{\text {III }}$ to eight-coordinated $\mathrm{Nd}^{\text {III }}$. In the Zn mineral hemimorphite the angle is $150^{\circ}$, but the conformation of the two tetrahedra is eclipsed rather than staggered.

Discrete chains of three or four linked $\mathrm{SiO}_{4}$ tetrahedra are extremely rare, but they exist in aminoffite $\mathrm{Ca}_{3}(\mathrm{BeOH})_{2}\left[\mathrm{Si}_{3} \mathrm{O}_{10}\right]$, kinoite $\mathrm{Cu}_{2} \mathrm{Ca}_{2}\left[\mathrm{Si}_{3} \mathrm{O}_{10}\right] \cdot 2 \mathrm{H}_{2} \mathrm{O}$, and vermilion $\mathrm{Ag}_{10}\left[\mathrm{Si}_{4} \mathrm{O}_{13}\right]$.
(b) Silicates containing cyclic $\left[\mathrm{SiO}_{3}\right]_{n}^{2 n-}$ ion

Cyclic $\left[\mathrm{SiO}_{3}\right]_{n}^{2 n-}$ having 3, 4, 6 or 8 linked tetrahedra are known, though 3 and 6 [as shown in Figs 14.4.9(c)-(d)] are the most common. These anions are exemplified by the minerals benitoite $\mathrm{BaTi}\left[\mathrm{Si}_{3} \mathrm{O}_{9}\right]$, catapleite $\mathrm{Na}_{2} \mathrm{Zr}\left[\mathrm{Si}_{3} \mathrm{O}_{9}\right] \cdot 2 \mathrm{H}_{2} \mathrm{O}$, beryl $\mathrm{Be}_{3} \mathrm{Al}_{2}\left[\mathrm{Si}_{6} \mathrm{O}_{18}\right]$, tourmaline $(\mathrm{Na}, \mathrm{Ca})\left(\mathrm{Li}, \mathrm{Al}_{3}\right)_{3} \mathrm{Al}_{6}(\mathrm{OH})_{4}\left(\mathrm{BO}_{3}\right)_{3}\left[\mathrm{Si}_{6} \mathrm{O}_{18}\right]$, and murite $\mathrm{Ba}_{10}(\mathrm{Ca}, \mathrm{Mn}, \mathrm{Ti})_{4}\left[\mathrm{Si}_{8} \mathrm{O}_{24}\right](\mathrm{Cl}, \mathrm{OH}, \mathrm{O})_{12} \cdot 4 \mathrm{H}_{2} \mathrm{O}$.
(c) Silicates with infinite chain or ribbon structure

Single chains formed by tetrahedral $\mathrm{SiO}_{4}$ groups sharing two vertices adopt various configurations in the crystal. There are different numbers of tetrahedra in the repeat unit for different minerals; for example, both diopside $\mathrm{CaMg}\left[\mathrm{SiO}_{3}\right]_{2}$ and enstatite $\mathrm{MgSiO}_{3}$ have two repeat units, as shown in Fig. 14.4.9(e).

In the double chains or ribbons, there are different kinds of tetrahedra sharing two and three vertices. The most numerous amphiboles and asbestos minerals, such as tremolite, $\mathrm{Ca}_{2} \mathrm{Mg}_{5}\left(\mathrm{Si}_{4} \mathrm{O}_{11}\right)_{2}(\mathrm{OH})_{2}$, adopt the $\left[\mathrm{Si}_{4} \mathrm{O}_{11}\right]_{n}{ }^{6 n-}$ double chain structure, as shown in Fig. 14.4.9(f).
(d) Silicates with layer structures

Silicates with layer structures include clay minerals, micas, asbestos, and talc. The simplest single layer has composition $\left[\mathrm{Si}_{2} \mathrm{O}_{5}\right]_{n}{ }^{2 n-}$, in which each $\mathrm{SiO}_{4}$ tetrahedron shares three vertices with three others, as shown in Fig. 14.4.9(g). Muscovite $\mathrm{KAl}_{2}\left[\mathrm{AlSi}_{3} \mathrm{O}_{10}\right](\mathrm{OH})_{2}$ is a layer silicate of the mica group. There are many and complex variations of structure based on one or more of the layer types. The vertices of the tetrahedra can form part of a hydroxide-like layer. Their bases can either be directly opposed, or can be fitted to hydroxyl or water layers. When layers of different types succeed each other with more or less regularity, the changes in stacking these layers together occur in an endless variety of ways. This irregularity of structure is no doubt related to their capacity to take up or lose water and mediate ion exchange. In many cases the structures swell or contract in different stages of hydration, and can take up replaceable ions.

## Structural Chemistry of Selected Elements

## (e) Silicates with framework structures

In silicates, the most important and widespread substitution is that of Al for Si in tetrahedral coordination to form $(\mathrm{Si}, \mathrm{Al}) \mathrm{O}_{4}$ tetrahedra, so that most of the "silicates" that occur in nature are in fact aluminosilicates. This substitution must be accompanied by the incorporation of cations to balance the charge on the $\mathrm{Si}-\mathrm{O}$ framework.

Sharing of all vertices of each $(\mathrm{Si}, \mathrm{Al}) \mathrm{O}_{4}$ tetrahedron leads to infinite 3D framework aluminosilicates, such as felspars, ultramarines, and zeolites. The felspars are the most abundant of all minerals and comprise about $60 \%$ of the earth's crust, and are subdivided into two groups according to the symmetry of their structures. Typical members of the groups are: (a) orthoclase $\mathrm{KAlSi}_{3} \mathrm{O}_{8}$ and celsian $\mathrm{BaAl}_{2} \mathrm{Si}_{2} \mathrm{O}_{8}$, and (b) the plagioclase felspar: albite $\mathrm{NaAlSi}_{3} \mathrm{O}_{8}$ and anorthite $\mathrm{CaAl}_{2} \mathrm{Si}_{2} \mathrm{O}_{8}$. Examples of ultramarine are sodalite $\mathrm{Na}_{8} \mathrm{Cl}_{2}\left[\mathrm{Al}_{6} \mathrm{Si}_{6} \mathrm{O}_{24}\right]$ and ultramarine $\mathrm{Na}_{8}\left(\mathrm{~S}_{2}\right)\left[\mathrm{Al}_{6} \mathrm{Si}_{6} \mathrm{O}_{24}\right]$.

## (2) Zeolites

Zeolites are crystalline, hydrated aluminosilicates that possess framework structures containing regular channels and/or polyhedral cavities. Zeolites generally contain loosely held water, which can be removed by heating the crystals and subsequently regained on exposure to a moist atmosphere. When occluded water is removed, it can be replaced by other small molecules. There is a close relationship between the size of molecules that can diffuse through the framework and the dimensions of the aperture or "bottle-neck" connecting one cavity to the next. This capacity of zeolites to admit molecules below a certain limiting size, while blocking passage to larger molecules, has led to their being termed "molecular sieves."

There are more than 40 natural zeolites and over 100 synthesized zeolites. Table 14.4.3 lists the ideal composition and the member of rings of some zeolites. Figure 14.4.10(a) shows the construction of a truncated cubo-octahedron ( $\beta$-cage) formed from 24 linked ( $\mathrm{Si}, \mathrm{Al}) \mathrm{O}_{4}$ tetrahedra, and Fig. 14.4.10(b) shows a simplified representation of this cavity formed by joining the $\operatorname{Si}(\mathrm{Al})$ atom positions. Several other types of polyhedra have also been observed.

Zeolite A is a synthetic zeolite that has not been found in nature. In the framework structure of dehydrated zeolite $4 \mathrm{~A}, \mathrm{Na}_{12}\left[\mathrm{Al}_{12} \mathrm{Si}_{12} \mathrm{O}_{48}\right]$, cubo-octahedra lie at the corners of the unit cell, generating small cubes at the centers of the cell edges and eight-membered rings at the face centers. Access through these eightmembered rings to a very large cavity (truncated cubo-octahedron, $\alpha$-cage) at

Table 14.4.3. Ideal composition and member of rings in some zeolites

| Zeolite | Ideal composition | Member of rings |
| :--- | :--- | :--- |
| Zeolite A | $\mathrm{Na}_{12}\left[\mathrm{Al}_{12} \mathrm{Si}_{12} \mathrm{O}_{48}\right] \cdot 27 \mathrm{H}_{2} \mathrm{O}$ | $4,6,8$ |
| Faujasite (Zeolite X and Y) | $\mathrm{Na}_{58}\left[\mathrm{Al}_{58} \mathrm{Si}_{134} \mathrm{O}_{384}\right] \cdot 240 \mathrm{H}_{2} \mathrm{O}$ | $4,6,12$ |
| Zeolite ZSM-5 | $\mathrm{Na}_{3}\left[\mathrm{Al}_{3} \mathrm{Si}_{93} \mathrm{O}_{192}\right] \cdot 16 \mathrm{H}_{2} \mathrm{O}$ | $4,5,6,7,8,10$ |
| Chabazite | $\mathrm{Na}_{4} \mathrm{Ca}_{8}\left[\mathrm{Al}_{20} \mathrm{Si}_{52} \mathrm{O}_{144}\right] \cdot 56 \mathrm{H}_{2} \mathrm{O}$ | $4,5,6,8,10$ |
| Mordenite | $\mathrm{Na}_{8}\left[\mathrm{Al}_{8} \mathrm{Si}_{40} \mathrm{O}_{96}\right] \cdot 24 \mathrm{H}_{2} \mathrm{O}$ | $4,5,6,8,12$ |

the center of the unit cell is facilitated. Figure 14.4.11(a) shows the structure of zeolite A framework.

Faujasite or zeolite X and Y exists in nature. Its framework can be formed as follows. The cubo-octahedra are placed at the positions of the carbon atoms in the diamond structure, and they are joined by hexagonal prisms through four of the eight hexagonal faces of each cubo-octahedron, as shown in Fig. 14.4.11(b).

Fig. 14.4.10.
Structure of cubo-octahedral cage ( $\beta$-cage): (a) arrangement of ( $\mathrm{Si}, \mathrm{Al}$ ) $\mathrm{O}_{4}$ (black circles represent Si and Al ), (b) simplified representation of the polyhedral cavity.

Fig. 14.4.11.
Structure of the framework of (a) zeolite A and (b) faujasite.

## (3) General rules governing the structures of natural silicates

The structures of natural silicates obey the following general rules:
(a) With some exceptions, such as stishovite, the Si atoms form $\mathrm{SiO}_{4}$ tetrahedra with little deviation of bond lengths and bond angles from the mean values: $\mathrm{Si}-\mathrm{O}=162 \mathrm{pm}, \mathrm{O}-\mathrm{Si}-\mathrm{O}=109.5^{\circ}$.
(b) The most important and widespread substitution is that of Al for Si in tetrahedral coordination, which is accompanied by the incorporation of cations to balance the charge. The mean Al-O bond length in $\mathrm{AlO}_{4}$ is 176 pm . In almost all silicates that occur as minerals, the anions are tetrahedral ( $\mathrm{Si}, \mathrm{Al}) \mathrm{O}_{4}$ groups. The Al atoms also occupy positions of octahedral coordination in aluminosilicates.
(c) The $(\mathrm{Si}, \mathrm{Al}) \mathrm{O}_{4}$ tetrahedra are linked to one another by sharing common corners rather than edges or faces. Since two $\mathrm{Si}-\mathrm{O}-\mathrm{Al}$ groups have a lower
energy content than one Al-O-Al plus one $\mathrm{Si}-\mathrm{O}-\mathrm{Si}$ group, the $\mathrm{AlO}_{4}$ tetrahedra do not share corners in tetrahedral framework structures if this can be avoided.
(d) One oxygen atom can belong to no more than two $\mathrm{SiO}_{4}$ tetrahedra.
(e) If $s$ is the number of oxygen atoms of a $\mathrm{SiO}_{4}$ tetrahedron shared with other $\mathrm{SiO}_{4}$ tetrahedra, then for a given silicate anion the difference between the $s$ values of all $\mathrm{SiO}_{4}$ tetrahedra tends to be small.

### 14.5 Structures of halides and oxides of heavier group 14 elements

### 14.5.1 Subvalent halides

Subvalent halides of heavier group 14 elements $\mathrm{MX}_{2}(\mathrm{M}=\mathrm{Ge}, \mathrm{Sn}$, and $\mathrm{Pb} ; \mathrm{X}$ $=\mathrm{F}, \mathrm{Cl}, \mathrm{Br}$, and I) and their complexes exhibit the following structural features and properties.

## (1) Stereochemically active lone pair

In the dihalides of $\mathrm{Ge}, \mathrm{Sn}$, and Pb and their complexes, the metal atom always has one lone pair. The discrete, bent $\mathrm{MX}_{2}$ molecules are only present in the gas phase with bond angles less than $120^{\circ}$. Figure 14.5.1(a) shows the structure of $\mathrm{SnCl}_{2}$, which has bond angle $95^{\circ}$ and bond distance 242 pm .

In the crystalline state, the coordination numbers of metal atoms are usually increased to three or four. Because of the existence of the lone pair, the $\mathrm{MX}_{3}{ }^{-}$or $\mathrm{MX}_{4}{ }^{2-}$ units all adopt the trigonal pyramidal or square-pyramidal configuration, as shown in Figs. 14.5.1(b) to 14.5.1(d). Figure 14.5.1(b) shows the structure of $\mathrm{Sn}_{2} \mathrm{~F}_{5}^{-}$in $\mathrm{NaSn}_{2} \mathrm{~F}_{5}$, in which each Sn is trigonal pyramidal with two close $\mathrm{F}_{t}\left(\mathrm{Sn}-\mathrm{F}_{t} 207\right.$ and 208 pm$)$ and one $\mathrm{F}_{b}\left(\mathrm{Sn}-\mathrm{F}_{b} 222 \mathrm{pm}\right)$. Figure 14.5.1(c) shows the structure of $\left(\mathrm{SnCl}_{2} \mathrm{~F}\right)^{-}$ in $\left[\mathrm{Co}(\mathrm{en})_{3}\right]\left(\mathrm{SnCl}_{2} \mathrm{~F}\right)\left[\mathrm{Sn}_{2} \mathrm{~F}_{5}\right] \mathrm{Cl}$. Figure $14.5 .1(\mathrm{~d})$ shows the structure of $\left(\mathrm{SnF}_{3}{ }^{-}\right)_{\infty}$ in $\mathrm{KSnF}_{3} \cdot \frac{1}{2} \mathrm{H}_{2} \mathrm{O}$. In this compound, the Sn atoms are square pyramidal and each bridging F atom is connected to two Sn atoms to give an infinite chain with $\mathrm{Sn}-\mathrm{F}_{b} 227 \mathrm{pm}$ and $\mathrm{Sn}-\mathrm{F}_{t} 201$ and 204 pm .

## (2) Oligomers and polymers

The structural chemistry of $\mathrm{MX}_{2}$ is complex, partly because of the stereochemical activity (or nonactivity) of the lone pair of electrons and partly because of
(a)

(c)

(b)

(d)

the propensity of $\mathrm{M}^{\mathrm{II}}$ to increase its coordination numbers by polymerization into larger structural units, such as rings, chains or layers. The $\mathrm{M}^{\mathrm{II}}$ center rarely adopts structures typical of spherically symmetrical ions because the lone pair of electrons, which is $n s^{2}$ in the free gaseous ion, is readily distorted in the condensed phase. This can be described in terms of ligand-field distortions or the adoption of some p-orbital character. The lone pair can act as a donor to vacant orbitals, and the vacant $n \mathrm{p}$ orbitals and $n$ d orbitals can act as acceptors in forming extra covalent bonds.

In the solid state, $\mathrm{GeF}_{2}$ has a unique structure in which trigonal pyramidal $\mathrm{GeF}_{3}$ units share two F atoms to form an infinite spiral chain. Reaction between $\mathrm{GeF}_{2}$ and $\mathrm{F}^{-}$gives $\mathrm{GeF}_{3}{ }^{-}$, which is a trigonal pyramidal ion.

Crystalline $\mathrm{SnF}_{2}$ is composed of $\mathrm{Sn}_{4} \mathrm{~F}_{8}$ tetramers, which are puckered eightmembered rings of alternating Sn and F atoms, with $\mathrm{Sn}-\mathrm{F}_{b} 218 \mathrm{pm}$ and $\mathrm{Sn}-\mathrm{F}_{t}$ 205 pm . The tetramers are interlinked by weaker $\mathrm{Sn}-\mathrm{F}$ interactions. Bridge formation is observed in $\mathrm{Na}\left(\mathrm{Sn}_{2} \mathrm{~F}_{5}\right), \mathrm{Na}_{4}\left(\mathrm{Sn}_{3} \mathrm{~F}_{10}\right)$, and other salts such as $\left[\mathrm{Co}(\mathrm{en})_{3}\right]\left[\mathrm{SnCl}_{2} \mathrm{~F}\right]\left[\mathrm{Sn}_{2} \mathrm{~F}_{5}\right] \mathrm{Cl}$.

The structure of $\mathrm{SnCl}_{2}$ is shown in Fig. 14.5.1(a). In the crystalline state it has a layer structure with chains of corner-shared, trigonal-pyramidal $\mathrm{SnCl}_{3}$ units. The commercially available solid hydrate $\mathrm{SnCl}_{2} \cdot 2 \mathrm{H}_{2} \mathrm{O}$ also has a puckeredlayer structure.

The dihalides $\mathrm{PbX}_{2}$ is much more stable thermally and chemically than $\mathrm{PbX}_{4}$. Structurally, $\alpha-\mathrm{PbF}_{2}, \mathrm{PbCl}_{2}$ and $\mathrm{PbBr}_{2}$ all form colorless orthorhombic crystals in which $\mathrm{Pb}^{\text {II }}$ is surrounded by nine X ligands (seven closer and two farther away) at the corners of a tricapped trigonal prism.

## (3) Stability

The stability of the dihalides of $\mathrm{Ge}, \mathrm{Sn}$, and Pb steady increases in the sequence $\mathrm{GeX}_{2}<\mathrm{SnX}_{2}<\mathrm{PbX}$. Thus $\mathrm{PbX}_{2}$ is more stable than $\mathrm{PbX}_{4}$, whereas $\mathrm{GeX}_{4}$ is more stable than $\mathrm{GeX}_{2}$. At $978 \mathrm{~K}, \mathrm{SnF}_{4}$ sublimes to give a vapor containing $\mathrm{SnF}_{4}$ molecules, which is thermally stable, but $\mathrm{PbF}_{4}$ (prepared by the action of $\mathrm{F}_{2}$ on Pb compounds) decomposes into $\mathrm{PbF}_{2}$ and $\mathrm{F}_{2}$ when heated.

The preference for the +2 over +4 oxidation state increases down the group, the change being due to relativistic effects that make an important contribution to the inert pair. The "inert pair" concept holds only for the lead ion $\mathrm{Pb}^{2+}(\mathrm{aq})$, which could have a $6 \mathrm{~s}^{2}$ configuration. In more covalent $\mathrm{Pb}^{\mathrm{II}}$ compounds and most $\mathrm{Sn}^{\mathrm{II}}$ compounds there are stereochemically active lone pairs. In some $\mathrm{MX}_{2}(\mathrm{M}=\mathrm{Ge}$ or Sn$)$ compounds Ge and Sn can act as donor ligands.

## (4) Mixed halides and mixed-valence complexes

Many mixed halides are known, such as all ten trihalogenostannate(II) anions $\left[\mathrm{SnCl}_{x} \mathrm{Br}_{y} \mathrm{I}_{z}\right]^{-}(x y z=300,210,201,120,102,111,021,012,030,003)$, have been observed and characterized by ${ }^{119} \mathrm{Sn}$ NMR spectroscopy. An example $\left(\mathrm{SnCl}_{2} \mathrm{~F}\right)^{-}$is shown in Fig. 14.5.1(c).

Many mixed halides of $\mathrm{Pb}^{\mathrm{II}}$ have also been characterized, including PbFCl , $\mathrm{PbFBr}, \mathrm{PbFI}$, and $\mathrm{PbX}_{2} \cdot 4 \mathrm{PbF}_{2}$. Of these, PbFCl has an important tetragonal layer structure, which is frequently adopted by large cations in the presence of two anions of differing size; its sparing solubility in water forms the basis of a gravimetric method for the determination of F .

Some mixed-valence halide complexes are known, such as $\mathrm{Ge}_{5} \mathrm{~F}_{12}=$ $\left(\mathrm{Ge}^{\mathrm{II}} \mathrm{F}_{2}\right)_{4}\left(\mathrm{Ge}^{\mathrm{IV}} \mathrm{F}_{4}\right), \alpha-\mathrm{Sn}_{2} \mathrm{~F}_{6}=\mathrm{Sn}^{\mathrm{II}} \mathrm{Sn}^{\mathrm{IV}} \mathrm{F}_{6}$, and $\mathrm{Sn}_{3} \mathrm{~F}_{8}=\mathrm{Sn}_{2}^{\mathrm{II}} \mathrm{Sn}^{\mathrm{IV}} \mathrm{F}_{8}$. In these compounds, the $\mathrm{M}^{\mathrm{II}}-\mathrm{X}$ bond distances are longer than the corresponding $\mathrm{M}^{\mathrm{IV}}-\mathrm{X}$ bond distances.

The coordination geometries of $\mathrm{M}^{\mathrm{IV}}$ in compounds or mixed-valence complexes, in contrast to $\mathrm{M}^{\mathrm{II}}$, tend to exhibit high symmetries; the $\mathrm{MX}_{4}$ molecules are tetrahedral and $\left[\mathrm{MX}_{6}\right]^{2-}$ units adopt the octahedral (or slightly distorted) configuration.

### 14.5.2 Oxides of $\mathrm{Ge}, \mathrm{Sn}$, and Pb

## (1) Subvalent oxides

Both SnO and PbO exist in several modifications. The most common blue-black modification of SnO and red PbO (litharge) have a tetragonal layer structure, in which the $\mathrm{M}^{\mathrm{II}}\left(\mathrm{Sn}^{\mathrm{II}}\right.$ and $\left.\mathrm{Pb}^{\mathrm{II}}\right)$ atom is bonded to four oxygen atoms arranged in a square to one side of it, with the lone pair of electrons presumably occupying the apex of the tetragonal pyramid ( $\mathrm{Sn}-\mathrm{O} 221 \mathrm{pm}$ and $\mathrm{Pb}-\mathrm{O} 230 \mathrm{pm}$ ). Each oxygen atom is surrounded tetrahedrally by four $\mathrm{M}^{\mathrm{II}}$ atoms. Figure 14.5 .2 shows the crystal structure of SnO (and PbO ).

Dark-brown crystalline GeO is obtained when germanium powder and $\mathrm{GeO}_{2}$ are heated or $\mathrm{Ge}(\mathrm{OH})_{2}$ is dehydrated, but this compound is not well characterized.

## (2) Dioxides

Germanium dioxide, $\mathrm{GeO}_{2}$, closely resembles $\mathrm{SiO}_{2}$ and exists in both $\alpha$-quartz and tetragonal rutile (Fig. 10.2.6) forms. In the latter, $\mathrm{Ge}^{\mathrm{IV}}$ is octahederally coordinated with $\mathrm{Ge}-\mathrm{O} 188 \mathrm{pm}$ (mean). $\mathrm{SnO}_{2}$ occurs naturally as cassiterite, adopting the rutile structure with $\mathrm{Sn}-\mathrm{O} 209 \mathrm{pm}$ (mean). There are two modifications of $\mathrm{PbO}_{2}$ : the tetragonal maroon form has the rutile structure with $\mathrm{Pb}-\mathrm{O} 218 \mathrm{pm}$ (mean), whereas $\alpha-\mathrm{PbO}_{2}$ is an orthorhombic black form whose structure is derived from hcp layers with half of the octahedral sites filled.

## (3) Mixed-valence oxides

$\mathrm{Pb}_{3} \mathrm{O}_{4}\left(\mathrm{~Pb}_{2}^{\mathrm{II}} \mathrm{Pb}^{\mathrm{IV}} \mathrm{O}_{4}\right)$ and $\mathrm{Pb}_{2} \mathrm{O}_{3}\left(\mathrm{~Pb}^{\mathrm{II}} \mathrm{Pb}^{\mathrm{IV}} \mathrm{O}_{3}\right)$ are the two well-known mixedvalence oxides of lead. Red lead $\mathrm{Pb}_{3} \mathrm{O}_{4}$ is important commercially as a pigment and primer. Its tetragonal crystal structure consists of chains of $\mathrm{Pb}^{\mathrm{IV}} \mathrm{O}_{6}$ octahedra sharing opposite edges (mean $\mathrm{Pb}^{\mathrm{IV}}-\mathrm{O} 214 \mathrm{pm}$ ). These chains are aligned

Fig. 14.5.2.
Crystal structure of SnO (and PbO ): (a)viewed from the side of a part of one layer, (b) the arrangement of bonds and lone pair at a metal atom.

parallel to the $c$ axis and linked by the $\mathrm{Pb}^{\mathrm{II}}$ atoms, each being pyramidally coordinated by three oxygen atoms $\left(\mathrm{Pb}^{\mathrm{II}} \mathrm{O}_{3}\right.$ unit, $\mathrm{Pb}^{\mathrm{II}}-\mathrm{O}$ two at 218 pm and one at 213 pm ). Figure 14.5 .3 shows a portion of the tetragonal unit cell of $\mathrm{Pb}_{3} \mathrm{O}_{4}$.

The sesquioxide $\mathrm{Pb}_{2} \mathrm{O}_{3}$ is a black monoclinic crystal, which consists of $\mathrm{Pb}^{\mathrm{IV}} \mathrm{O}_{6}$ octahedra $\left(\mathrm{Pb}^{\mathrm{IV}}-\mathrm{O} 218 \mathrm{pm}\right.$, mean) and very irregular six-coordinate $\mathrm{Pb}^{\mathrm{II}} \mathrm{O}_{6}$ units ( $\mathrm{Pb}^{\mathrm{II}}-\mathrm{O}$ 231, 243, 244, 264, 291 and 300 pm ). The $\mathrm{Pb}^{\mathrm{II}}$ atoms are situated between layers of distorted $\mathrm{Pb}^{\mathrm{IV}} \mathrm{O}_{6}$ octahedra.

Among the various mixed-valence oxides of tin that have been reported, the best characterized is $\mathrm{Sn}_{3} \mathrm{O}_{4}$, i.e., $\mathrm{Sn}_{2}^{\mathrm{II}} \mathrm{Sn}^{\mathrm{IV}} \mathrm{O}_{4}$, the structure of which is similar to that of $\mathrm{Pb}_{3} \mathrm{O}_{4}$. Mixed oxides of $\mathrm{Pb}^{\mathrm{IV}}$ (or $\mathrm{Pb}^{\mathrm{II}}$ ) with other metals find numerous applications in technology and industry. Specifically, $\mathrm{M}^{\mathrm{II}} \mathrm{Pb}^{\mathrm{IV}} \mathrm{O}_{3}$ and $\mathrm{M}^{\mathrm{II}} \mathrm{Pb}^{\mathrm{IV}} \mathrm{O}_{4}\left(\mathrm{M}^{\mathrm{II}}=\mathrm{Ca}, \mathrm{Sr}, \mathrm{Ba}\right)$ have important uses; for example, $\mathrm{CaPbO}_{3}$ is a priming pigment to protect steel corrosion by salt water. Mixed oxides of $\mathrm{Pb}^{\mathrm{II}}$ are also important. $\mathrm{PbTiO}_{3}, \mathrm{PbZrO}_{3}, \mathrm{PbHfO}_{3}, \mathrm{PbNb}_{2} \mathrm{O}_{6}$ and $\mathrm{PbTi}_{2} \mathrm{O}_{6}$ are ferroelectric materials. The high Curie temperature of many $\mathrm{Pb}^{\mathrm{II}}$ ferroelectrics makes them particularly useful for high-temperature applications.

### 14.6 Polyatomic anions of $\mathbf{G e}, \mathbf{S n}$, and Pb

Germanium, tin, and lead dissolve in liquid ammonia in the presence of alkali metals to give highly colored anions, which are identified as polyatomic species (e.g., $\mathrm{Sn}_{5}{ }^{2-}, \mathrm{Pb}_{5}{ }^{2-}, \mathrm{Sn}_{9}{ }^{4-}, \mathrm{Pb}_{9}{ }^{4-}$, and $\mathrm{Ge}_{10}{ }^{2-}$ ) in salts containing cryptated cations, e.g., $[\mathrm{Na}(\mathrm{C} 222)]_{2} \mathrm{~Pb}_{5},[\mathrm{Na}(\mathrm{C} 222)]_{4} \mathrm{Sn}_{9}$, and $[\mathrm{K}(\mathrm{C} 222)]_{3} \mathrm{Ge}_{9}$.

In an unusual synthesis, the compound $[\mathrm{K}(\mathrm{C} 222)]_{2} \mathrm{~Pb}_{10}$ was obtained by oxidation of a solution of $\mathrm{Pb}_{9}{ }^{4-}$ ions in ethylenediamine with $\mathrm{Au}^{\mathrm{I}}$ in the form of $\left[\mathrm{P}\left(\mathrm{C}_{6} \mathrm{H}_{5}\right)_{3} \mathrm{AuCl}\right]$ as the oxidizing agent:

$$
2 \mathrm{~Pb}_{9}{ }^{4-}+6 \mathrm{Au}^{+} \rightarrow \mathrm{Pb}_{10}{ }^{2-}+8 \mathrm{~Pb}^{0} \downarrow+6 \mathrm{Au}^{0}
$$

A single-crystal X-ray structure analysis revealed that the intensely brown colored $\mathrm{Pb}_{10}{ }^{2-}$ anion has a bicapped square-antiprismatic structure of nearly perfect $D_{4 \mathrm{~d}}$ symmetry.

Since the homopolyatomic anions and cations (Zintl ions) are devoid of ligand attachment, they are sometimes referred to as "naked" clusters. The structures of some naked anionic clusters are shown in Fig. 14.6.1: (a) tetrahedral $\mathrm{Ge}_{4}{ }^{4-}, \mathrm{Sn}_{4}{ }^{4-}, \mathrm{Pb}_{4}{ }^{4-}, \mathrm{Pb}_{2} \mathrm{Sb}_{2}{ }^{2-}$; (b) trigonal bipyramidal $\mathrm{Sn}_{5}{ }^{2-}, \mathrm{Pb}_{5}{ }^{2-}$; (c) octahedral $\mathrm{Sn}_{6}{ }^{2-}$; (d) tricapped-trigonal prismatic $\mathrm{Ge}_{9}{ }^{2-}$ and paramagnetic $\mathrm{Ge}_{9}{ }^{3-}, \mathrm{Sn}_{9}{ }^{3-}$; (e) monocapped square-antiprismatic $\mathrm{Ge}_{9}{ }^{4-}, \mathrm{Sn}_{9}{ }^{4-}, \mathrm{Pb}_{9}{ }^{4-}$; (f) bicapped square-antiprismatic $\mathrm{Ge}_{10}{ }^{2-}, \mathrm{Pb}_{10}{ }^{2-}, \mathrm{Sn}_{9} \mathrm{Tl}^{3-}$.

The bonding in these polyatomic anions is delocalized, and for the diamagnetic species the bond valence method (see Section 13.4) can be used to rationalize the observed structures. This method is to be applied according to the following rules:
(a) Each pair of neighbor M atoms is connected by a $\mathrm{M}-\mathrm{M} 2 c-2 e$ bond or MMM $3 c-2 e$ bond to form the cluster.
(b) Each M atom use its four valence orbitals to form chemical bonds to attain the octet configuration.

Fig. 14.5.3.
Crystal structure of $\mathrm{Pb}_{3} \mathrm{O}_{4}$ (large circles represent Pb atom, white $\mathrm{Pb}^{\mathrm{IV}}$ and shaded $\mathrm{Pb}^{\mathrm{II}}$; small circles represent O atom).

(c) Two M atoms cannot participate in forming both a $\mathrm{M}-\mathrm{M} 2 c-2 e$ bond and a MMM $3 c-2 e$ bond.

For example, the bond valence $(b)$ of $\mathrm{Ge}_{9}{ }^{4-}$ is $b=\frac{1}{2}(8 n-g)=\frac{1}{2}[9 \times 8-$ $(9 \times 4+4)]=16$, and the monocapped square-antiprismatic anion is stabilized by six MMM $3 c-2 e$ bonds and four M-M $2 c-2 e$ bonds. Bonding within the polyhedron involves a resonance hybrid of several canonical forms of the type shown in Fig. 14.6.2. The structures of the polyatomic anions are summarized in Table 14.6.1.
(a)

Fig. 14.6.2.
(a) Structure and atom numbering of $\mathrm{Ge}_{9}{ }^{4-}$. Bonding in $\mathrm{Ge}_{9}{ }^{4-}$ : (b) front view of a canonical structure, in which a M-M $2 c-2 e$ bond is represented by a solid line joining two atoms, and a MMM $3 c-2 e$ bond by three solid lines connecting atoms to the bond center; (c) rear view of the canonical structure.

The polystannide cluster $\mathrm{Sn}_{9}{ }^{4-}$ (or the related $\mathrm{Pb}_{9}{ }^{4-}$ ) reacts with $\mathrm{Cr}(\mathrm{CO})_{3}($ mes $)$ to form a bicapped square-antiprismatic cluster $\left[\mathrm{Sn}_{9} \mathrm{Cr}(\mathrm{CO})_{3}\right]^{4-}$;

$$
\mathrm{Cr}(\mathrm{CO})_{3}(\mathrm{mes})+\mathrm{K}_{4} \mathrm{Sn}_{9}+4 \mathrm{C} 222 \xrightarrow{\text { en/toluene }}[\mathrm{K}(\mathrm{C} 222)]_{4}\left[\mathrm{Sn}_{9} \mathrm{Cr}(\mathrm{CO})_{3}\right] .
$$

The nonastannide cluster is slightly distorted to accommodate the chromium carbonyl fragment at the open face. Figure 14.6.3 shows the structure of $\left[\mathrm{M}_{9} \mathrm{Cr}(\mathrm{CO})_{3}\right]^{4-}(\mathrm{M}=\mathrm{Sn}, \mathrm{Pb})$.

Table 14.6.1. Structure of polyatomic anions

| Anion | Polyhedron | $b$ | Bonding |
| :---: | :---: | :---: | :---: |
| $\mathrm{Ge}_{4}{ }^{4-}, \mathrm{Sn}_{4}{ }^{4-}, \mathrm{Pb}_{4}{ }^{4-}, \mathrm{Pb}_{2} \mathrm{Sb}_{2}{ }^{2-}$ | Tetrahedral | 6 | $6[\mathrm{M}-\mathrm{M} 2 c-2 e]$ |
| $\mathrm{Ge}_{5}{ }^{2-}, \mathrm{Pb}_{5}{ }^{2-}, \mathrm{Sn}_{5}{ }^{2-}$ | Trigonal bipyramidal | 9 | $9[\mathrm{M}-\mathrm{M} 2 c-2 e]$ |
| $\mathrm{Sn}_{6}{ }^{2-}$ | Octahedral | 11 | $4[$ MMM $3 c-2 e$ ] |
|  |  |  | $3[\mathrm{M}-\mathrm{M} 2 c-2 e]$ |
| $\mathrm{Ge}_{9}{ }^{2-}\left(\mathrm{Sn}_{9}{ }^{3-}, \mathrm{Ge}_{9}{ }^{3-}\right)$ | Tricapped-trigonal prismatic | 17 | 7[MMM 3c-2e] |
|  |  |  | $3[\mathrm{M}-\mathrm{M} 2 c-2 e]$ |
| $\mathrm{Ge}_{9}{ }^{4-}, \mathrm{Pb}_{9}{ }^{4-}, \mathrm{Sn}_{9}{ }^{4-} *$ | Monocapped | 16 | 6[MMM 3c-2e] |
|  | Square-antiprismatic |  | $4[\mathrm{M}-\mathrm{M} 2 c-2 e]$ |
| $\mathrm{Ge}_{10}{ }^{2-}, \mathrm{Pb}_{10}{ }^{2-}, \mathrm{Sn}_{9} \mathrm{Tl}^{3-}$ | Bicapped | 19 | 8[MMM $3 c-2 e$ ] |
|  | Square-antiprismatic |  | $3[\mathrm{M}-\mathrm{M} 2 c-2 e]$ |

*The cation $\mathrm{Bi}_{9}{ }^{5+}$ is isoelectronic and isostructural with these anions, and has the same kind of bonding.
The bond valence $(b)$ in the ten-atom cluster $\left[\mathrm{Sn}_{9} \mathrm{Cr}(\mathrm{CO})_{3}\right]^{4-}$ is

$$
\begin{aligned}
b & =\frac{1}{2}\left[8 n_{1}+18 n_{2}-g\right] \\
& =\frac{1}{2}[8 \times 9+18-(9 \times 4+6+6+4)] \\
& =19 .
\end{aligned}
$$

This anion has eight MMM $3 c-2 e$ bonds and three M-M $2 c-2 e$ bonds, just as in $\mathrm{B}_{10} \mathrm{H}_{10}^{2-}$, and the scheme is illustrated in Fig. 13.4.5(c).

### 14.7 Organometallic compounds of heavier group 14 elements

Elements $\mathrm{Ge}, \mathrm{Sn}$, and Pb form many interesting varieties of organometallic compounds, some of which are important commercial products. For example, $\mathrm{Et}_{4} \mathrm{~Pb}$ is an anti-knock agent, and organotin compounds are employed as polyvinylchloride (PVC) stabilizers against degradation by light and heat. Some examples and advances are discussed in the present section.

### 14.7.1 Cyclopentadienyl complexes

Cyclopentadienyl complexes of $\mathrm{Ge}, \mathrm{Sn}$, and Pb exist in a wide variety of composition and structure, such as half-sandwiches CpM and CpMX , bent and parallel sandwiches $\mathrm{Cp}_{2} \mathrm{M}$, and polymeric $\left(\mathrm{Cp}_{2} \mathrm{M}\right)_{x}$.

## (1) $\left(\eta^{5}-\mathrm{C}_{5} \mathrm{Me}_{5}\right) \mathrm{Ge}^{+}$and $\left(\eta^{5}-\mathrm{C}_{5} \mathrm{Me}_{5}\right) \mathbf{G e C l}$

In crystalline $\left[\eta^{5}-\left(\mathrm{C}_{5} \mathrm{Me}_{5}\right) \mathrm{Ge}\right]^{+}\left[\mathrm{BF}_{4}\right]^{-}$the cation has a half-sandwich structure, as shown in Fig. 14.7.1(a). In the chloride $\left(\eta^{5}-\mathrm{C}_{5} \mathrm{Me}_{5}\right) \mathrm{GeCl}$, the Ge atom is bonded to the Cl atom in a bent configuration, as shown in Fig. 14.7.1(b).
(2) $\left(\eta^{5}-\mathrm{C}_{5} \mathrm{R}_{5}\right)_{2} \mathrm{M}(\mathrm{R}=\mathrm{H}, \mathrm{Me}, \mathrm{Ph})$

The compounds $\left(\eta^{5}-\mathrm{C}_{5} \mathrm{H}_{5}\right)_{2} \mathrm{M}(\mathrm{M}=\mathrm{Ge}, \mathrm{Sn}$ and Pb$)$ are angular molecules in the gas phase, as shown in Fig. 14.7.1(c). The ring centroid-M-ring centroid

Fig. 14.6.3.
Structure of $\left[\mathrm{M}_{9} \mathrm{Cr}(\mathrm{CO})_{3}\right]^{4-}(\mathrm{M}=\mathrm{Sn}$, $\mathrm{Pb})$.

Fig. 14.7.1.
Structures of some cyclopentadienyl complexes: (a) $\left(\eta^{5}-\mathrm{C}_{5} \mathrm{Me}_{5}\right) \mathrm{Ge}^{+}$, (b) $\left(\eta^{5}-\mathrm{C}_{5} \mathrm{Me}_{5}\right) \mathrm{GeCl}$, (c) $\left(\eta^{5}-\mathrm{C}_{5} \mathrm{H}_{5}\right)_{2} \mathrm{M},(\mathrm{M}=\mathrm{Ge}, \mathrm{Sn}$ and Pb$)$, (d) $\left(\eta^{5}-\mathrm{C}_{5} \mathrm{Ph}_{5}\right)_{2} \mathrm{Sn}$ (only one C atom of each phenyl group is shown), and (e) $\left[\left(\eta^{5}-\mathrm{C}_{5} \mathrm{H}_{5}\right)_{2} \mathrm{~Pb}\right]_{x}$ chain.
angles of $\left(\eta^{5}-\mathrm{C}_{5} \mathrm{H}_{5}\right)_{2} \mathrm{M}$ are $-\mathrm{Ge}-130^{\circ},-\mathrm{Sn}-134^{\circ}$, and $-\mathrm{Pb}-135^{\circ}$. However, as the H atoms in Cp is substituted by other groups, the angles will be changed. For example, the angle in $\left(\eta^{5}-\mathrm{C}_{5} \mathrm{Me}_{5}\right)_{2} \mathrm{~Pb}$ is $151^{\circ}$. For $\left(\eta^{5}-\mathrm{C}_{5} \mathrm{Ph}_{5}\right)_{2} \mathrm{Sn}$, the two planar $\mathrm{C}_{5}$ rings are exactly parallel and staggered, as shown in Fig. 14.7.1(d), and the opposite canting of the phenyl rings with respect to the $\mathrm{C}_{5}$ rings results in overall $S_{10}$ molecular symmetry.

## (3) Polymeric $\left[\left(\eta^{5}-\mathrm{C}_{5} \mathrm{H}_{5}\right)_{2} \mathrm{~Pb}\right]_{x}$

There are three known crystalline modifications of $\left(\eta^{5}-\mathrm{C}_{5} \mathrm{H}_{5}\right)_{2} \mathrm{~Pb}$. When crystals are grown by sublimation, the structure features a zigzag chain with alternating bridging and nonbridging $\mathrm{C}_{5} \mathrm{H}_{5}$ groups; however, crystallization from toluene results in modification of the conformation of the polymeric chain [as shown in Fig. 14.7.1(e)], and also cyclization into a hexamer $\left[\left(\eta^{5}-\mathrm{C}_{5} \mathrm{H}_{5}\right)_{2} \mathrm{~Pb}\right]_{6}$.

### 14.7.2 Sila- and germa-aromatic compounds

Sila- and germa-aromatic compounds are Si - and Ge-containing $(4 n+2)$ $\pi$ electron ring systems that represent the heavier congeners of carbocyclic aromatic compounds. Several kinds of sila- and germa-aromatic compounds bearing a bulky hydrophobic $2,4,6$-tris[bis(trimethylsilyl)methyl]phenyl group $\left[\mathrm{Tbt}=2,4,6,-\left(\mathrm{CH}\left(\mathrm{SiMe}_{3}\right)_{2}\right)_{3} \mathrm{C}_{6} \mathrm{H}_{2}\right.$ ] on the $\mathrm{sp}^{2} \mathrm{Si}$ or Ge atom have been prepared and isolated as stable crystalline solids, as shown in Figs. 14.7.2(a)-(e).

X-ray diffraction analyses showed that all these compounds have an almost planar aromatic ring, and the geometry around the central Si or Ge atom is completely trigonal planar. The measured bond lengths of $\mathrm{Si}-\mathrm{C}$ or $\mathrm{Ge}-\mathrm{C}$ are
(a)

(d)

(b)

(e)

(c)

(f)

almost equal, the average values being $\mathrm{Si}-\mathrm{C} 175.4 \mathrm{pm}$ and $\mathrm{Ge}-\mathrm{C} 182.9 \mathrm{pm}$, which lie between those of typical double and single bonds.
The germabenzene shown in Fig. 14.7.2(d) serves as an $\eta^{6}$-arene ligand in reacting with $\left[\mathrm{M}\left(\mathrm{CH}_{3} \mathrm{CN}\right)_{3}(\mathrm{CO})_{3}\right](\mathrm{M}=\mathrm{Cr}, \mathrm{Mo}, \mathrm{W})$ to form sandwich complexes $\left[\left(\eta^{6}-\mathrm{C}_{5} \mathrm{H}_{5} \mathrm{GeTbt}\right) \mathrm{M}(\mathrm{CO})_{3}\right]$. Figure 14.7.2(f) shows a part of the structure of $\left[\left(\eta^{6}-\mathrm{C}_{5} \mathrm{H}_{5} \mathrm{GeTbt}\right) \mathrm{Cr}(\mathrm{CO})_{3}\right]$. This complexation of germa-aromatic compounds indicates that sila- and germa-benzenes have a $\pi$ electron delocalized structure with considerable aromaticity.

### 14.7.3 Cluster complexes of $\mathrm{Ge}, \mathrm{Sn}$, and Pb

Extensive research over the past decade has greatly increased the number of cluster complexes of $\mathrm{Ge}, \mathrm{Sn}$, and Pb . The properties of $\mathrm{M}-\mathrm{M}$ bonds and structures of these compounds are similar to the $\mathrm{C}-\mathrm{C}$ bonds and carbon skeletons in organic compounds. Table 14.7.1 lists some of these cluster compounds that have been synthesized, isolated, and characterized by X-ray crystallography. In

Fig. 14.7.2.

the table, the bond lengths are average values. The $b$ value of $\mathrm{M}_{n}$ is calculated according to formula (13.4.1), and the bond valence per M-M bond is listed for each compound.

In $\left[\mathrm{GeSi}^{t} \mathrm{Bu}_{3}\right]_{3}^{+}\left[\mathrm{BPh}_{4}\right]^{-}$, the cyclotrigermanium cation has a $\pi$ delocalized bond $\pi_{3}^{2}$ similar to that of the carbon analog, the cyclopropenium ion. The $\mathrm{Ge}-\mathrm{Ge}$ bond in this cation has bond valence $5 / 3$. Figure 14.7.3(a) shows the structure of the cluster.

The mixed-metal compound $\left[\mathrm{Ge}\left(\mathrm{SiMe}_{3}\right)_{3}\right]_{2} \mathrm{SnCl}_{2}$ is a bent molecule [as shown in Fig. 14.7.3(b)], which forms two $\mathrm{Ge}-\mathrm{Sn}$ bonds with bond lengths 263.6 and 262.6 pm .

The tetramer $\left[\mathrm{Ge}(\mathrm{Cl}) \mathrm{Si}\left(\mathrm{SiMe}_{3}\right)_{3}\right]_{4}$ forms a four-membered ring with $\mathrm{Ge}-$ Ge bond lengths 255.8 and 250.9 pm [as shown in Fig. 14.7.3(c)], while $\mathrm{Ge}_{4}\left(\mathrm{Si}^{t} \mathrm{Bu}_{3}\right)_{4}$ is the first molecular germanium compound with a $\mathrm{Ge}_{4}$ tetrahedron, as shown in Fig. 14.7.3(d).

The hexamer $\mathrm{Ge}_{6}\left[\mathrm{CH}\left(\mathrm{SiMe}_{3}\right)_{2}\right]_{6}$ has a prismane structure as shown in Fig. 14.7.3(e). The Ge-Ge distances within the two triangular faces are 258 pm , being longer than those in the quadrilateral edges, which are 252 pm . On the other hand, the hexamer $\left(\mathrm{SnPh}_{2}\right)_{6}$ exists in the chair conformation, (as shown in Fig. 14.7.3(f)) with $\mathrm{Sn}-\mathrm{Sn}$ distances 277 to 278 pm .

Both $\mathrm{Sn}_{5}\left(2,6-\mathrm{Et}_{2} \mathrm{C}_{6} \mathrm{H}_{3}\right)_{6}$ and $\mathrm{Sn}_{7}\left(2,6-\mathrm{Et}_{2} \mathrm{C}_{6} \mathrm{H}_{3}\right)_{8}$ have a pentastanna[1.1.1] propellane structure, which consists of three fused three-membered rings, as shown in Figs. 14.7.3(g) and (h). In these two compounds, the bridgehead Sn atoms each have all four bonds directed to one side of the relevant atom, thus forming "inverted configuration" $\mathrm{Sn} \cdots \mathrm{Sn}$ bonds, the distances of which
are 336.7 and 334.8 pm , respectively. These distances far exceed the longest known $\mathrm{Sn}-\mathrm{Sn}$ single-bond length of 280 pm . These structures are also similar to that of 1-cyanotetracyclo-decane [Fig. 14.3.5(d)], in which the two bridgehead C atoms form a very long ( 164.3 pm ) $\mathrm{C}-\mathrm{C}$ bond.

The octagermacubanes $\mathrm{Ge}_{8}\left(\mathrm{CMeEt}_{2}\right)_{8}$ and $\mathrm{Ge}_{8}\left(2,6-\mathrm{Et}_{2} \mathrm{C}_{6} \mathrm{H}_{3}\right)_{8}$ have a cubic structure, as shown in Fig. 14.7.3(i), with Ge-Ge bond lengths 247.8 to 250.3 pm , with a mean value of 249.0 pm . The polycyclic octagermane $\mathrm{Ge}_{8}{ }^{t} \mathrm{Bu}_{8} \mathrm{Br}_{2}$ forms a chiral $C_{2}$ symmetric skeleton, as shown in Fig. 14.7.3(j). The average $\mathrm{Ge}-\mathrm{Ge}$ bond length is 248.4 pm .

The pentaprismane skeleton of $\mathrm{Sn}_{10}\left(2,6-\mathrm{Et}_{2} \mathrm{C}_{6} \mathrm{H}_{3}\right)_{10}$ is composed of five four-membered rings and two five-membered rings, as shown in Fig. 14.7.3(k). The average $\mathrm{Sn}-\mathrm{Sn}$ bond length is 285.6 pm .

### 14.7.4 Metalloid clusters of Sn

Literature information is available for high-nuclearity metalloid clusters $\left[\mathrm{Sn}_{x} \mathrm{R}_{y}\right](x>y)$, including $\left[\mathrm{Sn}_{8} \mathrm{R}_{4}\right],\left[\mathrm{Sn}_{8} \mathrm{R}_{6}\right]^{2-},\left[\mathrm{Sn}_{9} \mathrm{R}_{3}\right]$, and $\left[\mathrm{Sn}_{10} \mathrm{R}_{3}\right]^{-}$, in which R represents a bulky aryl or silyl ligand, and their structures are displayed in Figs. 14.7.4(a)-(d), respectively.

The largest tin clusters known to date are the pair of isoleptic amido complexes $\left[\mathrm{Sn}_{15} \mathrm{Z}_{6}\right]\left(\mathrm{Z}=\mathrm{N}\left(2,6-{ }^{i} \mathrm{Pr}_{2} \mathrm{C}_{6} \mathrm{H}_{3}\right)\left(\mathrm{SiMe}_{2} \mathrm{X}\right) ; \mathrm{X}=\mathrm{Me}, \mathrm{Ph}\right)$. Both

Structural Chemistry of Selected Elements

possess a common polyhedral core consisting of fourteen tin atoms that fully encapsulates a central tin atom. The eight ligand-free peripheral tin atoms constitute the corners of a distorted cube, with each of its six faces capped by a $\mathrm{Sn}\left\{\mathrm{N}\left(2,6-{ }_{-} \mathrm{Pr}_{2} \mathrm{C}_{6} \mathrm{H}_{3}\right)\left(\mathrm{SiMe}_{2} \mathrm{X}\right)\right\}$ moiety, as shown in Fig. 14.7.4(e). The edges of the $\mathrm{Sn}_{14}$ polyhedron have an average length of 302 pm . The Sn (central)Sn bonds in this high-nuclearity $\mathrm{Sn} @ \mathrm{Sn}_{14}$ metalloid cluster have an average length of 315 pm , which is close to the corresponding value of 310 pm in gray tin ( $\alpha$ - Sn , diamond lattice) but considerably longer than that in white tin ( $\beta$-Sn).

Interestingly, the isoleptic compound $\mathrm{Si}_{8} \mathrm{R}_{6}\left(\mathrm{R}=\mathrm{Si}^{t} \mathrm{Bu}_{3}\right.$; "supersilyl") does not exhibit a cubanoid cluster skeleton, but instead contains an unsubstituted $\mathrm{Si}_{2}$ dumbbell with a short $\mathrm{Si}-\mathrm{Si}$ single bond of $229(1) \mathrm{pm}$, which is sandwiched between two almost parallel $\mathrm{Si}_{3} \mathrm{R}_{3}$ rings, as illustrated in Fig. 14.7.4(f). Each terminal of the $\mathrm{Si}_{2}$ dumbbell acts as a bridgehead with an "inverted" tetrahedral bond configuration analogous to that found in 1-cyano-tetracyclodecane (see Section 14.3.5), forming two normal $\mathrm{Si}-\mathrm{Si}$ bonds of 233 pm to one $\mathrm{Si}_{3} \mathrm{R}_{3}$ ring and a longer one of 257 pm to the other. In the crystal structure, the atoms of the $\mathrm{Si}_{2}$ dumbbell are disordered over six sites.

An intermetalloid cluster is a metalloid cluster composed of more than one metal, for example $\left[\mathrm{Ni}_{2} @ \mathrm{Sn}_{17}\right]^{4-}$. Known intermetalloid clusters involving other Group 14 elements and various transition metals include $\left[\mathrm{Pd}_{2} @ \mathrm{Ge}_{18}\right]^{4-}$, $\left[\mathrm{Ni}\left(\mathrm{Ni} @ \mathrm{Ge}_{9}\right)_{2}\right]^{4-},\left[\mathrm{Ni} @ \mathrm{~Pb}_{10}\right]^{2-}$, and $\left[\mathrm{Pt} @ \mathrm{~Pb}_{12}\right]^{2-}$; in the latter complex, the Pt atom is encapsulated by a $\mathrm{Pb}_{12}$ icosahedron (see Fig. 9.6.18).

### 14.7.5 Donor-acceptor complexes of $\mathrm{Ge}, \mathrm{Sn}$ and Pb

The system $\mathrm{R}_{2} \mathrm{Sn} \rightarrow \mathrm{SnCl}_{2}$, with $\left.\mathrm{R}=\mathrm{CH}\left(\mathrm{SiMe}_{3}\right) \mathrm{C}_{9} \mathrm{H}_{6} \mathrm{~N}\right)$, provides the first example of a stable donor-acceptor complex between two tin centers, as shown in Fig. 14.7.5. The alkyl ligand R is bonded in a $C, N$-chelating fashion to a Sn atom which adopts a pentacoordinate square-pyramidal geometry. This Sn atom is bonded directly to the other Sn atom of the $\mathrm{SnCl}_{2}$ fragment with a Sn Sn distance of 296.1 pm , which is significantly longer than the similar distance of 276.8 pm in $\mathrm{R}_{2} \mathrm{Sn}=\mathrm{SnR}_{2}\left[\mathrm{R}=\mathrm{CH}\left(\mathrm{SiMe}_{3}\right)_{2}\right]$, and much shorter than the similar distance of 363.9 pm in $\mathrm{Ar}_{2} \mathrm{Sn}-\mathrm{SnAr}_{2}\left[\mathrm{Ar}=2,4,6-\left(\mathrm{CF}_{3}\right)_{3} \mathrm{C}_{6} \mathrm{H}_{2}\right]$. The fold angle defined as the angle between the $\mathrm{Sn}-\mathrm{Sn}$ vector and the $\mathrm{SnCl}_{2}$ plane is $83.3^{\circ}$.

Some donor-acceptor complexes containing $\mathrm{Ge}-\mathrm{Ge}$ and $\mathrm{Sn}-\mathrm{Sn}$ bonds are listed in Table 14.7.2.

The compounds listed in Table 14.7.2 have the formal formula: which indicate the presence of a $\mathrm{M}=\mathrm{M}$ double bond, but the measured $\mathrm{M}-\mathrm{M}$ bond lengths vary over a wide range. The $\mathrm{M}_{2} \mathrm{C}_{4}$ (or $\mathrm{M}_{2} \mathrm{Si}_{4}$ ) skeleton is not planar, in contrast with that of an olefin. Thus the properties of the formal $\mathrm{M}=\mathrm{M}$ bonds are diverse and interesting. Two examples listed in this table are discussed below.

As reference data, the "normal" values $\mathrm{M}-\mathrm{M}$ single-bond lengths are calculated from the covalent radii (Table 3.4.3) and the "normal" bond lengths of $\mathrm{M}=\mathrm{M}$ double bonds are estimated as $0.9 \times$ (single-bond lengths). Thus the

(b)

Fig. 14.7.5.
Structure of the $\mathrm{R}_{2} \mathrm{Sn} \rightarrow \mathrm{SnCl}_{2}(\mathrm{R}=$ $\left.\mathrm{CH}\left(\mathrm{SiMe}_{3}\right) \mathrm{C}_{9} \mathrm{H}_{6} \mathrm{~N}\right)$. (a) Molecular structure (the $\mathrm{SiMe}_{3}$ groups have been omitted for clarity), (b) the lone pair forming a donor-acceptor bond.
"normal" bond lengths are
$\mathrm{Ge}-\mathrm{Ge} 244 \mathrm{pm}, \mathrm{Ge}=\mathrm{Ge} 220 \mathrm{pm}$,
Sn-Sn 280 pm, $\mathrm{Sn}=\mathrm{Sn} 252 \mathrm{pm}$.

Compound A in Table 14.7.2, $\left(\mathrm{Me}_{3} \mathrm{SiN}=\mathrm{PPh}_{2}\right)_{2} \mathrm{C}=\mathrm{Ge} \rightarrow \mathrm{Ge}=\mathrm{C}\left(\mathrm{Ph}_{2} \mathrm{P}=\right.$ $\left.\mathrm{NSiMe}_{3}\right)_{2}$, comprises two germavinylidene units $\mathrm{Ge}=\mathrm{C}\left(\mathrm{Ph}_{2} \mathrm{P}=\mathrm{NSiMe}_{3}\right)_{2}$ bonded together in a head-to-head manner. The molecule is asymmetrical with

C

(a)

(b)

two different Ge environments: four-coordinate Ge and two-coordinate Ge , and shows trans linkage of the $\mathrm{C}=\mathrm{Ge}-\mathrm{Ge}=\mathrm{C}$ skeleton, the torsion angle about the $\mathrm{Ge}-\mathrm{Ge}$ axis being $43.9^{\circ}$. The $\mathrm{Ge}-\mathrm{Ge}$ bond distance of 248.3 pm is consistent with a single bond, and both observed $\mathrm{Ge}-\mathrm{C}$ bond lengths 190.5 and 190.8 pm are between those of standard $\mathrm{Ge}-\mathrm{C}$ and $\mathrm{Ge}=\mathrm{C}$ bonds. Therefore, the $\mathrm{Ge}-\mathrm{Ge}$ bond in compound A is more approximately described as a donor-acceptor interaction similar to that of $\mathrm{R}_{2} \mathrm{Sn} \rightarrow \mathrm{SnCl}_{2}$ (as shown in Fig. 14.7.5), and the four-coordinate Ge behaves as the donor and the two-coordinate Ge as a Lewis acid center.

The compound $\left[\mathrm{Sn}\left\{\mathrm{CH}\left(\mathrm{SiMe}_{3}\right)_{2}\right\}_{2}\right]_{2}$ does not possess a planar $\mathrm{Sn}_{2} \mathrm{C}_{4}$ framework, and the $\mathrm{Sn}-\mathrm{Sn}$ bond length ( 276.8 pm ) is too long to be consistent with a "normal" double bond. A bonding model involving overlap of filled $\mathrm{sp}^{2}$ hybrids and vacant 5 p atomic orbitals has been suggested, as shown in Fig. 14.7.6. The structure is similar to that in Fig. 14.4.7(e), but the trans-bent angle is larger.

The digermanium alkyne analog 2,6-Dipp ${ }_{2} \mathrm{H}_{3} \mathrm{C}_{6} \mathrm{Ge} \equiv \mathrm{GeC}_{6} \mathrm{H}_{3}-2,6-\mathrm{Dipp}_{2}$ (Dipp $=\mathrm{C}_{6} \mathrm{H}_{3}-2,6-{ }^{i} \mathrm{Pr}_{2}$ ) was synthesized by the reaction of $\mathrm{Ge}(\mathrm{Cl}) \mathrm{C}_{6} \mathrm{H}_{3}-2,6-$ $\mathrm{Dipp}_{2}$ with potassium in THF or benzene. It was isolated as orange-red crystals and fully characterized by spectroscopic methods and X-ray crystallography. The digermyne molecule is centrosymmetric with a planar trans-bent C(ipso)-$\mathrm{Ge}-\mathrm{Ge}-\mathrm{C}$ (ipso) skeleton, and the central aryl ring of the terphenyl ligand is virtually coplanar with the molecular skeleton, each flanking aryl ring being oriented at $\sim 82^{\circ}$ with respect to it. The structural parameters are $\mathrm{C}-\mathrm{Ge}, 199.6$ $\mathrm{pm} ; \mathrm{Ge}-\mathrm{Ge}, 228.5 \mathrm{pm}$ (considerably shorter than the Ge-Ge single-bond distance of approx. 244 pm ); $\mathrm{C}-\mathrm{Ge}-\mathrm{Ge}, 128.67^{\circ}$. The measured $\mathrm{Ge}-\mathrm{Ge}$ distance lies on the short side of the known range (221-46 pm) for digermenes, the digermanium analogs of alkenes.

By analogy to the model used to describe a $\mathrm{Sn}=\mathrm{Sn}$ double bond, the observed geometry of the digermyne molecule and its multiple bonding character can be rationalized as shown in Fig. 14.7.7. Each germanium atom is considered to be sp hybridized in the $\mathrm{C}-\mathrm{Ge}-\mathrm{Ge}-\mathrm{C}$ plane; a singly filled sp hybrid orbital is used to form a covalent bond with the terphenyl ligand, and the other sp hybrid is
completely filled and forms a donor bond with an empty in-plane 4 p orbital on the other germanium atom. Two half-filled $4 \mathrm{p}_{z}$ orbitals, one on each germanium atom and lying perpendicular to the molecular skeleton, then overlap to form a much weaker $\pi$ bond. This simplified bonding description is consistent with the trans-bent molecular geometry and the fact that the formal $\mathrm{Ge} \equiv \mathrm{Ge}$ bond length is not much shorter than that of the $\mathrm{Ge}=\mathrm{Ge}$ bond.

The distannyne $\mathrm{Ar}^{\prime} \mathrm{SnSnAr}{ }^{\prime}$ and diplumbyne $\mathrm{Ar}^{*} \mathrm{PbPbAr}^{*}\left(\mathrm{Ar}^{*}=2,4,6-\right.$ $\left.\left(\mathrm{C}_{6} \mathrm{H}_{3}-2,6-{ }^{i} \mathrm{Pr}_{2}\right)_{3} \mathrm{C}_{6} \mathrm{H}_{2}\right)$ have also been synthesized as crystalline solids and fully characterized. They are isostructural with digermyne, and their structural parameters are $\mathrm{Sn}-\mathrm{Sn}, 266.75 \mathrm{pm} ; \mathrm{C}-\mathrm{Sn}-\mathrm{Sn}, 125.24^{\circ}$; $\mathrm{Pb}-\mathrm{Pb}, 318.81$ $\mathrm{pm} ; \mathrm{C}-\mathrm{Pb}-\mathrm{Pb}, 94.26^{\circ}$. Recent studies of the chemical reactivities of digermynes showed that it has considerable diradical character, which can be represented by a canonical form with an unpaired electron on each germanium atom, i.e., negligible overlap between the half-filled $4 p_{z}$ orbitals. The reactivity of the alkyne analogs decreases in the order $\mathrm{Ge}>\mathrm{Sn}>\mathrm{Pb}$. In the diplumbyne, the $\mathrm{Pb}-\mathrm{Pb}$ bond length is significantly longer than the value of approximately 290 pm normally found in organometallic lead-lead bonded species, e.g., $\mathrm{Me}_{3} \mathrm{PbPbMe}_{3}$. This suggests that a lone pair resides in the 6 s orbital of each lead atom in the dilead compound, and a single $\sigma$ bond results from head-to-head overlap of 6 p orbitals.

In summary, it is noted that multiple bonding between the heavier Group 14 elements $\mathrm{E}(\mathrm{Ge}, \mathrm{Sn}, \mathrm{Pb})$ differs in nature in comparison with the conventional $\sigma$ and $\pi$ covalent bonds in alkenes and alkynes. In an $\mathrm{E}=\mathrm{E}$ bond, both components are of the donor-acceptor type, and a formal $\mathrm{E} \equiv \mathrm{E}$ bond involves two donoracceptor components plus a $p-p \pi$ bond. There is also the complication that the bond order may be lowered when each E atom bears an unpaired electron or a lone pair. The simple bonding models provide a reasonable rationale for the marked difference in molecular geometries, as well as the gradation of bond properties in formally single, double and triple bonds, in compounds of carbon versus those of its heavier congeners.

## Structural Chemistry of Group 15 Elements

### 15.1 The $\mathbf{N}_{2}$ molecule, all-nitrogen ions and dinitrogen complexes

### 15.1.1 The $\mathrm{N}_{2}$ molecule

Nitrogen is the most abundant uncombined element in the earth's surface. It is one of the four essential elements ( $\mathrm{C}, \mathrm{H}, \mathrm{O}, \mathrm{N}$ ) that support all forms of life. It constitutes, on the average, about $15 \%$ by weight in proteins. The industrial fixation of nitrogen in the production of agricultural fertilizers and other chemical products is now carried out on a vast scale.

The formation of a triple bond, $\mathrm{N} \equiv \mathrm{N}$, comprising one $\sigma$ and two $\pi$ components with bond length 109.7 pm , accounts for the extraordinary stability of the dinitrogen molecule $\mathrm{N}_{2}$; the energy level diagram for $\mathrm{N}_{2}$ is shown in Fig. 3.3.3(a). Gaseous $\mathrm{N}_{2}$ is rather inert at room temperature mainly because of the great strength of the $\mathrm{N} \equiv \mathrm{N}$ bond and the large energy gap between the HOMO and LUMO $(\sim 8.6 \mathrm{eV})$, as well as the absence of bond polarity. The high bond dissociation energy of the $\mathrm{N}_{2}$ molecule, $945 \mathrm{~kJ} \mathrm{~mol}^{-1}$, accounts for the following phenomena:
(a) Molecular nitrogen constitutes $78.1 \%$ by volume (about $75.5 \%$ by weight) of the earth's atmosphere.
(b) It is difficult to "fix" nitrogen, i.e., to convert molecular nitrogen into other nitrogen compounds by means of chemical reactions.
(c) Chemical reactions that release $\mathrm{N}_{2}$ as a product are highly exothermic and often explosive.

### 15.1.2 Nitrogen ions and catenation of nitrogen

There are three molecular ions which consist of nitrogen atoms only.

## (1) Nitride ion $\mathbf{N}^{3-}$

The $\mathrm{N}^{3-}$ ion exists in salt-like nitrides of the types $\mathrm{M}_{3} \mathrm{~N}$ and $\mathrm{M}_{3} \mathrm{~N}_{2}$. In $\mathrm{M}_{3} \mathrm{~N}$ compounds, M is an element of group $1(\mathrm{Li})$ or Group $11(\mathrm{Cu}, \mathrm{Ag})$. In $\mathrm{M}_{3} \mathrm{~N}_{2}$ compounds, M is an element of group $2(\mathrm{Be}, \mathrm{Mg}, \mathrm{Ca}, \mathrm{Sr}, \mathrm{Ba})$ or Group $12(\mathrm{Zn}$, $\mathrm{Cd}, \mathrm{Hg})$. In these compounds, the bonding interactions between N and M atoms are essentially ionic, and the radius of $\mathrm{N}^{3-}$ is 146 pm . Nitride $\mathrm{Li}_{3} \mathrm{~N}$ exhibits

## Structural Chemistry of Selected Elements

high ionic conductivity with $\mathrm{Li}^{+}$as the current carrier. The crystal structure of $\mathrm{Li}_{3} \mathrm{~N}$ has been discussed in Section 12.2.

## (2) Azide $\mathbf{N}_{3}^{-}$

The azide ion $\mathrm{N}_{3}^{-}$is a symmetrical linear group that can be formed by neutralization of hydrogen azide $\mathrm{HN}_{3}$ with alkalis. The bent configuration of $\mathrm{HN}_{3}$ is shown below:

The Group 1 and 2 azides $\mathrm{NaN}_{3}, \mathrm{KN}_{3}, \operatorname{Sr}\left(\mathrm{~N}_{3}\right)_{2}$ and $\mathrm{Ba}\left(\mathrm{N}_{3}\right)_{2}$ are wellcharacterized colorless crystalline salts which can be melted with little decomposition. The corresponding Group 11 and 12 metal azides such as $\mathrm{AgN}_{3}$, $\mathrm{Cu}\left(\mathrm{N}_{3}\right)_{2}$ and $\mathrm{Pb}\left(\mathrm{N}_{3}\right)_{2}$, are shock-sensitive and detonate readily, and they are far less ionic with more complex structures. The salt $\left(\mathrm{PPh}_{4}\right)^{+}\left(\mathrm{N}_{3} \mathrm{HN}_{3}\right)^{-}$has been synthesized from the reaction of $\mathrm{Me}_{3} \mathrm{SiN}_{3}$ with $\left(\mathrm{PPh}_{4}\right)\left(\mathrm{N}_{3}\right)$ in ethanol; the $\left(\mathrm{N}_{3} \mathrm{HN}_{3}\right)^{-}$anion has a nonplanar bent structure consisting of distinct $\mathrm{N}_{3}^{-}$ and $\mathrm{HN}_{3}$ units connected by a hydrogen bond, as shown in Fig. 15.1.1(a). In $\mathrm{Cu}_{2}\left(\mathrm{~N}_{3}\right)_{2}\left(\mathrm{PPh}_{3}\right)_{4}$ and $\left[\mathrm{Pd}_{2}\left(\mathrm{~N}_{3}\right)_{6}\right]^{2-}, \mathrm{N}_{3}^{-}$acts either as a terminal or a bridging ligand, as shown in Figs. 15.1.1(b) and (c), respectively. The azide ion $\mathrm{N}_{3}^{-}$can also be combined with a metalloid ion such as $\mathrm{As}^{5+}$ to form $\left[\mathrm{As}\left(\mathrm{N}_{3}\right)_{6}\right]^{-}$, as shown in Fig. 15.1.1(d). Table 15.1.1 lists the coordination modes of $\mathrm{N}_{3}^{-}$in its metal complexes; the highest-ligation $\mu-1,1,1,3,3,3$ mode (h) was found to exist in the double salt $\mathrm{AgN}_{3} \cdot 2 \mathrm{AgNO}_{3}$.

The uranium(IV) heptaazide anion $\mathrm{U}\left(\mathrm{N}_{3}\right)_{7}^{3-}$ has been synthesized as the $n$-tetrabutylammonium salt. This is the first homoleptic azide of an actinide

as well as the first structurally characterized heptaazide. Two polymorphs of $\left(\mathrm{Bu}_{4} \mathrm{~N}\right)_{3}\left[\mathrm{U}\left(\mathrm{N}_{3}\right)_{7}\right]$ were obtained from crystallization in $\mathrm{CH}_{3} \mathrm{CN} / \mathrm{CFCl}_{3}$ (form A ) or $\mathrm{CH}_{3} \mathrm{CH}_{2} \mathrm{CN}$ (form B). Form A belongs to space group $\mathrm{Pa} \overline{3}$ with $Z=8$, and hence the U atom and one of the three independent azide groups are located on a crystallographic 3-axis. This results in a 1:3:3 monocapped octahedral arrangement of the azide ligands around the central uranium atom, as illustrated in Fig. 15.1.2(a). Form B crystallizes in space group $P 2{ }_{1} / c$ with $Z=4$, and the azide ligands exhibit a distorted 1:5:1 pentagonal-bipyramidal coordination mode, as shown in Fig. 15.1.2(b). The $\mathrm{U}-\mathrm{N}_{\alpha}$ bond lengths range from 232 to 243 pm.

Two isomeric polymorphs of $\left[\left(\mathrm{C}_{5} \mathrm{Me}_{5}\right)_{2} \mathrm{U}(\mu-\mathrm{N}) \mathrm{U}\left(\mu-\mathrm{N}_{3}\right)\left(\mathrm{C}_{5} \mathrm{Me}_{5}\right)_{2}\right]_{4}$ have been synthesized and structurally characterized by X-ray crystallography. In the tetrameric macrocycle, eight $\left(\eta^{5}-\mathrm{C}_{5} \mathrm{Me}_{5}\right)_{2} \mathrm{U}^{2+}$ units are charge-balanced by four $\mathrm{N}_{3}^{-}$(azide) ligands and four formally $\mathrm{N}^{3-}$ (nitride) ligands. Isomer A has a $\left(\mathrm{UNUN}_{3}\right)_{4}$ ring in a pseudo-crown (or chair) conformation, whereas that of isomer B exhibits a pseudo-saddle (or boat) geometry, as shown in Fig. 15.1.3. The observed $\mathrm{U}-\mathrm{N}$ (azide) bond distances in the range 246.7-252.5 pm are longer than typical U(IV)-N single bonds. The U-N(nitride) bond lengths in the range

$$

asymmetrical nitride bridging

## (3) Pentanitrogen cation $\mathbf{N}_{5}{ }^{+}$

The pentanitrogen cation $\mathrm{N}_{5}^{+}$was first synthesized in 1999 as the white solid $\mathrm{N}_{5}{ }^{+} \mathrm{AsF}_{6}{ }^{-}$, which is not very soluble in anhydrous HF but stable at $-78^{\circ} \mathrm{C}$. The $\mathrm{N}_{5}^{+}$cation has a closed-shell singlet ground state, and its $C_{2 \mathrm{v}}$ symmetry was characterized by Raman spectroscopy and NMR of ${ }^{14} \mathrm{~N}$ and ${ }^{15} \mathrm{~N}$ nuclei. A series of 1:1 salts of $\mathrm{N}_{5}^{+}$have also been prepared with the monoanions $\mathrm{HF}_{2}^{-}$(as the adduct $\left.\mathrm{N}_{5}^{+} \mathrm{HF}_{2}^{-} \cdot n \mathrm{HF}\right), \mathrm{BF}_{4}^{-}, \mathrm{PF}_{6}^{-}, \mathrm{SO}_{3} \mathrm{~F}^{-},\left(\mathrm{Sb}_{2} \mathrm{~F}_{11}\right)^{-}, \mathrm{B}\left(\mathrm{N}_{3}\right)_{4}^{-}$and $\mathrm{P}\left(\mathrm{N}_{3}\right)_{6}^{-}$. A determination of the crystal structure of $\mathrm{N}_{5}^{+}\left(\mathrm{Sb}_{2} \mathrm{~F}_{11}\right)^{-}$, which is stable at room temperature, yielded the structural parameters shown in Fig. 15.1.4. Note that each terminal $\mathrm{N}-\mathrm{N}-\mathrm{N}$ segment in $\mathrm{N}_{5}^{+}$deviates from exact linearity. A description of the bonding in this cation is given in Chapter 5, Section 5.8.3.

The catenation of nitrogen refers to the tendency of N atoms to be connected to each other, and is far lower than those of C and P . This is because the repulsion of lone pairs on adjacent N atoms weakens the $\mathrm{N}-\mathrm{N}$ single bond, and the lone pairs can easily react with electrophilic species. The structures and examples of known compounds that contain chains and rings of N atoms are listed in Table 15.1.2. Note that none of these has a linear configuration of nitrogen atoms.

### 15.1.3 Dinitrogen complexes

Molecular nitrogen can react directly with some transition-metal compounds to form dinitrogen complexes, the structure and properties of which are of considerable interest because they may serve as models for biological nitrogen

Table 15.1.2. Species containing catenated N atoms

| Number of N atoms | Chain or ring | Example |
| :---: | :---: | :---: |
| 3 | $[\mathrm{N}-\mathrm{N}-\mathrm{N}]^{+}$ | $\left[\mathrm{H}_{2} \mathrm{NNMe}_{2} \mathrm{NH}_{2}\right] \mathrm{Cl}$ |

| 5 |  |  |

fixation and as intermediates in synthetic applications. The known coordination modes of dinitrogen are discussed below and summarized in Table 15.1.3. The skeletal views of dinitrogen coordination modes in some metal complexes are shown in Fig. 15.1.5.
(1) $\eta^{1}-\mathbf{N}_{2}$

The first complex containing molecular nitrogen as a ligand, $\left[\mathrm{Ru}\left(\mathrm{NH}_{3}\right)_{5}\left(\mathrm{~N}_{2}\right)\right] \mathrm{Cl}_{2}$, was synthesized and identified in 1965 [Fig. 15.1.5(a)]. The complex $\left(\mathrm{Et}_{2} \mathrm{PCH}_{2} \mathrm{CH}_{2} \mathrm{PEt}_{2}\right)_{2} \mathrm{Fe}\left(\mathrm{N}_{2}\right)$ exhibits trigonal bipyramidal coordination geometry, with $\mathrm{N}_{2}$ lying in the equatorial plane, as shown in Fig. 15.1.5(a'). Most examples of stable dinitrogen complexes have been found to belong to the $\eta^{1}-$ $\mathrm{N}_{2}$ category, in which the dinitrogen ligand binds in a linear, end-on mode with only a slightly elongated $\mathrm{N}-\mathrm{N}$ bond length ( $112-24 \mathrm{pm}$ ) as compared to that in gaseous dinitrogen ( 109.7 pm ). The stable monomeric titanocene complexes $\left\{\left(\mathrm{PhMe}_{2} \mathrm{Si}^{2} \mathrm{C}_{5} \mathrm{H}_{4}\right\}_{2} \mathrm{TiX}\left(\mathrm{X}=\mathrm{N}_{2}, \mathrm{CO}\right)\right.$ are isomorphous, with a crystallographic $C_{2}$ axis passing through the Ti atom and the $\eta^{1}-\mathrm{X}$ ligand. The measured bond distances (in pm ) are $\mathrm{Ti}-\mathrm{N}=201.6(1), \mathrm{N}-\mathrm{N}=111.9(2)$ for the dinitrogen complex, and $\mathrm{Ti}-\mathrm{C}=197.9(2), \mathrm{C}-\mathrm{O}=115.1(2)$ for the carbonyl complex.
(2) $\mu$-(bis- $\left.\eta^{1}\right)-\mathbf{N}_{2}$

As a bridging ligand in dinuclear systems, dinitrogen may formally be classified into three types.
(a) $\mathrm{M}-\mathrm{N} \equiv \mathrm{N}-\mathrm{M}$ : This dinitrogen ligand corresponds to a neutral $\mathrm{N}_{2}$ molecule, which uses its lone pairs to coordinate to two M atoms. Complexes of this type show a relatively short $\mathrm{N}-\mathrm{N}$ distance of $112-20 \mathrm{pm}$. In $\left[\left(\eta^{5}-\mathrm{C}_{5} \mathrm{Me}_{5}\right)_{2} \mathrm{Ti}\right]_{2}\left(\mathrm{~N}_{2}\right)$, the binuclear molecular skeleton consists of two $\left(\eta^{5}-\mathrm{C}_{5} \mathrm{Me}_{5}\right)_{2} \mathrm{Ti}$ moieties bridged by the $\mathrm{N}_{2}$ ligand in an essentially linear $\mathrm{Ti}-\mathrm{N} \equiv \mathrm{N}-\mathrm{Ti}$ arrangement, as shown in Fig. 15.1.5(b). The $\mathrm{N}-\mathrm{N}$ distance is 116 pm (av.).
(b) $\mathrm{M}=\mathrm{N}=\mathrm{N}=\mathrm{M}$ : This dinitrogen ligand corresponds to diazenido(-2). The $\left(\mathrm{N}_{2}\right)^{2-}$ anion coordinates to two M atoms. In $(\mathrm{Mes})_{3} \mathrm{Mo}\left(\mathrm{N}_{2}\right) \mathrm{Mo}(\mathrm{Mes})_{3}$
(where Mes $=2,4,6-\mathrm{Me}_{3} \mathrm{C}_{6} \mathrm{H}_{2}$ ), $\mathrm{Mo}=\mathrm{N}=\mathrm{N}=\mathrm{Mo}$ forms a linear chain. The length of the $\mathrm{N}-\mathrm{N}$ distance is 124.3 pm .
(c) $\mathrm{M} \equiv \mathrm{N}-\mathrm{N} \equiv \mathrm{M}$ : This dinitrogen ligand corresponds to hydrazido(-4). The $\left(\mathrm{N}_{2}\right)^{4-}$ anion coordinates to two M atoms. In $\left[\mathrm{PhP}\left(\mathrm{CH}_{2} \mathrm{SiMe}_{2} \mathrm{NPh}_{2}\right)_{2} \mathrm{NbCl}_{2}\right.$ $\left(\mathrm{N}_{2}\right)$, the $\mathrm{Nb} \leftrightarrows \mathrm{N}-\mathrm{N} \cong \mathrm{Nb}$ moiety is linear, and the distance of $\mathrm{N}-\mathrm{N}$ is 123.7 pm.
(3) $\mu_{3}-\eta^{1}: \eta^{1}: \eta^{2}-\mathbf{N}_{2}$

In the $\left[\left(\mathrm{C}_{10} \mathrm{H}_{8}\right)\left(\mathrm{C}_{5} \mathrm{H}_{5}\right)_{2} \mathrm{Ti}_{2}\right]\left(\mu_{3}-\mathrm{N}_{2}\right)\left[\left(\mathrm{C}_{5} \mathrm{H}_{4}\right)\left(\mathrm{C}_{5} \mathrm{H}_{5}\right)_{3} \mathrm{Ti}_{2}\right]$ complex, the dinitrogen ligand is coordinated simultaneously to three Ti atoms, as shown in Fig. 15.1.5(c). The $\mathrm{N}-\mathrm{N}$ distance is 130.1 pm .
(4) $\mu_{3}-\eta^{1}: \eta^{1}: \eta^{1}-\mathbf{N}_{2}$

In the mixed-metal complex $\left[\mathrm{WCl}(\mathrm{py})(\mathrm{PMePh})_{3}\left(\mu_{3}-\mathrm{N}_{2}\right)\right]_{2}\left(\mathrm{AlCl}_{2}\right)_{2}$, both WNN linkages are essentially linear, and the four metal atoms and two $\mu_{3}-\mathrm{N}_{2}$ ligands almost lie in the same plane, as shown in Fig. 15.1.5(d).
(5) $\mu-\left(\eta^{1}: \eta^{2}\right)-\mathbf{N}_{2}$

In $\left[\mathrm{PhP}\left(\mathrm{CH}_{2} \mathrm{SiMe}_{2} \mathrm{NPh}\right)_{2}\right]_{2} \mathrm{Ta}_{2}(\mu-\mathrm{H})_{2}\left(\mathrm{~N}_{2}\right)$, the dinitrogen moiety is end-on bound to one Ta atom and side-on bound to the other, as shown in Fig. 15.1.5(e). The N-N distance of 131.9 pm is consistent with a formal assignment of the bridging dinitrogen moiety as $\left(\mathrm{N}_{2}\right)^{4-}$. The shortest distance of the end-on TaN bond is 188.7 pm , which is consistent with its considerable double-bond character.
(6) $\quad \mu-\left(\right.$ bis $\left.-\eta^{2}\right)-\mathbf{N}_{2}$ (planar)

Figure 15.1.5(f) shows a planar, side-on bonded $\mathrm{N}_{2}$ ligand between two Zr atoms in the compound $\left[\mathrm{Cp}^{\prime \prime}{ }_{2} \mathrm{Zr}\right]_{2}\left(\mathrm{~N}_{2}\right)\left[\mathrm{Cp}^{\prime \prime}=1,3-\left(\mathrm{SiMe}_{2}\right)_{2} \mathrm{C}_{5} \mathrm{H}_{3}\right]$. The $\mathrm{N}-\mathrm{N}$ bond length is 147 pm . Side-on coordination of the dinitrogen ligand appears to be important for its reduction.
(7) $\mu-\left(\right.$ bis $\left.-\eta^{2}\right)-\mathrm{N}_{2}$ (nonplanar)

In the compound $\operatorname{Li}\left\{\left[\left(\mathrm{SiMe}_{3}\right)_{2} \mathrm{~N}\right]_{2} \mathrm{Ti}\left(\mathrm{N}_{2}\right)\right\}_{2}$, each Ti atom is side-on bound to two $\mathrm{N}_{2}$ molecules, as shown in Fig. 15.1.5(g). The $\mathrm{N}-\mathrm{N}$ distance is 137.9 pm .
(8) $\mu_{4}-\eta^{1}: \eta^{1}: \eta^{2}: \eta^{2}-\mathbf{N}_{2}$

In $\left[\mathrm{Ph}_{2} \mathrm{C}\left(\mathrm{C}_{4} \mathrm{H}_{3} \mathrm{~N}\right)_{2} \mathrm{Sm}\right]_{4}\left(\mathrm{~N}_{2}\right)$, the $\mathrm{N}_{2}$ moiety is end-on bound to two Sm atoms and side-on bound to the other two, as shown in Fig. 15.1.5(h). The bond lengths are: $\mathrm{N}-\mathrm{N} 141.2 \mathrm{pm}, \operatorname{Sm}($ terminal $)-\mathrm{N} 217.7 \mathrm{pm}$ and $\operatorname{Sm}($ bridging $)-\mathrm{N} 232.7 \mathrm{pm}$.
(9) $\mu_{5}-\eta^{1}: \eta^{1}: \eta^{2}: \eta^{2}: \eta^{2}-\mathbf{N}_{2}$

In $\left\{\left[\left(-\mathrm{CH}_{2}-\right)_{5}\right]_{4} \text { calixtetrapyrrole }\right\}_{2} \mathrm{Sm}_{3} \mathrm{Li}_{2}\left(\mathrm{~N}_{2}\right)\left[\mathrm{Li}(\mathrm{THF})_{2}\right] \cdot(\mathrm{THF})$, the $\mathrm{N}_{2}$ moiety is end-on bound to two Li atoms and side-on bound to three Sm atoms, as shown in Fig. 15.1.5(i). The bond lengths are N-N 150.2 pm, $\mathrm{Sm}-\mathrm{N} 233.3$ pm(av.), and Li-N 191.0 pm(av.).

Dinitrogen coordination modes in metal complexes.
(10) $\mu_{6}-\eta^{1}: \eta^{1}: \eta^{2}: \eta^{2}: \eta^{2}: \eta^{2}-\mathbf{N}_{2}$

In $\left[(\mathrm{THF})_{2} \mathrm{Li}(\mathrm{OEPG}) \mathrm{Sm}_{2} \mathrm{Li}_{4}\left(\mathrm{~N}_{2}\right)(\mathrm{OEPG}=\right.$ octaethylporphyrinogen $)$, the $\mathrm{N}_{2}$ moiety is end-on bound to two Li atoms and side-on bound to two Sm atoms and two Li atoms, as shown in Fig. 15.1.5(j). The bond lengths are $\mathrm{N}-\mathrm{N} 152.5$ pm, Sm-N 235.0 pm (av.), and Li-N 195.5 pm(av.).

The bonding of dinitrogen to transition metals may be divided into the "endon" and "side-on" categories. In the end-on arrangement, the coordination of the $\mathrm{N}_{2}$ ligand is accomplished by a $\sigma$ bond between the $2 \sigma_{\mathrm{g}}$ orbital of the nitrogen molecule and a hybrid orbital of the metal, and by $\pi$ back-bonding from a doubly degenerate metal $\mathrm{d} \pi$ orbitals ( $\mathrm{d}_{x z}, \mathrm{~d}_{y z}$ ) to the vacant $1 \pi_{\mathrm{g}}^{*}$ orbitals ( $\pi_{x z}^{*}, \pi_{y z}^{*}$ ) of the nitrogen molecule, as shown in Fig. 15.1.6.

In the side-on arrangement, the bonding is considered to arise from two interdependent components. In the first part, $\sigma$ overlap between the filled $\pi$ orbital of $\mathrm{N}_{2}$ and a suitably directed vacant hybrid metal orbital forms a donor bond. In the second part, the M atom and $\mathrm{N}_{2}$ molecule are involved in two back-bonding interactions, one having $\pi$ symmetry as shown in Fig. 15.1.7(a), and the other with $\delta$ symmetry as shown in Fig. 15.1.7(b). These $\pi$ and $\delta$-back bonds synergically reinforce the $\sigma$ bond.

Since the overlap of a $\delta$ bond should be less effective than that of a $\pi$ bond, the end-on mode is generally preferred over the side-on form.
The transition-metal dinitrogen complexes have been investigated theoretically, and the results lead to the following generalizations:
(a) Both $\sigma$ donation and $\pi$ or $\delta$ back donation are related to the formation of the metal-nitrogen bond, the former interaction being more important.
(b) The $\mathrm{N}-\mathrm{N}$ bond of the side-on complex is appreciably weakened by electron donation from the bonding $\pi$ and $\sigma$ orbitals of the $\mathrm{N}_{2}$ ligand to the vacant orbitals of the metal.
(c) The end-on coordination mode takes precedence over the side-on one. The weak $\mathrm{N}-\mathrm{N}$ bond in the side-on complex indicates that the $\mathrm{N}_{2}$ ligand in this type of compound is fairly reactive. The reduction of the coordinated nitrogen molecule may proceed through this activated form.

### 15.2 Compounds of nitrogen

### 15.2.1 Molecular nitrogen oxides

Nitrogen displays nine oxidation states ranging from -3 to +5 . Since it is less electronegative than oxygen, nitrogen forms oxides and oxidized compounds with an oxidation number between +1 and +5 . Eight oxides of nitrogen, $\mathrm{N}_{2} \mathrm{O}$, $\mathrm{NO}, \mathrm{N}_{2} \mathrm{O}_{2}, \mathrm{~N}_{2} \mathrm{O}_{3}, \mathrm{NO}_{2}, \mathrm{~N}_{2} \mathrm{O}_{4}, \mathrm{~N}_{2} \mathrm{O}_{5}$ and $\mathrm{N}_{4} \mathrm{O}$, are known, and the ninth, $\mathrm{NO}_{3}$, exists as an unstable intermediate in various reactions involving nitrogen oxides. Their structures and some properties are presented in Table 15.2.1 and Fig. 15.2.1.

All nitrogen oxides have planar structures. Nitrogen displays all its positive oxidation states in these compounds, and in $\mathrm{N}_{2} \mathrm{O}, \mathrm{N}_{2} \mathrm{O}_{3}$ and $\mathrm{N}_{4} \mathrm{O}$ the N atoms in

## (1) $\mathrm{N}_{2} \mathrm{O}$

Dinitrogen oxide (nitrous oxide), $\mathrm{N}_{2} \mathrm{O}$, is a linear unsymmetrical molecule with a structure similar to its isoelectronic analog $\mathrm{CO}_{2}$ :

$$
\overline{\mathrm{N}} \leftarrow \stackrel{+}{\mathrm{N}}=\mathrm{O} \longleftrightarrow \mathrm{~N} \equiv \stackrel{+}{\mathrm{N}}-\overline{\mathrm{O}}
$$

Dinitrogen oxide is unstable and undergoes dissociation when heated to about 870 K:

$$
\mathrm{N}_{2} \mathrm{O} \longrightarrow \mathrm{~N}_{2}+{ }^{1} / 2 \mathrm{O}_{2}
$$

The activation energy for this process is high ( $\sim 520 \mathrm{~kJ} \mathrm{~mol}^{-1}$ ), so $\mathrm{N}_{2} \mathrm{O}$ is relatively unreactive at room temperature. Dinitrogen oxide has a pleasant odor and sweet taste, and its past use as an anaesthetic with undesirable side effect accounts for its common name as "laughing gas."

## (2) NO and $(\mathrm{NO})_{2}$

The simplest thermally stable odd-electron molecule known is nitrogen monoxide, NO, which is discussed in the next section. High-purity nitrogen monoxide partially dimerizes when it liquefies to give a colorless liquid. The heat of dissociation of the dimer is $15.5 \mathrm{~kJ} \mathrm{~mol}^{-1}$. The structure of the $(\mathrm{NO})_{2}$ dimer in the crystalline and vapor states are shown in Figs. 15.2.1(c) and 15.2.1(d), respectively. The $(\mathrm{NO})_{2}$ dimer adopts the cis arrangement with $C_{2 \mathrm{v}}$ symmetry. In the crystalline state, the $\mathrm{N}-\mathrm{N}$ distance is 218 pm ( 223.7 pm in the gas phase), and the $\mathrm{O} \cdots \mathrm{O}$ distance is 262 pm . The very long $\mathrm{N}-\mathrm{N}$ distance has not been accounted for satisfactorily in bonding models.

## (3) $\quad \mathbf{N}_{2} \mathrm{O}_{3}$

Dinitrogen trioxide is formed by the reaction of stoichiometric quantities of NO and $\mathrm{O}_{2}$ :

$$
2 \mathrm{NO}+{ }^{1} / 2 \mathrm{O}_{2} \rightarrow \mathrm{~N}_{2} \mathrm{O}_{3} .
$$

At temperatures below $172.6 \mathrm{~K}, \mathrm{~N}_{2} \mathrm{O}_{3}$ crystallizes as a pale blue solid. On melting it forms an intensely blue liquid which, as the temperature is raised, is increasingly dissociated into NO and an equilibrium mixture of $\mathrm{NO}_{2}$ and $\mathrm{N}_{2} \mathrm{O}_{4}$. This dissociation occurs significantly above 243 K and the liquid assumes a greenish hue resulting from the brown color of $\mathrm{NO}_{2}$ mixed with the blue. The $\mathrm{N}-\mathrm{N}$ distance of the $\mathrm{N}_{2} \mathrm{O}_{3}$ molecule, 186.9 pm , is considerably longer than the typical $\mathrm{N}-\mathrm{N}$ single bond ( 145 pm ) in hydrazine, $\mathrm{H}_{2} \mathrm{~N}-\mathrm{NH}_{2}$.

## (4) $\mathrm{NO}_{2}$ and $\mathrm{N}_{2} \mathrm{O}_{4}$

Nitrogen dioxide and dinitrogen tetroxide are in rapid equilibrium that is highly dependent on temperature. Below the melting point ( 262.0 K ) the oxide consists entirely of colorless, diamagnetic $\mathrm{N}_{2} \mathrm{O}_{4}$ molecules. As the temperature is raised to the boiling point ( 294.3 K ), the liquid changes to an intense red-brown

## Structural Chemistry of Selected Elements

colored, highly paramagnetic phase containing $0.1 \% \mathrm{NO}_{2}$. At 373 K , the proportion of $\mathrm{NO}_{2}$ increases to $90 \%$. The configuration, bond distances, and bond angles of $\mathrm{NO}_{2}$ and $\mathrm{N}_{2} \mathrm{O}_{4}$ are given in Figs. 15.2.1(f) and 15.2.1(g). In view of the large bond angle of $\mathrm{NO}_{2}$ and its tendency for dimerization, bonding in the molecule can be described in terms of resonance between the following canonical structures:

The $\mathrm{N}-\mathrm{N}$ distance in planar $\mathrm{N}_{2} \mathrm{O}_{4}$ is 175 pm , with a rotation barrier of about $9.6 \mathrm{~kJ} \mathrm{~mol}^{-1}$. Although the $\mathrm{N}-\mathrm{N}$ bond is of the $\sigma$ type, it is lengthened because the bonding electron pair is delocalized over the entire $\mathrm{N}_{2} \mathrm{O}_{4}$ molecule with a large repulsion between the doubly occupied MOs on the two N atoms.

## (5) $\quad \mathrm{N}_{2} \mathrm{O}_{5}$ and $\mathrm{NO}_{3}$

Nitrogen pentoxide, $\mathrm{N}_{2} \mathrm{O}_{5}$, is a colorless, light- and heat-sensitive crystalline compound that consists of linear $\mathrm{NO}_{2}^{+}$cations ( $\mathrm{N}-\mathrm{O} 115.4 \mathrm{pm}$ ) and planar $\mathrm{NO}_{3}^{-}$ anions ( $\mathrm{N}-\mathrm{O} 124 \mathrm{pm}$ ). In the gas phase $\mathrm{N}_{2} \mathrm{O}_{5}$ is molecular but its configuration and dimensions have not been reliably measured. Also, $\mathrm{N}_{2} \mathrm{O}_{5}$ is the anhydride of nitric acid and can be obtained by carefully dehydrating the concentrated acid with $\mathrm{P}_{4} \mathrm{O}_{10}$ at low temperatures:

$$
4 \mathrm{HNO}_{3}+\mathrm{P}_{4} \mathrm{O}_{10} \xrightarrow{-10^{\circ} \mathrm{C}} 2 \mathrm{~N}_{2} \mathrm{O}_{5}+4 \mathrm{HPO}_{3} .
$$

The existence of the fugitive, paramagnetic trioxide $\mathrm{NO}_{3}$ is also implicated in the $\mathrm{N}_{2} \mathrm{O}_{5}$-catalyzed decomposition of ozone, and its concentration is sufficiently high for its absorption spectrum to be recorded. It has not been isolated as a pure compound, but probably has a symmetrical planar structure like that of $\mathrm{NO}_{3}^{-}$.

## (6) $\mathrm{N}_{4} \mathrm{O}$

Nitrosyl azide, $\mathrm{N}_{4} \mathrm{O}$, is a pale yellow solid formed by the reaction of activated, anhydrous $\mathrm{NaN}_{3}$ and NOCl , followed by low-temperature vacuum sublimation. The Raman spectrum and ab initio calculation characterized the structure of $\mathrm{N}_{4} \mathrm{O}$ as that shown in Fig. 15.2.1(i). The bonding in the $\mathrm{N}_{4} \mathrm{O}$ molecule can be represented by the following resonance structures:

## (7) Molecule of the year for 1992: nitric oxide

Nitric oxide, NO, was named molecule of the year for 1992 by the journal Science. It is one of the most extensively investigated molecules in inorganic and bioinorganic chemistry.

Nitric oxide is biosynthesized in animal species, and its polarity and small molecular dimensions allow it to readily diffuse through cell walls, acting as a messenger molecule in biological systems. It plays an important role in the normal maintenance of many important physiological functions, including neurotransmission, blood clotting, regulation of blood pressure, muscle relaxation, and annihilation of cancer cells.

The valence shell electron configuration of NO in its ground state is $(1 \sigma)^{2}\left(1 \sigma^{*}\right)^{2}(1 \pi)^{4}(2 \sigma)^{2}\left(1 \pi^{*}\right)^{1}$, which accounts for the following properties:
(a) The NO molecule has a net bond order of 2.5 , bond energy $627.5 \mathrm{~kJ} \mathrm{~mol}^{-1}$, bond length 115 pm , and an infrared stretching frequency of $1840 \mathrm{~cm}^{-1}$.
(b) The molecule is paramagnetic in view of its unpaired $\pi^{*}$ electron.
(c) NO has a much lower ionization energy ( $891 \mathrm{~kJ} \mathrm{~mol}^{-1}$ or 9.23 eV ) than $\mathrm{N}_{2}(15.6 \mathrm{eV})$ or $\mathrm{O}_{2}(12.1 \mathrm{eV})$.
(d) NO has a dipole moment of $0.554 \times 10^{-30} \mathrm{C} \mathrm{m}$, or 0.166 Debye.
(e) Employing its lone-pair electrons, NO serves as a terminal or bridging ligand in forming numerous coordination compounds.
(f) NO is thermodynamically unstable ( $\Delta G^{o}=86.57 \mathrm{~kJ} \mathrm{~mol}^{-1}, \Delta S^{o}=$ $217.32 \mathrm{~kJ} \mathrm{~mol}^{-1} \mathrm{~K}^{-1}$ ) and decomposes to $\mathrm{N}_{2}$ and $\mathrm{O}_{2}$ at high temperature. It is capable of undergoing a variety of redox reactions. The electrochemical oxidation of NO around 1.0 V has been used to devise NO-selective amperometric microprobe electrodes to detect its release in biological tissues.

As a result of its unique structure and properties, the NO molecule exhibits a wide variety of reactions with various chemical species. In particular, it readily releases an electron in the antibonding $\pi^{*}$ orbital to form the stable nitrosyl cation $\mathrm{NO}^{+}$, increasing the bond order from 2.5 to 3.0 , so that the bond distance decreases by 9 pm . The NO species in an aqueous solution of nitrous acid, HONO, is $\mathrm{NO}^{+}$:

$$
\mathrm{HONO}+\mathrm{H}^{+} \longrightarrow \mathrm{NO}^{+}+\mathrm{H}_{2} \mathrm{O}
$$

There are many nitrosyl salts, including (NO) $\mathrm{HSO}_{4},(\mathrm{NO}) \mathrm{ClO}_{4},\left(\mathrm{NO}^{2}\right) \mathrm{BF}_{4}$, $(\mathrm{NO}) \mathrm{FeCl}_{4},(\mathrm{NO}) \mathrm{AsF}_{6}$, $(\mathrm{NO}) \mathrm{PtF}_{6}$, (NO) $\mathrm{PtCl}_{6}$, and (NO) $\mathrm{N}_{3}$.

Nitrosyl halides are formed when NO reacts with $\mathrm{F}_{2}, \mathrm{Cl}_{2}$, and $\mathrm{Br}_{2}$, and they all have a bent structure:

$$
\begin{array}{ll}
\mathrm{X}^{\mathrm{N}=\mathrm{O}} & \mathrm{X}=\mathrm{F}, \mathrm{X}-\mathrm{N} 152 \mathrm{pm}, \mathrm{~N}=\mathrm{O} 114 \mathrm{pm}, \mathrm{X}-\mathrm{N}=\mathrm{O} 110^{\circ} \\
& \mathrm{X}=\mathrm{Cl}, \mathrm{X}-\mathrm{N} 197 \mathrm{pm}, \mathrm{~N}=\mathrm{O} 114 \mathrm{pm}, \mathrm{X}-\mathrm{N}=\mathrm{O} 113^{\circ} \\
& \mathrm{X}=\mathrm{Br}, \mathrm{X}-\mathrm{N} 213 \mathrm{pm}, \mathrm{~N}=\mathrm{O} 114 \mathrm{pm}, \mathrm{X}-\mathrm{N}=\mathrm{O} 117^{\circ}
\end{array}
$$

Because of its close resemblance to $\mathrm{O}_{2}$ and its paramagnetism, NO has been used extensively as an $\mathrm{O}_{2}$ surrogate to probe the metal environment of various metalloproteins. In particular, NO has been shown to bind to $\mathrm{Fe}^{2+}$ in heme-containing oxygen-transporting proteins, in a fashion nearly identical to $\mathrm{O}_{2}$, with the important consequence of rendering the complex paramagnetic and thus detectable by EPR spectroscopy. Since the unpaired electron assumes appreciable iron d-orbital character, analysis of the EPR characteristics of hemo-protein nitrosyl complexes yields valuable information on both the ligand-binding environment around the heme and on the conformational state of the protein.

Nitric oxide can bind to metals in both terminal and bridging modes to give metal nitrosyl complexes. Depending upon the stereochemistry of the complexes, NO may exhibit within one given complex either $\mathrm{NO}^{+}$or $\mathrm{NO}^{-}$ character, as illustrated in Table 15.2.2.

Nitric oxide contains one more electron than CO and generally behaves as a three-electron donor in metal nitrosyl complexes. Formally this may be regarded as the transfer of one electron to the metal atom, thereby reducing its oxidation state by one, followed by coordination of the resulting $\mathrm{NO}^{+}$to the metal atom as a two-electron donor. This is in accordance with the general rule that three terminal CO groups in a metal carbonyl compound may be replaced by two NO groups. In this type of bonding the $\mathrm{M}-\mathrm{N}-\mathrm{O}$ bond angle would formally be $180^{\circ}$. However, in many instances this bond angle is somewhat less than $180^{\circ}$, and slight bent M-N-O groups with angles in the range $165^{\circ}$ to $180^{\circ}$ are frequently found.

In a second type of bonding in nitrosyl coordination compounds, the M-N-O bond angle lies in the range of $120^{\circ}$ to $140^{\circ}$ and the NO molecule acts as a oneelectron donor. Here the situation is analogous to XNO compounds and the $\mathrm{M}-\mathrm{N}$ bond order is one.

It should be emphasized that the $\mathrm{NO}^{+}$and $\mathrm{NO}^{-}$"character" of NO and the linear or bent angle in a nitrosyl complex do not necessarily imply that NO would be released from the complex in the free form NO or as $\mathrm{NO}^{+}$or $\mathrm{NO}^{-}$.

### 15.2.2 Oxo-acids and oxo-ions of nitrogen

The oxo-acids of nitrogen known either as the free acids or in the form of their salts are listed in Tables 15.2.3 and 15.2.4. The structures of these species are shown in Figs. 15.2.2 and 15.2.3.

## (1) Hyponitrous acid, $\mathrm{H}_{2} \mathrm{~N}_{2} \mathrm{O}_{2}$

Spectroscopic data indicate that hyponitrous acid, $\mathrm{HON}=\mathrm{NOH}$, has the planar trans configuration. Its structural isomer nitramide, $\mathrm{H}_{2} \mathrm{~N}-\mathrm{NO}_{2}$, is a weak acid. The structure of nitramide is shown in Fig. 15.2.2(a); in this molecule, the angle between the $\mathrm{NNO}_{2}$ plane and the $\mathrm{H}_{2} \mathrm{~N}$ plane is $52^{\circ}$. Both trans and cis forms of the hyponitrite ion, $(\mathrm{ONNO})^{2-}$, are known. The trans isomer, as illustrated in Fig. 15.2.3(a), is the stable form with considerable $\pi$ bonding over the molecular skeleton; in the cis isomer, the $\mathrm{N}=\mathrm{N}$ and $\mathrm{N}-\mathrm{O}$ bond lengths are 120 and 140 pm , respectively.

## (2) Nitroxyl, HNO

This is a transient species whose structure is shown in Fig. 15.2.2(b). The existence of the $\mathrm{NO}^{-}$anion has been established by single-crystal X-ray analysis of $\left(\mathrm{Et}_{4} \mathrm{~N}\right)_{5}\left[(\mathrm{NO})\left(\mathrm{V}_{12} \mathrm{O}_{32}\right)\right]$, in which the $\mathrm{NO}^{-}$group lies inside the cage of

(d)

$\left(\mathrm{V}_{12} \mathrm{O}_{32}\right)^{4-}$. The bond length of $\mathrm{NO}^{-}$is 119.8 pm , which is longer than that of the neutral molecule $\mathrm{NO}, 115.0 \mathrm{pm}$.

## (3) Hyponitric acid, $\mathrm{H}_{2} \mathrm{~N}_{2} \mathrm{O}_{3}$

Hyponitric acid has not been isolated in pure form, but its salts are known. In the hyponitrate anion $\mathrm{N}_{2} \mathrm{O}_{3}^{2-}$, both N atoms each bears a lone pair $\left(\mathrm{O}=\ddot{\mathrm{N}}-\ddot{\mathrm{N}}-\mathrm{O}_{\mathrm{O}^{-}}^{\mathrm{O}^{-}}\right)$ tion, which can exist in both cis and trans forms, as shown in Figs. 15.2.3(b) and 15.2.3(c).

(a)

(d)

(g)

(b)

(e)

(c)

(f)
(h)

## (4) Nitrous acid, $\mathrm{HNO}_{2}$

Although nitrous acid has never been isolated as a pure compound, its aqueous solution is a widely used reagent. Nitrous acid is a moderately weak acid with $\mathrm{p} K \mathrm{a}=3.35$ at 291 K . In the gaseous state, it adopts the trans-planar structure, as shown in Fig. 15.2.2(c).

The nitrite ion, $\mathrm{NO}_{2}^{-}$is bent with $C_{2 \mathrm{v}}$ symmetry, and its structure can be represented by two simple resonance formulas:

Many stable metal nitrites $\left(\mathrm{Li}^{+}, \mathrm{Na}^{+}, \mathrm{K}^{+}, \mathrm{Rb}^{+}, \mathrm{Cs}^{+}, \mathrm{Ag}^{+}, \mathrm{Tl}^{+}, \mathrm{Ba}^{2+}, \mathrm{NH}_{4}^{+}\right)$ contain the bent $(\mathrm{O}-\mathrm{N}-\mathrm{O})^{-}$anion with $\mathrm{N}-\mathrm{O}$ bond length in the range of 113-123 pm , and the angle $116^{\circ}-132^{\circ}$, as shown in Fig. 15.2.3(d).

## (5) Nitric acid, $\mathrm{HNO}_{3}$

Nitric acid is one of the three major inorganic acids in the chemical industry. Its structural parameters in the gaseous state are shown in Fig. 15.2.2(d). The crystals of nitric acid monohydrate consist of $\mathrm{H}_{3} \mathrm{O}^{+}$and $\mathrm{NO}_{3}^{-}$, which are connected by strong hydrogen bonds. In the acid salts, $\mathrm{HNO}_{3}$ molecules are bound to nitrate ions by strong hydrogen bonds. For example, the structures of $\left[\mathrm{H}\left(\mathrm{NO}_{3}\right)_{2}\right]^{-}$in $\mathrm{K}\left[\mathrm{H}\left(\mathrm{NO}_{3}\right)_{2}\right]$ and $\left[\mathrm{H}_{2}\left(\mathrm{NO}_{3}\right)_{3}\right]^{-}$in $\left(\mathrm{NH}_{4}\right) \mathrm{H}_{2}\left(\mathrm{NO}_{3}\right)_{3}$ are as follows:

The nitrate ion $\mathrm{NO}_{3}^{-}$has $D_{3 \mathrm{~h}}$ symmetry, as shown in Fig. 15.2.3(e), and its bonding can be represented by the following resonance structures:

## (6) Orthonitric acid, $\mathrm{H}_{3} \mathrm{NO}_{4}$

Orthonitric acid is still unknown, but its salts $\mathrm{Na}_{3} \mathrm{NO}_{4}$ and $\mathrm{K}_{3} \mathrm{NO}_{4}$ have been characterized by X-ray crystallography. The $\mathrm{NO}_{4}^{3-}$ ion has regular $T_{\mathrm{d}}$ symmetry, and its bonding can be represented by resonance structures:

## (7) Oxo-cations, $\mathrm{NO}^{+}$and $\mathrm{NO}_{2}^{+}$

The nitrosonium $\mathrm{NO}^{+}$and nitronium $\mathrm{NO}_{2}^{+}$ions, which have been mentioned in previous sections, have $C_{\infty \mathrm{v}}$ and $D_{\infty \mathrm{h}}$ symmetry, respectively. Their structures shown in Figs. 15.2.3(g) and 15.2.3(h) can be represented by the familiar Lewis structures: $\mathrm{N} \equiv \mathrm{O}^{+}$and $\mathrm{O}=\mathrm{N}^{+}=\mathrm{O}$.

### 15.2.3 Nitrogen hydrides

## (1) Ammonia, $\mathrm{NH}_{3}$

The most important nitrogen hydride is ammonia, which is a colorless, alkaline gas with a unique odor. Its melting point is 195 K . Its boiling point 240 K is far higher than that of $\mathrm{PH}_{3}(185.4 \mathrm{~K})$. This is due to the strong hydrogen bonds between molecules in liquid ammonia. Liquid ammonia is an excellent solvent and a valuable medium for chemical reactions, as its high heat of vaporization ( $23.35 \mathrm{~kJ} \mathrm{~mol}^{-1}$ ) makes it relatively easy to handle. As its dielectric constant ( $\varepsilon=22$ at 239 K ) and self-ionization are both lower than those of water, liquid ammonia is a poorer ionizing solvent but a better one for organic compounds. The self-ionization of ammonia is represented as

$$
2 \mathrm{NH}_{3} \rightleftarrows \mathrm{NH}_{4}^{+}+\mathrm{NH}_{2}^{-}, K=10^{-33}(223 \mathrm{~K}),
$$

and ammonium compounds behave as Lewis acids while amides are bases.
Ammonia is an important industrial chemical used principally (over 80\%) as fertilizers in various forms, and is employed in the production of many other compounds such as urea, nitric acid, and explosives.

## (2) Hydrazine, $\mathbf{H}_{2} \mathbf{N N H}_{2}$

Hydrazine is an oily, colorless liquid in which nitrogen has an oxidation number of -2 . The length of the $\mathrm{N}-\mathrm{N}$ bond is 145 pm , and there is a lone pair on each N atom. Its most stable conformer is the gauche form, rather than the trans or cis form. The rotational barrier through the trans or staggered position is 15.5 kJ $\mathrm{mol}^{-1}$, and through the cis or eclipsed position is $49.7 \mathrm{~kJ} \mathrm{~mol}^{-1}$. These numbers reflect the modest repulsion of the nonbonding electrons for a neighboring bond pair and the significantly greater repulsion of the nonbonding pairs for each other in the cis arrangement. The melting point of hydrazine is 275 K , and the boiling point is 387 K . The very high exothermicity of its combustion makes it a valuable rocket fuel.

## (3) Diazene, $\mathrm{HN}=\mathrm{NH}$

Diazene (or diimide) is a yellow crystalline compound that is unstable above 93 K . In the molecule, each N atom uses two $\mathrm{sp}^{2}$ hybrids for $\sigma$ bonding with the neighboring N and H atoms, and the lone pair occupies the remaining $\mathrm{sp}^{2}$ orbital. The molecule adopts the trans configuration:

## (4) Hydroxylamine, $\mathbf{N H}_{2} \mathbf{O H}$

Anhydrous $\mathrm{NH}_{2} \mathrm{OH}$ is a colorless, thermally unstable hygroscopic compound which is usually handled as an aqueous solution or in the form of its salts. Pure hydroxylamine melts at 305 K and has a very high dielectric constant (77.6-77.9). Aqueous solutions are less basic than either ammonia or hydrazine:

$$
\mathrm{NH}_{2} \mathrm{OH}(\mathrm{aq})+\mathrm{H}_{2} \mathrm{O} \rightleftharpoons \mathrm{NH}_{3} \mathrm{OH}^{+}+\mathrm{OH}^{-}, K=6.6 \times 10^{-9}(298 \mathrm{~K}) .
$$

Hydroxylamine can exist as two configurational isomers (cis and trans) and in numerous intermediate gauche conformations. In the crystalline form, hydrogen bonding tends to favor packing in the trans conformation. The $\mathrm{N}-\mathrm{O}$ bond length is 147 pm , consistent with its formulation as a single bond. Above room temperature the compound decomposes by internal oxidation-reduction reactions into a mixture of $\mathrm{N}_{2}, \mathrm{NH}_{3}, \mathrm{~N}_{2} \mathrm{O}$, and $\mathrm{H}_{2} \mathrm{O}$. Aqueous solutions are much more stable, particularly acid solutions in which the protonated species $\left[\mathrm{NH}_{3}(\mathrm{OH})\right]^{+}$ is generally used as a reducing agent.

### 15.3 Structure and bonding of elemental phosphorus and $\mathbf{P}_{\mathrm{n}}$ groups

Homonuclear aggregates of phosphorus atoms exist in many forms: discrete molecules, covalent networks in crystals, polyphosphide anions, and phosphorus fragments in molecular compounds.

### 15.3.1 Elemental phosphorus

## (1) $P_{4}$ and $P_{2}$ molecules

Elemental phosphorus is known in several allotropic forms. All forms melt to give the same liquid which consists of tetrahedral $\mathrm{P}_{4}$ molecules, as shown in Fig. 15.3.1(a). The same molecular entity exists in the gas phase, the $\mathrm{P}-\mathrm{P}$ bond length being 221 pm . At high temperature $\left(>800^{\circ} \mathrm{C}\right)$ and low pressure $\mathrm{P}_{4}$ is in equilibrium with $P_{2}$ molecules, in which the $P \equiv P$ bond length is 189.5 pm .

The bonding between phosphorous atoms in the $\mathrm{P}_{4}$ molecule can be described by a simple bent bond model, which is formed by the overlap of $\mathrm{sp}^{3}$ hybrids of the P atoms. Maximum overlap of each pair of $\mathrm{sp}^{3}$ orbitals does not occur along an edge of the tetrahedron. Instead, the $\mathrm{P}-\mathrm{P}$ bonds are bent, as shown in Fig. 15.3.1(b). In a more elaborate model, the $\mathrm{P}_{4}$ molecule is further stabilized by the d orbitals of P atoms which also participate in the bonding.

## (2) White phosphorus

White phosphorus (or yellow phosphorus when impure) is formed by condensation of phosphorus vapor. Composed of $\mathrm{P}_{4}$ molecules, it is a soft, waxy, translucent solid, and is soluble in many organic solvents. It oxidizes spontaneously in air, often bursting into flame. It is a strong poison and as little as 50 mg can be fatal to humans.

Fig. 15.3.1.
(a) Structure of $\mathrm{P}_{4}$ molecule; (b) bent bonds in $\mathrm{P}_{4}$ molecule.

At normal temperature, white phosphorus exists in the cubic $\alpha$-form, which is stable from $-77^{\circ} \mathrm{C}$ to its melting point $\left(44.1^{\circ} \mathrm{C}\right)$. The crystal data of $\alpha$-white phosphorus are $a=1.851 \mathrm{~nm}, Z=56\left(\mathrm{P}_{4}\right)$, and $D=1.83 \mathrm{~g} \mathrm{~cm}^{-3}$, but its crystal structure is still unknown. At $-77^{\circ} \mathrm{C}$ the cubic $\alpha$-form transforms to a hexagonal $\beta$-form with a density of $1.88 \mathrm{~g} \mathrm{~cm}^{-3}$.

## (3) Black phosphorus

Black phosphorus is thermodynamically the most stable form of the element and exists in three known crystalline modifications: orthorhombic, rhombohedral, and cubic, as well as in an amorphous form. Unlike white phosphorus, the black forms are all highly polymeric, insoluble, and practically non-flammable, and have comparatively low vapor pressures. The black phosphorus varieties represent the densest and chemically the least reactive of all known forms of the element.

Under high pressure, orthorhombic black phosphorus undergoes reversible transitions to produce denser rhombohedral and cubic forms. In the rhombohedral form the simple hexagonal layers are not as folded as in the orthorhombic form, and in the cubic form each atom has an octahedral environment, as shown in Figs. 15.3.2(a)-(c).

## (4) Violet phosphorus

Violet phosphorus (Hittorf's phosphorus) is a complex three-dimensional polymer in which each P atom has a pyramidal arrangement of three bonds linking it to neighboring P atoms to form a series of interconnected tubes, as shown in Fig. 15.3.3. These tubes lie parallel to each other, forming double layers, and in the crystal structure one layer has its tubes packed at right angles to those in adjacent layers.

(b)

(c)

Structure of black phosphorus: (a) orthorhombic, (b) rhombohedral, and (c) cubic black phosphorus.

Fig. 15.3.3.
Structure of the tube in violet phosphorus

## (5) Red phosphorus

Red phosphorus is a term used to describe a variety of different forms, some of which are crystalline and all are more or less red in color. They show a range of densities from 2.0 to $2.4 \mathrm{~g} \mathrm{~cm}^{-3}$ with melting points in the range of $585-610^{\circ} \mathrm{C}$. Red phosphorus is a very insoluble species. It behaves as a high polymer that is inflammable and almost non-toxic.

### 15.3.2 Polyphosphide anions

Almost all metals form phosphides, and over 200 different binary compounds are now known. In addition, there are many ternary mixed-metal phosphides. These phosphides consist of metal cations and phosphide anions. In addition to some simple anions ( $\mathrm{P}^{3-}, \mathrm{P}_{2}^{4-}, \mathrm{P}_{3}^{5-}$ ), there are many polyphosphide anions that exist in the form of rings, cages, and chains, as shown in Fig. 15.3.4.

In some metal phosphides, the polyphosphide anions constitute infinite chains and sheets, as shown in Fig. 15.3.5.

### 15.3.3 Structure of $\mathrm{P}_{\mathrm{n}}$ groups in transition-metal complexes

Transition-metal complexes with phosphorus bonded to metal atoms have been investigated extensively. They include single P atoms encapsulated in cages of metal atoms, and various $\mathrm{P}_{n}$ groups where $n=2$ to at least 12 . These $\mathrm{P}_{n}$ groups can be chains, rings, or fragments which are structurally related to their valence electron numbers. Figure 15.3.6 shows some skeletal structures of the transition-metal complexes with $\mathrm{P}_{n}$ groups.

Fig. 15.3.6(a) shows the coordination of a pair of $\mathrm{P}_{2}$ groups to metal centers in the dinuclear complex $\left(\mathrm{Cp}^{\prime \prime} \mathrm{Co}\right)_{2}\left(\mathrm{P}_{2}\right)_{2}$. In Figs. 15.3.6(b), (f), (j), and $(\mathrm{n})$, the $\mathrm{P}_{n}$ groups $\mathrm{P}_{3}, \mathrm{P}_{4}, \mathrm{P}_{5}$, and $\mathrm{P}_{6}$ form planar three-, four-, five-, and sixmembered rings, respectively. They can be considered as isoelectronic species of planar $(\mathrm{CH})_{3},(\mathrm{CH})_{4},(\mathrm{CH})_{5}$, and $(\mathrm{CH})_{6}$ molecules. The $\left[\left(\mathrm{P}_{5}\right)_{2} \mathrm{Ti}\right]^{2-}$ anion [Fig. 15.3.6( j$)$ ] is the first entirely inorganic metallocene, the structure of which has a pair of parallel and planar $\mathrm{P}_{5}$ rings symmetrically positioned about the central Ti atom. The average $\mathrm{P}-\mathrm{P}$ bond distance is 215.4 pm , being intermediate

$[\mathrm{Cp} * \operatorname{Ir}(\mathrm{CO})]_{2} \mathrm{P}_{8}\left[\mathrm{Cr}(\mathrm{CO})_{5}\right]_{3}$, (s) $\left(\mathrm{Cp}^{\prime} \mathrm{Rh}\right)_{4} \mathrm{P}_{10}$, (t) $\left[\mathrm{CpCr}(\mathrm{CO})_{2}\right]_{5} \mathrm{P}_{10}$, (u) $\left.\mathrm{Cp}^{P r} \mathrm{Fe}(\mathrm{CO})_{2}\right] \mathrm{P}_{11}\left[\mathrm{Cp}^{P r} \mathrm{Fe}(\mathrm{CO})\right]_{2}$, and (v) $\left[\mathrm{CpCo}(\mathrm{CO})_{2}\right]_{3} \mathrm{P}_{12}$.
multidentate ligands are exemplified by the structures shown in Figs. 15.3.6(g), (h), (l), and (m). Metal complexes containing bi- and tricyclic $\mathrm{P}_{n}$ rings are shown in Figs. 15.3.6(d) and (p), respectively. The skeletons of metal complexes of polyphosphorus $\mathrm{P}_{n}$ ligands with $n>6$ are shown in Figs. 15.3.6(q) to (v).

The reaction of $\mathrm{Cp} * \mathrm{FeP}_{5}$ with CuCl in $\mathrm{CH}_{2} \mathrm{Cl}_{2} / \mathrm{CH}_{3} \mathrm{CN}$ solvent leads to the formation of $\left[\mathrm{Cp}^{*} \mathrm{FeP}_{5}\right]_{12}(\mathrm{CuCl})_{10}\left(\mathrm{Cu}_{2} \mathrm{Cl}_{3}\right)_{5}\left\{\mathrm{Cu}\left(\mathrm{CH}_{3} \mathrm{CN}\right)_{2}\right\}_{5}$. In this large molecule, the cyclo $-\mathrm{P}_{5}$ rings of $\mathrm{Cp} * \mathrm{FeP}_{5}$ are surrounded by six-membered $\mathrm{P}_{4} \mathrm{Cu}_{2}$ rings that result from the coordination of each of the P atomic lone pairs to CuCl metal centers, which are further coordinated by P atoms of other cyclo- $\mathrm{P}_{5}$ rings. Thus five- and six-membered rings are fused in a manner reminiscent of the formation of the fullerene- $\mathrm{C}_{60}$ molecule. Figure 15.3.7 shows the structure of a hemisphere of this globular molecule. The two hemispheres are joined by $\left[\mathrm{Cu}_{2} \mathrm{Cl}_{3}\right]^{-}$as well as by $\left[\mathrm{Cu}\left(\mathrm{CH}_{3} \mathrm{CN}\right)_{2}\right]^{+}$units,

Fig. 15.3.7.

The central Fe atom is omitted for clarity.

and this inorganic fullerene-like molecule has an inner diameter of 1.25 nm and an outer diameter of 2.13 nm , making it about three times as large as $\mathrm{C}_{60}$.

### 15.3.4 Bond valence in $P_{n}$ species

The bonding in $\mathrm{P}_{n}$ species can be expressed by their bond valence $b$, which corresponds to the number of $\mathrm{P}-\mathrm{P}$ bonds. Let $g$ be the total number of valence electrons in $\mathrm{P}_{n}$. When a covalent bond is formed between two P atoms, each of them gains one electron in its valence shell. In order to satisfy the octet rule for $\mathrm{P}_{n}, \frac{1}{2}(8 n-g)$ electron pairs must be involved in bonding between the P atoms. The number of these bonding electron pairs is defined as the bond valence $b$ of the $\mathrm{P}_{n}$ species:

$$
b=\frac{1}{2}(8 n-g)
$$

Applying this simple formula:

$$
\begin{aligned}
\mathrm{P}_{4}: & b=\frac{1}{2}(4 \times 8-4 \times 5)=6, \quad 6 \mathrm{P}-\mathrm{P} \text { bonds; } \\
\mathrm{P}_{7}^{3-}: & b=\frac{1}{2}[7 \times 8-(7 \times 5+3)]=9, \quad 9 \mathrm{P}-\mathrm{P} \text { bonds } ; \\
\mathrm{P}_{11}^{3-}: & b=\frac{1}{2}[11 \times 8-(11 \times 5+3)]=15, \quad 15 \mathrm{P}-\mathrm{P} \text { bonds } \\
\mathrm{P}_{16}^{2-}: & b=\frac{1}{2}[16 \times 8-(16 \times 5+2)]=23, \quad 23 \mathrm{P}-\mathrm{P} \text { bonds. }
\end{aligned}
$$

In these $\mathrm{P}_{n}$ species, the $b$ value is exactly equal to the bond number in the structural formula, as shown in Figs. 15.3.1, 15.3.4, and 15.3.5. But for the
planar ring $\mathrm{P}_{6}$ [Fig. 15.3.6(n)],

$$
b=\frac{1}{2}[6 \times 8-(6 \times 5)]=9,
$$

which implies the existence of three $\mathrm{P}-\mathrm{P}$ bonds and three $\mathrm{P}=\mathrm{P}$ bonds, and hence aromatic behavior as in the benzene molecule.

Structure of $\mathrm{P}_{4}$ group in some transition-metal complexes (large circle represents P atom and arrow $\rightarrow$ represents dative bond): (a) $\mathrm{P}_{4}$ molecule, (b) $\left(\mathrm{P}_{4}\right) \mathrm{Ni}\left(\mathrm{PPh}_{2} \mathrm{CH}_{2}\right)_{3} \mathrm{CCH}_{3}$, (c) $\left(\mathrm{P}_{4}\right) \mathrm{Nb}(\mathrm{CO})_{2} \mathrm{Cp}^{*}$, (d) $\left(\mathrm{P}_{4}\right) \mathrm{Rh}_{2}(\mathrm{CO})(\mathrm{Cp})\left(\mathrm{Cp}^{*}\right)$, (e) $\left(\mathrm{P}_{4}\right) \mathrm{Co}(\mathrm{CO}) \mathrm{Cp}^{*}$, (f) $\left(\mathrm{P}_{4}\right)\left[\mathrm{Co}(\mathrm{CO}) \mathrm{Cp}^{*}\right]_{2}$, (g) $\left(\mathrm{P}_{2}\right)_{2} \mathrm{Rh}_{2}(\mathrm{Cp})_{2}$, and (h) $(\mathrm{P})_{4}(\mathrm{NiCp})_{4}$.

(c)

(b)

(d)

Fig. 15.3.9.
Structure of transition-metal complexes of $\mathrm{P}_{7}^{3-}, \mathrm{As}_{7}^{3-}$, and $\mathrm{Sb}_{7}^{3-}$ : (a)
$\left[\mathrm{P}_{7} \mathrm{Cr}(\mathrm{CO})_{3}\right]^{3-}$, (b) $\left[\mathrm{As}_{7} \mathrm{Mo}(\mathrm{CO})_{3}\right]^{3-}$,
(c) $\left[\mathrm{P}_{7} \mathrm{Ni}(\mathrm{CO})\right]^{3-}$, and
(d) $\left[\mathrm{Sb}_{7} \mathrm{Ni}_{3}(\mathrm{CO})_{3}\right]^{3-}$.

The bond valence of a $\mathrm{P}_{n}$ group changes with its number of valence electrons. The $\mathrm{P}_{4}$ species is a good example, as shown in Fig. 15.3.8. In these structures, each transition metal atom also conforms to the 18 -electron rule.

The bonding structure of transition-metal complexes with $\mathrm{P}_{n}$ group can be classified into four types:
(1) Covalent $\mathrm{P}-\mathrm{M} \sigma$ bond: each atom donates one electron to bonding and the $g$ value of $\mathrm{P}_{n}$ increases by one, as shown in Fig. 15.3.8(e).
(2) $\mathrm{P} \rightarrow \mathrm{M}$ dative bond: the $g$ value of $\mathrm{P}_{n}$ species does not change, as shown in Fig. 15.3.8(b).
(3) $\|_{\mathrm{P}} \rightarrow \mathrm{M} \pi$ dative bond: the $g$ value of $\mathrm{P}_{n}$ species also does not change, as shown in Fig. 15.3.8 (c).
(4) $\left(\eta^{n}-\mathrm{P}_{n}\right) \rightarrow \mathrm{M}$ dative bond: the $\mathrm{P}_{n}$ ring $(n=3-6)$ donates its delocalized $\pi$ electrons to the M atom, and the $g$ value of $\mathrm{P}_{n}$ group does not change.

Some molecular transition-metal complexes of $\mathrm{P}_{7}^{3-}, \mathrm{As}_{7}^{3-}$, and $\mathrm{Sb}_{7}^{3-}$ have been isolated as salts of cryptated alkali metal ions. The structures of the complex anions are shown in Fig. 15.3.9. The bond valence $b$ and bond number of these complex anions are as follows:
(a) $\left[\mathrm{P}_{7} \mathrm{Cr}(\mathrm{CO})_{3}\right]^{3-}$ in $\left[\mathrm{Rb} \cdot \operatorname{crypt}_{3}\left[\mathrm{P}_{7} \mathrm{Cr}(\mathrm{CO})_{3}\right]: b=12\right.$, eight $\mathrm{P}-\mathrm{P}$ and four $\mathrm{P}-\mathrm{Cr}$ bonds.
(b) $\left[\mathrm{As}_{7} \mathrm{Mo}(\mathrm{CO})_{3}\right]^{3-}$ in $\left[\mathrm{Rb} \cdot \mathrm{crypt}_{3}\left[\mathrm{As}_{7} \mathrm{Mo}(\mathrm{CO})_{3}\right]: b=12\right.$, eight As-As and four $\mathrm{As}-\mathrm{Mo}$ bonds.
(c) $\left[\mathrm{P}_{7} \mathrm{Ni}(\mathrm{CO})\right]^{3-}$ in $\left[\mathrm{Rb} \cdot \mathrm{crypt}^{2}\right]_{3}\left[\mathrm{P}_{7} \mathrm{Ni}(\mathrm{CO})\right]: b=12$, eight $\mathrm{P}-\mathrm{P}$ and four $\mathrm{P}-\mathrm{Ni}$ bonds.
(d) $\left[\mathrm{Sb}_{7} \mathrm{Ni}_{3}(\mathrm{CO})_{3}\right]^{3-}$ in $\left[\mathrm{K} \cdot \mathrm{crypt}_{3}\left[\mathrm{Sb}_{7} \mathrm{Ni}_{3}(\mathrm{CO})_{3}\right]: b=18\right.$, four $\mathrm{Sb}-\mathrm{Sb}$, five $\mathrm{SbSbNi} 3 c-2 e$, and two SbNiNi $3 c-2 e$ bonds.

### 15.4 Bonding type and coordination geometry of phosphorus

### 15.4.1 Potential bonding types of phosphorus

To illustrate the potential diversity of structure and bonding of phosphorus, the classic Lewis representations for each possible coordination number one to six are shown in Fig. 15.4.1. Many of these bonding types have been observed in stable compounds, which are discussed in the following sections.

Fig. 15.4.1.
Potential bond types of phosphorus.

Phosphines are classical Lewis bases or ligands in transition-metal complexes, but the cationic species shown in Fig. 15.4.1(i) are likely to exhibit Lewis acidity by virtue of the positive charge. Despite their electron-rich nature, an extensive coordination chemistry has been developed for Lewis acidic phosphorus. For example, the compound shown below has a coordinatively unsaturated $\mathrm{Ga}(\mathrm{I})$ ligand bonded to a phosphenium cation; it can be considered as a counter-example of the traditional coordinate bond since the metal center (Ga) behaves as a Lewis donor (ligand) and the non-metal center $(\mathrm{P})$ behaves as a Lewis acceptor.

### 15.4.2 Coordination geometries of phosphorus

Phosphorus forms various compounds with all elements except $\mathrm{Sb}, \mathrm{Bi}$, and the inert gases for the binary compounds. The stereochemistry and bonding of phosphorus are very varied. Some typical coordination geometries are summarized in Table 15.4.1 and illustrated in Fig. 15.4.2. Many of these compounds will be discussed below.

Table 15.4.1. Coordination geometries of phosphorus atoms in compounds

| CN | Coordination geometry | Example | Structure (in Fig. 15.4.1) |
| :---: | :---: | :---: | :---: |
| 1 | Linear | $\mathrm{P} \equiv \mathrm{N}, \mathrm{F}-\mathrm{C} \equiv \mathrm{P}$ | (a) |
| 2 | Bent | $\left[\mathrm{P}(\mathrm{CN})_{2}\right]^{-}$ | (b) |
| 3 | Pyramidal | $\mathrm{PX}_{3}(\mathrm{X}=\mathrm{H}, \mathrm{F}, \mathrm{Cl}, \mathrm{Br}, \mathrm{I})$ | (c) |
|  | Planar | $\mathrm{PhP}\left\{\mathrm{Mn}\left(\mathrm{C}_{5} \mathrm{H}_{5}\right)(\mathrm{CO})_{2}\right\}_{2}$ | (d) |
| 4 | Tetrahedral | $\mathrm{P}_{4} \mathrm{O}_{10}$ | (e) |
|  | Square | $\left.{ }^{\text {P }}\left\{\mathrm{Zr}(\mathrm{H}) \mathrm{Cp}_{2}\right\}_{4}\right]^{+}$ | (f) |
| 5 | Square pyramidal | $\mathrm{Os}_{5}(\mathrm{CO})_{15}\left(\mu_{4}-\mathrm{POMe}\right)$ | (g) |
|  | Trigonal bipyramidal | $\mathrm{PF}_{5}$ | (h) |
| 6 | Octahedral | $\mathrm{PCl}_{6}^{-}$ | (i) |
|  | Trigonal prismatic | $\left(\mu_{6}-\mathrm{P}\right)\left[\mathrm{Os}(\mathrm{CO})_{3}\right]_{6}^{-}$ | (j) |
| 7 | Monocapped trigonal prismatic | $\mathrm{Ta}_{2} \mathrm{P}$ | (k) |
| 8 | Cubic | $\mathrm{Ir}_{2} \mathrm{P}$ | (1) |
|  | Bicapped trigonal prismatic | $\mathrm{Hf}_{2} \mathrm{P}$ | (m) |
| 9 | Monocapped square antiprismatic | $\left[\mathrm{Rh}_{9}(\mathrm{CO})_{21} \mathrm{P}\right]^{2-}$ | (n) |
|  | Tricapped trigonal prismatic | $\mathrm{Cr}_{3} \mathrm{P}$ | (o) |
| 10 | Bicapped square antiprismatic | $\left[\mathrm{Rh}_{10}(\mathrm{CO})_{22} \mathrm{P}\right]^{3-}$ | (p) |

## (1) Coordination number 1

Coordination number 1 is represented by the compounds $\mathrm{P} \equiv \mathrm{N}, \mathrm{P} \equiv \mathrm{C}-\mathrm{H}, \mathrm{P} \equiv \mathrm{C}-$ $\mathrm{X}(\mathrm{X}=\mathrm{F}, \mathrm{Cl})$, and $\mathrm{P} \equiv \mathrm{C}-\mathrm{Ar}\left(\mathrm{Ar}={ }^{t} \mathrm{Bu}_{3} \mathrm{C}_{6} \mathrm{H}_{2}\right)$. In these compounds, the P atom

Fig. 15.4.2.
Coordination geometries of the phosphorus atom in some compounds (black circles represent P , open circles represent other atoms): (a) $\mathrm{P} \equiv \mathrm{N}$, (b) $\left[\mathrm{P}(\mathrm{CN})_{2}\right]^{-}$, (c) $\mathrm{PX}_{3}$, (d) $\mathrm{PhP}\left\{\mathrm{Mn}\left(\mathrm{C}_{5} \mathrm{H}_{5}\right)(\mathrm{CO})_{2}\right\}_{2}$, (e) $\mathrm{P}_{4} \mathrm{O}_{10}$, (f) $\left[\mathrm{P}\left\{\mathrm{Zr}(\mathrm{H}) \mathrm{Cp}_{2}\right\}_{4}\right]^{+}$, (g) $\mathrm{Os}_{5}(\mathrm{CO})_{15}\left(\mu_{4}-\mathrm{POMe}\right)$, (h) $\mathrm{PF}_{5}$, (i) $\left[\mathrm{PCl}_{6}\right]^{-}$, (j) $\left[\mathrm{Os}(\mathrm{CO})_{3}\right]_{6} \mathrm{P}$, (k) $\mathrm{Ta}_{2} \mathrm{P}$, (l) $\mathrm{Ir}_{2} \mathrm{P}$, (m) $\mathrm{Hf}_{2} \mathrm{P}$, (n) $\left[\mathrm{Rh}_{9}(\mathrm{CO})_{21} \mathrm{P}\right]^{2-}$, (o) $\mathrm{Cr}_{3} \mathrm{P}$, and (p) $\left[\mathrm{Rh}_{10}(\mathrm{CO})_{22} \mathrm{P}\right]^{3-}$.
forms a triple bond with the N or C atom. The bond length are $\mathrm{P} \equiv \mathrm{N} 149 \mathrm{pm}$, $\mathrm{P} \equiv \mathrm{C} 154 \mathrm{pm}$.

## (2) Coordination number 2

Compounds of this coordination number have three bond types:

$\mathrm{P}(\mathrm{CN})_{2}{ }^{-}$

$\mathrm{R}_{2} \mathrm{~N}-\mathrm{P}=\mathrm{NR}$

In $\mathrm{P}(\mathrm{CN})_{2}^{-}$, the bond length $\mathrm{P}-\mathrm{C}$ is $173 \mathrm{pm}, \mathrm{C} \equiv \mathrm{N}$ is 116 pm , and bond angle $\mathrm{C}-\mathrm{P}-\mathrm{C}$ is $95^{\circ}$.

## (3) Coordination number 3

In compounds of this coordination number, the pyramidal configuration is the most common type, and the planar one is much less favored. In pyramidal $\mathrm{PX}_{3}$, the three X groups are either the same or different, $\mathrm{X}=\mathrm{F}, \mathrm{Cl}, \mathrm{Br}, \mathrm{I}, \mathrm{H}, \mathrm{OR}$, $\mathrm{OPh}, \mathrm{Ph},{ }^{t} \mathrm{Bu}$, etc. The observed data of some $\mathrm{PX}_{3}$ compounds are listed below:

| $\mathrm{PX}_{3}$ | $\mathrm{PH}_{3}$ | $\mathrm{PF}_{3}$ | $\mathrm{PCl}_{3}$ | $\mathrm{PBr}_{3}$ | $\mathrm{PI}_{3}$ |
| :--- | :--- | :--- | :--- | :--- | :--- |
| $\mathrm{P}-\mathrm{X}$ bond length $(\mathrm{pm})$ | 144 | 157 | 204 | 222 | 252 |
| $\mathrm{X}-\mathrm{P}-\mathrm{X}$ bond angle | $94^{\circ}$ | $96^{\circ}$ | $100^{\circ}$ | $101^{\circ}$ | $102^{\circ}$ |

Since $\mathrm{PX}_{3}$ has a lone pair at the P atom and the X groups can be varied, the molecules $\mathrm{PX}_{3}$ are important ligands. The strength of the coordinate bond $\mathrm{X}_{3} \mathrm{P} \rightarrow \mathrm{M}$ is influenced by different X groups in three aspects:
(a) $\sigma \mathrm{P} \rightarrow \mathrm{M}$ bonding

The stability of the $\sigma \mathrm{P} \rightarrow \mathrm{M}$ interaction, which uses the lone pair of electrons on P atom and a vacant orbital on M atom, is influenced by different X groups in the sequence:

$$
\mathrm{P}^{t} \mathrm{Bu}_{3}>\mathrm{P}(\mathrm{OR})_{3}>\mathrm{PR}_{3} \approx \mathrm{PPh}_{3}>\mathrm{PH}_{3}>\mathrm{PF}_{3}>\mathrm{P}(\mathrm{OPh})_{3} .
$$

(b) $\pi$ back donation

The possibility of synergic $\pi$ back donation from a nonbonding $\mathrm{d}_{\pi}$ pair of electrons on M into a vacant $3 \mathrm{~d}_{\pi}$ orbital on P varies in the sequence:

$$
\mathrm{PF}_{3}>\mathrm{P}(\mathrm{OPh})_{3}>\mathrm{PH}_{3}>\mathrm{P}(\mathrm{OR})_{3}>\mathrm{PPh}_{3} \approx \mathrm{PR}_{3}>\mathrm{P}^{t} \mathrm{Bu}_{3}
$$

## (c) Steric interference

The stability of the $\mathrm{P}-\mathrm{M}$ bonds are influenced by steric interference of the X groups, in accordance with the sequence:

$$
\mathrm{P}^{t} \mathrm{Bu}_{3}>\mathrm{PPh}_{3}>\mathrm{P}(\mathrm{OPh})_{3}>\mathrm{PMe}_{3}>\mathrm{P}(\mathrm{OR})_{3}>\mathrm{PF}_{3}>\mathrm{PH}_{3} .
$$

In the $\mathrm{PhP}\left\{\mathrm{Mn}\left(\mathrm{C}_{5} \mathrm{H}_{5}\right)(\mathrm{CO})_{2}\right\}_{2}$ molecule, the P atom is bonded to two Mn atoms and one phenyl C atom by single bonds in a planar configuration, as shown in Fig. 15.4.2(d). The bond angle $\mathrm{Mn}-\mathrm{P}-\mathrm{Mn}$ is $138^{\circ}$.

## (4) Coordination number 4

This very common coordination number usually leads to a tetrahedral configuration for phosphoric acid, phosphates, and many phosphorus(V) compounds. In these compounds, the $\mathrm{P}(\mathrm{V})$ atom forms one double bond and three single bonds with other atoms. Figure 15.4.2(e) shows the structure of $\mathrm{P}_{4} \mathrm{O}_{10}$, whose symmetry is $T_{\mathrm{d}}$. The length of the terminal $\mathrm{P}=\mathrm{O}$ bond is 143 pm , and the bridging $\mathrm{P}-\mathrm{O}$ bond is 160 pm . The bond angle $\mathrm{O}-\mathrm{P}-\mathrm{O}$ is $102^{\circ}$, and $\mathrm{P}-\mathrm{O}-\mathrm{P}$ is $123^{\circ}$.

The compound $\mathrm{P}_{4} \mathrm{O}_{10}$, known as "phosphorus pentoxide," is the most common and most important oxide of phosphorus. This compound exists in three modifications. When phosphorus burns in air and condenses rapidly from the
vapor, the common hexagonal $(\mathrm{H})$ form of $\mathrm{P}_{4} \mathrm{O}_{10}$ is obtained. The H form is metastable and can be transformed into a metastable orthorhombic $(\mathrm{O})$ form by heating for 2 h at $400^{\circ} \mathrm{C}$, and into a stable orthorhombic ( $\mathrm{O}^{\prime}$ ) form by heating for 24 h at $450^{\circ} \mathrm{C}$. All three modifications undergo hydrolysis in cold water to give phosphoric acid, $\mathrm{H}_{3} \mathrm{PO}_{4}$.

Square-planar geometry of the P atom occurs in the compound $\left[\mathrm{P}\left\{\mathrm{Zr}(\mathrm{H}) \mathrm{Cp}_{2}\right\}_{4}\right]\left[\mathrm{BPh}_{4}\right]$. Figure 15.4.2(f) shows the structure of $\mathrm{P}\left\{\mathrm{Zr}(\mathrm{H}) \mathrm{Cp}_{2}\right\}_{4}^{+}$, in which the $\mathrm{Zr}-\mathrm{P}-\mathrm{Zr}$ angles are very close to $90^{\circ}$, and the bridging hydrogens and the Zr atoms form a nearly planar eight-membered ring that encircles the central P atom.

## (5) Coordination number 5

Figure 15.4.2(g) shows the structure of $\mathrm{Os}_{5}(\mathrm{CO})_{15}\left(\mu_{4}-\mathrm{POMe}\right)$, in which five Os atoms constitute a square-pyramidal cluster. Each Os atom is coordinated by three CO ligands, and only the four basal Os atoms are bonded to the apical P atom.

Various structures have been found for phosphorus pentahalides:
(a) The molecular structure of $\mathrm{PF}_{5}$ is trigonal bipyramidal, as shown in Fig. 15.4.2(h). The axial P-F bond length is 158 pm , which is longer than the equatorial $\mathrm{P}-\mathrm{F}$ bond length of 153 pm .
(b) In the gaseous phase, $\mathrm{PCl}_{5}$ is trigonal bipyramidal with axial $\mathrm{P}-\mathrm{Cl}_{\mathrm{ax}}$ bond length 214 pm and equatorial $\mathrm{P}-\mathrm{Cl}_{\mathrm{eq}}$ bond length 202 pm . In the crystalline phase, $\mathrm{PCl}_{5}$ consists of a packing of tetrahedral $\left[\mathrm{PCl}_{4}\right]^{+}$and octahedral $\left[\mathrm{PCl}_{6}\right]^{-}$ions; in the latter anion shown in Fig. 15.4.2(i), the $\mathrm{P}-\mathrm{Cl}$ bond length is 208 pm .
(c) In the crystalline phase, $\mathrm{PBr}_{5}$ consist of a packing of $\left[\mathrm{PBr}_{4}\right]^{+}$and $\mathrm{Br}^{-}$. Owing to steric overcrowding, $\left[\mathrm{PBr}_{6}\right]^{-}$cannot be formed by grouping six bulky Br atoms surrounding a relatively small P atom.
(d) There is as yet no evidence for the existence of $\mathrm{PI}_{5}$.

## (6) Coordination number $\geq 6$

In each of the structures shown in Figs. 15.4.2(j)-(p), the transition-metal atoms form a polyhedron around the P atom, which donates five valence electrons to stabilize the metal cluster.

### 15.5 Structure and bonding in phosphorus-nitrogen and phosphorus-carbon compounds

### 15.5.1 Types of $\mathrm{P}-\mathrm{N}$ bonds

When phosphorus and nitrogen atoms are directly bonded, they form one of the most intriguing and chemically diverse linkages in inorganic chemistry. A convenient classification of phosphorus-nitrogen compounds can be made on the basis of formal bonding. Azaphosphorus compounds containing the $\mathrm{P}-\mathrm{N}$ group are known as phosphazanes, those containing the $\mathrm{P}=\mathrm{N}$ group are

Table 15.5.1. The common types of phosphorus-nitrogen bonds*
Phosphazanes

* The hybridization of the P atom is enclosed in parentheses. The symbols $\sigma$ and $\lambda$ represent the coordination number and bonding number of P atoms.
phosphazenes, and those with the $\mathrm{P} \equiv \mathrm{N}$ group are phosphazynes. The common types of phosphorus-nitrogen bonds of these three classes of compounds are displayed in Table 15.5.1.

Phosphazynes are rare. The bond length of the diatomic molecule $\mathrm{P} \equiv \mathrm{N}$ is 149 pm . The first stable compound containing the $\mathrm{P} \equiv \mathrm{N}$ group is $[\mathrm{P} \equiv \mathrm{N}-$ $\mathrm{R}]^{+}\left[\mathrm{AlCl}_{4}\right]^{-},\left[\mathrm{R}=\mathrm{C}_{6} \mathrm{H}_{2}\left(2,4,6-{ }^{t} \mathrm{Bu}_{3}\right)\right]$, in which the length of the $\mathrm{P} \equiv \mathrm{N}$ bond is 147.5 pm .

### 15.5.2 Phosphazanes

Some examples of phosphazanes are described below according to the types of $\mathrm{P}-\mathrm{N}$ bonds.

In this bonding type, the P atom uses its $\mathrm{sp}^{2}$ hybrid orbitals, one of which accommodates a lone pair. A bent molecular structure of this type

## Structural Chemistry of Selected Elements

is found for $\left({ }^{t} \operatorname{Pr}_{2} \mathrm{~N}\right)_{2} \mathrm{P}^{+}$:

The bond length of $\mathrm{P}-\mathrm{N}$ is 161.2 pm , shorter than the standard $\mathrm{P}-\mathrm{N}$ singlebond distance of 177 pm observed in $\mathrm{H}_{3} \mathrm{~N}-\mathrm{PO}_{3}$, which does not have a lone pair on the N atom. The bond angle $\mathrm{N}-\mathrm{P}-\mathrm{N}$ is $115^{\circ}$, smaller than idealized $120^{\circ}$, due to the repulsion of the lone pairs.
(2)

The configuration of most $\mathrm{R}_{2} \mathrm{P}-\mathrm{NR}_{2}$ compounds is represented by $\mathrm{F}_{2} \mathrm{P}-\mathrm{NMe}_{2}$, which features a short $\mathrm{P}-\mathrm{N}$ distance ( 162.8 pm ) and trigonal planar arrangement ( $\mathrm{sp}^{2}$ hybridization) at the N atom. The plane defined by the $\mathrm{C}_{2} \mathrm{~N}$ unit bisects the $\mathrm{F}-\mathrm{P}-\mathrm{F}$ angle. This configuration minimizes steric repulsion between the substituents on P and N and also orients the lone pairs on the P and N atoms at a dihedral angle of about $90^{\circ}$, as shown in Fig. 15.5.1(a).
The geometry of the molecule and the short $\mathrm{P}-\mathrm{N}$ distance indicate that there is $\pi$ bonding between the P and N atoms. In the molecule, the $z$ axis is perpendicular to the $\mathrm{PNC}_{2}$ plane and the $x$ axis lies parallel to the $\mathrm{P}-\mathrm{N}$ bond. The $\mathrm{p}_{z}(\mathrm{~N})$ orbital with a lone pair and the empty $\mathrm{d}_{x z}(\mathrm{P})$ orbital overlap to form a $\pi$ bond, as shown in Fig. 15.5.1(b).

The structure of $\mathrm{F}_{2} \mathrm{PNH}_{2}$ resembles that of $\mathrm{F}_{2} \mathrm{PNMe}_{2}$ with a $\mathrm{P}-\mathrm{NH}_{2}$ bond distance of 166 pm .
(3) $>\mathrm{P}^{+}-\mathrm{N}^{-}$

Many compounds contain formally a single-bonded $\mathrm{P}-\mathrm{N}$ group, such as the cation $\left[\mathrm{PCl}_{2}\left(\mathrm{NMe}_{2}\right)_{2}\right]^{+}$in crystalline $\left[\mathrm{PCl}_{2}\left(\mathrm{NMe}_{2}\right)_{2}\right]\left(\mathrm{SbCl}_{6}\right)$, the cation $\left[\mathrm{P}\left(\mathrm{NH}_{2}\right)_{4}\right]^{+}$, and the anion $\left[\mathrm{P}(\mathrm{NR})_{4}\right]^{3-}$. The bond length of $\mathrm{P}-\mathrm{N}$ in $\left[\mathrm{P}\left(\mathrm{NH}_{2}\right)_{4}\right]^{+}$ is 160 pm , and that in $\left[\mathrm{P}(\mathrm{NR})_{4}\right]^{3-}$ is 164.5 pm .
(4)

An important group of compounds such as $\left(\mathrm{Me}_{2} \mathrm{~N}\right)_{2} \mathrm{POCl},\left(\mathrm{Me}_{2} \mathrm{~N}\right) \mathrm{POCl}_{2}$, and $\left(\mathrm{R}_{2} \mathrm{~N}\right)_{3} \mathrm{PO}$ possess this bonding type. For example, $\left(\mathrm{Me}_{2} \mathrm{~N}\right)_{3} \mathrm{PO}$ is a colorless

Fig. 15.5.1.
(a) Molecular structure of $\mathrm{F}_{2} \mathrm{P}-\mathrm{NMe}_{2}$, (b) overlap between the $\mathrm{d}_{x z}$ orbital of the P atom and the $\mathrm{p}_{z}$ orbital of the N atom.
mobile liquid which is miscible with water in all proportions. It forms an adduct with $\mathrm{HCCl}_{3}$, dissolves ionic compounds, and can dissolve alkali metals to give blue paramagnetic solutions which are strong reducing agents.

The compound $\mathrm{F}_{4} \mathrm{P}-\mathrm{NEt}_{2}$ has this bonding type, in which the P atom uses $\mathrm{sp}^{3} \mathrm{~d}$ hybrid orbitals.

The phosphatranes that have this bonding type are analogs of silatranes. The cage molecule shown on the right is a trigonal bipyramidal five-coordinated phosphazane with a rather long $\mathrm{P}-\mathrm{N}$ bond.

The adduct $\mathrm{F}_{5} \mathrm{P} \leftarrow \mathrm{NH}_{3}$ is an octahedral six-coordinated phosphanane, in which the $\mathrm{P}-\mathrm{N}$ bond length is 184.2 pm . In another example, $\mathrm{Cl}_{5} \mathrm{P} \longleftarrow \mathrm{N}^{\prime}$ bond length is 202.1 pm , which is longer than the former. This difference is due to the high electronegativity of F , which renders the $\mathrm{F}_{5} \mathrm{P}$ group a better acceptor as compared to $\mathrm{Cl}_{5} \mathrm{P}$.

### 15.5.3 Phosphazenes

Phosphazenes, formerly known as phosphonitrilic compounds, are characterized by the presence of the group $\mathrm{P}=\mathrm{N}$. Known compounds, particularly those containing the $\searrow_{\mathrm{P}}=\mathrm{N}-$ group, are very numerous and they have important potential applications.

## (1) Bonding types of phosphazenes

(a) Containing $-\mathrm{P}=\mathrm{N}$ - bonding type

In this bonding type, the P atom uses $\mathrm{sp}^{2}$ hybrid orbitals, one of which contains the lone-pair electrons. This type of phosphazene compounds exists in a bent configuration. For example, the structure of $\left(\mathrm{SiMe}_{3}\right)_{2} \mathrm{NPN}\left(\mathrm{SiMe}_{3}\right)$ is shown below:

(b) Containing ${ }_{\mathrm{P}=\mathrm{N}-\text { bonding type }}$

The compound $\left(\mathrm{Me}_{3} \mathrm{Si}_{2} \mathrm{~N}-\mathrm{P}\left(\mathrm{NSiMe}_{3}\right)_{2}\right.$ belongs to this type, as shown below:

(c) Containing $\underset{\succ}{\backslash} \mathrm{P}=\mathrm{N}-$ bonding type

The simplest compound of this type is iminophosphorane, $\mathrm{H}_{3} \mathrm{P}=\mathrm{NH}$, whose derivatives are very numerous, including $\mathrm{R}_{3} \mathrm{P}=\mathrm{NR}^{\prime}, \mathrm{Cl}_{3} \mathrm{P}=\mathrm{NR},(\mathrm{RO})_{3} \mathrm{P}=\mathrm{NR}^{\prime}$, and $\mathrm{Ph}_{3} \mathrm{P}=\mathrm{NR}$. In these compounds the P atom uses its $\mathrm{sp}^{3}$ hybrid orbitals to form four $\sigma$ bonds, and is also strengthened by $\mathrm{d} \pi-\mathrm{p} \pi$ overlap with N and other atoms.

## (2) Structure and bonding of cyclic phosphazenes

The main products of refluxing a mixture of $\mathrm{PCl}_{5}$ and $\mathrm{NH}_{4} \mathrm{Cl}$ using tetrachloroethane as solvent are the cyclic trimer $\left(\mathrm{PNCl}_{2}\right)_{3}$ and tetramer $\left(\mathrm{PNCl}_{2}\right)_{4}$, which are stable white crystalline compounds that can be isolated and purified by recrystallization from nonpolar solvents.

The trimer $\left(\mathrm{PNCl}_{2}\right)_{3}$ has a planar six-membered ring structure of $D_{3 \mathrm{~h}}$ symmetry with the six Cl atoms disposed symmetrically above and below the plane of the ring. The $\mathrm{P}-\mathrm{N}$ bonds within the ring are of the same length, 158 pm , and the interior angles are all close to $120^{\circ}$. The $\mathrm{Cl}-\mathrm{P}-\mathrm{Cl}$ planes are perpendicular to the plane of the central ring, and the $\mathrm{Cl}-\mathrm{P}-\mathrm{Cl}$ angle is $120^{\circ}$. Figure 15.5 .2 shows the structures of $\left(\mathrm{PNCl}_{2}\right)_{3}$ and chair-like $\left(\mathrm{PNCl}_{2}\right)_{4}$.

The shortness and equality of the $\mathrm{P}-\mathrm{N}$ bond lengths in $\left(\mathrm{PNCl}_{2}\right)_{3}$ arise from electron delocalization involving the d orbitals of the P atoms and the p orbitals of the N atoms. In such a system, the $\sigma$ bonds formed from phosphorus $\mathrm{sp}^{3}$ orbitals overlapping with the nitrogen $\mathrm{sp}^{2}$ orbitals are enhanced by $\pi$ bonding between the nitrogen $\mathrm{p}_{z}$ orbitals and the phosphorus d orbitals.

In $\left(\mathrm{PNCl}_{2}\right)_{3}$, the $\pi$ bonding occurs over the entire ring. Firstly, $\mathrm{d} \pi-\mathrm{p} \pi$ overlap occurs between the nitrogen $\mathrm{p}_{z}$ orbital ( $z$ axis perpendicular to the ring plane) and the $\mathrm{d}_{x z}$ orbital of phosphorus. Figure 15.5.3(a) shows the orientation of one $\mathrm{d}_{x z}$ orbital of the P atom and two $\mathrm{p}_{z}$ orbitals of neighbor N atoms. Figure 15.5.3(b) shows a projection of the overlap of $\mathrm{d}_{x z}$ with the $\mathrm{p}_{z}$ orbitals. Secondly, "in-plane" electron delocalization probably arises from overlap of the

(b)

Fig. 15.5.3.
$\mathrm{d} \pi-\mathrm{p} \pi$ Bonding in the ring of $\left(\mathrm{PNCl}_{2}\right)_{3}$ : (a) orientation of $\mathrm{d}_{x z}$ of P atom and $\mathrm{p}_{z}$ of N atom; (b) overlap of $\mathrm{d}_{x z}$ and $\mathrm{p}_{z}$; (c) overlap of $\mathrm{d}_{x^{2}-y^{2}}$ of P atom and lone pair ( $\mathrm{sp}^{2}$ ) of N atom; (d) possible mismatch of the $\mathrm{d}_{x z}$ orbital of P atom and $\mathrm{p}_{z}$ orbital of the N atom.
lone-pair orbitals on nitrogen with the $\mathrm{d}_{x^{2}-y^{2}}$ orbitals on phosphorus, forming additional $\pi^{\prime}$ bonds in the plane of the ring. Fig. 15.5.3(c) shows the $\mathrm{d}_{x^{2}-y^{2}}$ of P overlapping with the lone-pair ( $\mathrm{sp}^{2}$ ) orbitals of two adjacent N atoms. Thirdly, the $\mathrm{d}_{z^{2}}$ orbitals of P atoms overlap with the p orbitals of the exocyclic Cl atoms. Fig. 15.5.3(d) shows that electron delocalization around the ring is hindered by a mismatch of orbital symmetry. A simplified description of the bonding in this molecule based on the group-theoretic method is given in Chapter 7 .

The geometric disposition of the d orbitals in $\mathrm{d} \pi-\mathrm{p} \pi$ systems allows puckering and accounts for the variety of ring conformations found among larger cyclic phosphazene compounds, such as $\left(\mathrm{PNCl}_{2}\right)_{4}$.

Of the five binary phosphorus-nitrogen molecules described in the literature, namely $\mathrm{P}_{4} \mathrm{~N}_{4}, \mathrm{P}\left(\mathrm{N}_{3}\right)_{3}, \mathrm{P}\left(\mathrm{N}_{3}\right)_{5}$, the anion in the ionic compound $\left(\mathrm{N}_{5}\right)^{+}\left[\mathrm{P}\left(\mathrm{N}_{3}\right)_{6}\right]^{-}$, and the phosphazene derivative $\left[\mathrm{PN}\left(\mathrm{N}_{3}\right)_{2}\right]_{3}$, only the last has been fully structurally characterized. These compounds are difficult to isolate and handle owing to their highly endothermic character and extremely low energy barriers, which often lead to uncontrollable explosive decomposition. Single-crystal X-ray analysis of $\left[\mathrm{PN}\left(\mathrm{N}_{3}\right)_{2}\right]_{3}$ conducted in 2006 showed that it is a structural analog of $\left[\mathrm{PNCl}_{2}\right]_{3}$, with three azide groups oriented nearly parallel to the phosphazene ring and the other three nearly perpendicular to the ring.

A hybrid borazine-phosphazine ring system has been found in
$\left[\mathrm{ClBNMePCl} 2_{2} \mathrm{NPCl}_{2} \mathrm{NMe}\right]\left(\mathrm{GaCl}_{4}\right)$; an X-ray study revealed that the $6 \pi$ aromatic cation (structural formula shown on the right) is virtually planar with $\mathrm{B}-\mathrm{N}$ bond lengths of 143.6(9) and $142.2(10) \mathrm{pm}$, which are close to those found in borazines ( 143 pm ).

All phosphazenes, whether cyclic or chain-like, contain the formally unsaturated group $\mathrm{P}=\mathrm{N}$ with four-coordinate P and two-coordinate N atoms. Based on available experimental data, the following generalizations may be made in regard to their structure and properties:
(a) The rings and chains are very stable.
(b) The skeletal interatomic distances are equal within the ring or along the chain, unless there is different substitution at various P atoms.
(c) The $\mathrm{P}-\mathrm{N}$ distances are shorter than expected for a covalent single bond $(\sim 177 \mathrm{pm})$ and are usually in the range $158 \pm 2 \mathrm{pm}$.
(d) The $\mathrm{N}-\mathrm{P}-\mathrm{N}$ angles are usually in the range $120 \pm 2^{\circ}$; but the $\mathrm{P}-\mathrm{N}-\mathrm{P}$ angles in various compounds span the range $120^{\circ}-148^{\circ}$.
(e) Skeletal N atoms are weakly basic and can coordinate to metals or be protonated, especially when the P atoms carry electron-releasing groups.
(f) Unlike many aromatic systems, the phosphazene skeleton is difficult to reduce electrochemically.
(g) Spectral effects associated with organic $\pi$ systems are not exhibited.

### 15.5.4 Bonding types in phosphorus-carbon compounds

Phosphorus and carbon are diagonal relatives in the Periodic Table. The diagonal analogy stresses the electronegativity of the element ( C 2.5 vs P 2.2 ) which governs its ability to release or accept electrons. This property controls the reactivity of any species containing the element. This section covers the types of phosphorus-carbon bonds and the structures of representative species.

## (1) Phosphinidenes and phosphinidene complexes, $\frac{\searrow}{\nearrow} \mathrm{C}-\ddot{\mathrm{P}}$.

Phosphinidenes (recommended IUPAC name: phosphanylidenes) are unstable species and analogous to the carbenes. The parent compound H-P is a sixelectron species that is still unknown, but its organic derivatives can give rise to seven different types of complexes, as listed in Table 15.5.2.
(2) Phosphaalkenes, $\mathrm{R}^{1} \mathrm{R}^{2} \mathrm{C}=\mathrm{PR}^{3}$

Phosphaalkenes are tervalent phosphorus derivatives with a double bond between carbon and phosphorus. The observed $\mathrm{P}=\mathrm{C}$ bond lengths range from 161 to 171 pm (average 167 pm ), appreciably shorter than the single $\mathrm{P}-\mathrm{C}$ bond length of 185 pm .

Phosphaalkenes may coordinate to transition-metal fragments in various ways:
(a) $\eta^{1}$ mode via the lone pair on P atom. An example is

$$
\mathrm{P}=\mathrm{C} \quad 167.9 \mathrm{pm}
$$

Types

* In the complex Mes- $\mathrm{P}=\mathrm{Mo}(\mathrm{Cp})_{2}, \mathrm{P}=\mathrm{Mo} 237.0 \mathrm{pm}$, $\mathrm{Mo}-\mathrm{P}-\mathrm{C} 115.8^{\circ}$.
${ }^{\dagger}$ In the complex Mes- $\mathrm{P} \equiv \mathrm{WCl}_{2}(\mathrm{CO})\left(\mathrm{PMePh}_{2}\right), \mathrm{P} \equiv \mathrm{W} 216.9 \mathrm{pm}, \mathrm{C}-\mathrm{P}-\mathrm{W}$ $168.2^{\circ}$.
(b) $\eta^{2}$ mode via the $\pi$ bond electrons. An example is

In $\eta^{2}$ complexes the $\mathrm{P}-\mathrm{C}$ bond length is longer than that in $\eta^{1}$ complexes or the free ligands.
(c) $\eta^{1}, \eta^{2}$ mode via both the lone pair and $\pi$ bond electrons. An example is

[^7] triple bond. Figure 15.5.4 shows the structure of ${ }^{t} \mathrm{Bu}-\mathrm{C} \equiv \mathrm{P}$, whose $\mathrm{P} \equiv \mathrm{C}$ bond

Fig. 15.5.4.
Structure of ${ }^{t} \mathrm{Bu}-\mathrm{C} \equiv \mathrm{P}$ (bond lengths in $\mathrm{pm})$.

Table 15.5.3. Coordination modes of phosphaalkynes

| Coordination mode | Example and structure |
| :---: | :---: |
| $\eta^{1} \quad \mathrm{R}-\mathrm{C} \equiv \mathrm{P} \longrightarrow \mathrm{M}$ | $\begin{gathered} {\left[{ }^{t} \mathrm{Bu}-\mathrm{C} \equiv \mathrm{P}-\mathrm{Fe}(\mathrm{H})(\mathrm{dppe})_{2}\right]\left[\mathrm{BPh}_{4}\right]} \\ \mathrm{C} \equiv \mathrm{P} 151.2 \mathrm{pm} \end{gathered}$ |
|  |  |
| $\eta^{1}, \eta^{2} \quad \mathrm{R}-\mathrm{C} \underset{\overline{\eta_{\square}}}{ } \mathrm{P} \longrightarrow \mathrm{M}$ |  |
| 4 e | ${ }^{t} \mathrm{BuCP}\left[\mathrm{Fe}_{2}(\mathrm{CO})_{5}\left(\mathrm{PPh}_{2} \mathrm{CH}_{2} \mathrm{PPh}_{2}\right)\right]$ <br> [Fig. 15.5.5(a)] |
| $6 e$ | ${ }^{t} \mathrm{BuCP}\left[\mathrm{W}(\mathrm{CO})_{5}\right]\left[\mathrm{Co}_{2}(\mathrm{CO})_{6}\right]$ <br> [Fig. 15.5.5(b)] |

is very short $(154.8 \mathrm{pm})$, and the electronic ionization energies $\left[I_{1}(\pi \mathrm{MO})=\right.$ $9.61 \mathrm{eV}, I_{2}(\mathrm{P}$ lone pair $\left.)=11.44 \mathrm{eV}\right]$ are low, suggesting that it may have a chemistry closely related to that of the alkynes.

Phosphaalkynes have a rich coordination chemistry, in which both the triple bond and the lone pair of the P atom can participate. Table 15.5.3 lists the coordination modes of phosphaalkynes, and two structures are shown in Fig. 15.5.5.

Fig. 15.5.5.
Structure of
(a) ${ }^{t} \mathrm{Bu}-\mathrm{CP}\left[\mathrm{Fe}_{2}(\mathrm{CO})_{5}\left(\mathrm{PPh}_{2} \mathrm{CH}_{2} \mathrm{PPh}_{2}\right)\right]$ and (b) ${ }^{t} \mathrm{Bu}-\mathrm{CP}\left[\mathrm{W}(\mathrm{CO})_{5}\right]\left[\mathrm{Co}_{2}(\mathrm{CO})_{6}\right]$.

Some oligomers of the phosphaalkynes ${ }^{t} \mathrm{BuCP}$ have been characterized. The phosphaalkyne cyclotetramer exists in several isomeric forms, whose structures are shown in Fig. 15.5.6(a) to Fig. 15.5.6(e). In cubane-like $\mathrm{P}_{4} \mathrm{C}_{4}{ }^{t} \mathrm{Bu}_{4}$, the $\mathrm{P}-\mathrm{C}$ bond lengths are all identical ( 188 pm ), and are typical for single bonds. The angle at P is reduced from the idealized $90^{\circ}$ to $85.6^{\circ}$, while that at C is widened to $94.4^{\circ}$.

The phosphaalkyne pentamer $\mathrm{P}_{5} \mathrm{C}_{5}{ }^{t} \mathrm{Bu}_{5}$ has the cage structure shown in Fig. 15.5.6(f), which can be derived from the tetramer by replacing one corner C atom of the "cube" by a $\mathrm{C}_{2} \mathrm{P}$ triangular fragment.

(b) $\left[\mathrm{RuH}(\mathrm{dppe})_{2}(\mathrm{C} \equiv \mathrm{P})\right], \mathrm{C} \equiv \mathrm{P}_{1}$
157.3(2), Ru-C 205.7(2), Ru-P ${ }_{2}$ 233.42(5), Ru- $\mathrm{P}_{3}$ 233.15(5), Ru- $\mathrm{P}_{4}$ 232.22(5), Ru-P $233.96(4)$.

## (4) Cyaphide $\mathbf{P} \equiv \mathbf{C}^{-}$

The quest for cyaphide, the phosphorus homolog of cyanide, as a ligand in a stable metal complex came to a satisfactory conclusion in 2006. The pair of related complexes $\left[\mathrm{RuH}(\mathrm{dppe})_{2}\left(\mathrm{Ph}_{3} \mathrm{SiC} \equiv \mathrm{P}\right)\right] \mathrm{OTf}$ and $\left[\mathrm{RuH}(\mathrm{dppe})_{2}(\mathrm{C} \equiv \mathrm{P})\right]$ were obtained via a new synthetic route and structurally characterized by Xray crystallography. Their molecular geometries are displayed in Fig. 15.5.7. As expected, the $\mathrm{Si}-\mathrm{C} \equiv \mathrm{P}$ and $\mathrm{P} \equiv \mathrm{C}^{-}$ligands are $P$ - and $C$-coordinated to the $\mathrm{Ru}(\mathrm{II})$ center, respectively. The long $\mathrm{C} \equiv \mathrm{P}$ bond in the cyaphide complex likely arises from back donation from Ru to the $\pi^{*}$ orbitals of the ligand.

## Structural Chemistry of Selected Elements

Table 15.5.4. Coordination modes of diphosphenes
Coordination mode Example and structure
$\mu\left(\eta^{1}: \eta^{1}\right)$

### 15.5.5 $\pi$-Coordination complexes of phosphorus-carbon compounds

## (1) Diphosphenes ( $\mathbf{R}-\mathbf{P}=\mathbf{P}-\mathbf{R}$ )

Diphosphenes contain the $-\mathrm{P}=\mathrm{P}$ - group, the majority of which adopt a transconfiguration. For example, the stable compound

$$
\left(\mathrm{Ar}=2,4,6-{ }^{t} \mathrm{Bu}_{3} \mathrm{C}_{6} \mathrm{H}_{2}\right)
$$

exhibits the trans form with a $\mathrm{P}=\mathrm{P}$ bond length of 203.4 pm .
Various coordination modes of diphosphenes toward transition metals involve $\sigma$ and $\pi$ interaction with the metal center, as listed in Table 15.5.4.

## (2) $\eta^{3}$-Phosphaallyl and $\eta^{3}$-phosphirenes

The phosphaallyl anions $\qquad$ ) and the phosphirenes which contain the group ( metals. Some examples are shown below:

## (3) $\eta^{4}$-Phosphadienes and diphosphacyclobutadienes

Phosphadienes,

 that can form complexes with transition metals, for example:

Many metal complexes containing the 1,2 or 1,3-diphosphacyclobutadiene ring have been characterized, and Fig. 15.5.8 shows the structures of some examples.

Interestingly, it has proved impossible to displace the $\eta^{4}$-ligated $\left(\mathrm{P}_{2} \mathrm{C}_{2}{ }^{t} \mathrm{Bu}_{2}\right)$ rings from any of the above complexes, in contrast with the behavior of the analogous $\eta^{4}$-ligated cyclobutadiene ring complexes. This may be attributed to the significantly stronger $\pi$ interaction between the metal and the phosphoruscontaining ring system.

## (4) $\eta^{5}$-Phospholyl complexes

The phospholyl unit, which contains one to five P atoms, is an analog of the cyclopentadienyl ligand. Figures 15.5 .9 (a) to 15.5 .9 (f) show some phosphametallocenes, including sandwich, half-sandwich, and tilted structures. Figures $15.5 .9(\mathrm{~g})$ to $15.5 .9(\mathrm{j})$ show some complex phosphametallocenes, in which only essential parts of the structure are displayed. Figure 15.5.9(k) shows the supramolecular structure of $\left[\mathrm{Sm}\left(\eta^{5}-\mathrm{PC}_{4} \mathrm{Me}_{4}\right)_{2}\left(\eta^{1}-\mathrm{PC}_{4} \mathrm{Me}_{4}\right) \mathrm{K}\left(\eta^{6}-\right.\right.$ $\left.\left.\mathrm{C}_{6} \mathrm{H}_{5} \mathrm{Me}\right)\right] \mathrm{Cl}$.

Fig. 15.5.8.
Structure of diphosphacyclobutadiene complexes: (a) $\mathrm{Fe}(\mathrm{CO})_{3}\left[\eta^{4}-\mathrm{P}_{2} \mathrm{C}_{2}{ }^{t} \mathrm{Bu} \mathrm{u}_{2}\right]$, (b) $\mathrm{Ni}\left[\eta^{4}-\mathrm{P}_{2} \mathrm{C}_{2}{ }^{t} \mathrm{Bu} u_{2}\right]_{2}$, (c) $\mathrm{Mo}\left[\eta^{4}-\mathrm{P}_{2} \mathrm{C}_{2}{ }^{t} \mathrm{Bu}_{2}\right]_{3}$, (d) $\mathrm{Ti}\left(\eta^{4}-\mathrm{P}_{2} \mathrm{C}_{2}{ }^{t} \mathrm{Bu}_{2}\right)\left(\eta^{8}-\mathrm{COT}\right)$, (e) $\mathrm{Co}\left(\eta^{4}-\mathrm{P}_{2} \mathrm{C}_{2}{ }^{t} \mathrm{Bu}_{2}\right)\left(\eta^{5}-\mathrm{P}_{2} \mathrm{C}_{3}{ }^{t} \mathrm{Bu}_{3}\right)$, and (f) $\mathrm{Rh}\left(\eta^{4}-\mathrm{P}_{2} \mathrm{C}_{2}{ }^{t} \mathrm{Bu}_{2}\right)\left(\eta^{5}-\mathrm{C}_{2} \mathrm{~B}_{9} \mathrm{H}_{11}\right)$.

## (5) $\quad \boldsymbol{\eta}^{\mathbf{6}}$-Phosphinine complexes

The phosphinine rings $\left(\mathrm{PC}_{5} \mathrm{R}_{5}, \mathrm{P}_{2} \mathrm{C}_{4} \mathrm{R}_{4}, \ldots \mathrm{P}_{6}\right)$ are analogs of benzene and form sandwich structures with the transition metals. In $\eta^{6}$-phosphinine complexes, the phosphinine rings are all planar.

### 15.6 Structural chemistry of $\mathbf{A s}, \mathrm{Sb}$, and Bi

### 15.6.1 Stereochemistry of $\mathrm{As}, \mathrm{Sb}$, and Bi

The series $\mathrm{As}, \mathrm{Sb}$, and Bi show a gradation of properties from non-metallic to metallic, but the discrete molecules and ions of these elements exhibit similar stereochemistry, as listed in Table 15.6.1 and shown in Fig. 15.6.1. The presence of a lone pair (denoted by E in the table) in these atoms implies $\mathrm{M}^{\mathrm{III}}$; otherwise it is $\mathrm{M}^{\mathrm{V}}$.

Many compounds of the $\mathrm{MX}_{3} \mathrm{E}$ type have been prepared, and all 12 trihalides of $\mathrm{As}, \mathrm{Sb}$, and Bi are well known and available commercially. In either the gaseous or solid state, the lone pair causes the bond angles to be less than the ideal tetrahedral angle in every case. For example, $\mathrm{SbCl}_{3}$ in the gas phase has bond length 233 pm and bond angle $97.1^{\circ}$, and in the crystal it has three short $\mathrm{Sb}-\mathrm{Cl} 236 \mathrm{pm}$ and three long $\mathrm{Sb} \cdots \mathrm{Cl} \geq 350 \mathrm{pm}$, and the bond angle $\mathrm{Cl}-\mathrm{Sb}-\mathrm{Cl}$ is $95^{\circ}$. The cations of $\mathrm{MX}_{4}^{+}$are all tetrahedral. The anion $\mathrm{SbF}_{4}^{-}$is known in the monomeric form and has the $\mathrm{MX}_{4} \mathrm{E}$ type disphenoidal geometry. In the dimer $\mathrm{Sb}_{2} \mathrm{~F}_{7}^{-}$both Sb atoms have a disphenoidal geometry with the bridging fluorine in one axial position.

Table 15.6.1. Stereochemistry of As , Sb , and Bi

| Total number of electron pairs | General formula* | Geometry | Example (refer to Fig. 15.6.1) |
| :---: | :---: | :--- | :--- |
| 4 | $\mathrm{MX}_{3} \mathrm{E}$ | Trigonal pyramidal | $\mathrm{AsCl}_{3}, \mathrm{SbCl}_{3}, \mathrm{BiCl}_{3}(\mathrm{a})$ |
| 4 | $\mathrm{MX}_{4}$ | Tetrahedral | $\mathrm{AsCl}_{4}^{+}, \mathrm{SbCl}_{4}^{+}(\mathrm{b})$ |
| 5 | $\mathrm{MX}_{4} \mathrm{E}$ | Disphenoidal | $\mathrm{SbF}_{4}^{-}(\mathrm{c})$ |
| 5 | $\mathrm{MX}_{5}$ | Trigonal bipyramidal | $\mathrm{AsF}_{5}, \mathrm{SbCl}_{5}, \mathrm{BiF}_{5}(\mathrm{~d})$ |
| 5 | $\mathrm{MX}_{5}$ | Square pyramidal | $\mathrm{Sb}_{\left(\mathrm{C}_{6} \mathrm{H}_{5}\right) 5, \mathrm{Bi}\left(\mathrm{C}_{6} \mathrm{H}_{5}\right) 5(\mathrm{e})}$ |
| 6 | $\mathrm{MX}_{5} \mathrm{E}$ | Square pyramidal | $\mathrm{SbCl}_{5}^{2-}(\mathrm{f})$ |
| 6 | $\mathrm{MX}_{6}$ | Octahedral | $\mathrm{SbBr}_{6}^{-}(\mathrm{g})$ |
| 7 | $\mathrm{MX}_{6} \mathrm{E}$ | Octahedral | $\mathrm{SbBr}_{6}^{3-}, \mathrm{BiBr}_{6}^{3-}(\mathrm{g})$ |

${ }^{*} \mathrm{M}=\mathrm{As}, \mathrm{Sb}$, or $\mathrm{Bi}, \mathrm{X}=$ ligand atom or group, $\mathrm{E}=$ lone pair.
(a) (a)
(b)

(c)

(f)

(a) $\mathrm{AsCl}_{3}$, (b) $\mathrm{AsCl}_{4}^{+}$, (c) $\mathrm{SbF}_{4}^{-}$, (d)
$\mathrm{SbCl}_{5}$, (e) $\mathrm{Bi}\left(\mathrm{C}_{6} \mathrm{H}_{5}\right)_{5}$, (f) $\mathrm{SbCl}_{5}^{2-}$, and
(g) $\mathrm{SbBr}_{6}^{3-}$ and $\mathrm{BiBr}_{6}^{3-}$.

Compounds of the $\mathrm{MX}_{5}$ type exhibit two geometries, trigonal bipyramidal (more common) and square pyramidal. In the trigonal bipyramidal molecules, the axial bonds are longer than the equatorial bonds. If there are different ligands, the more electronegative ones usually occupy the axial positions. The compounds $\mathrm{Bi}\left(\mathrm{C}_{6} \mathrm{H}_{5}\right)_{5}$ and $\mathrm{Sb}\left(\mathrm{C}_{6} \mathrm{H}_{5}\right)_{5}$ have a square-pyramidal shape, as shown in Fig. 15.6.1(e), for which the bond lengths and bond angles are as follows:

$$
\begin{array}{llll}
\mathrm{Bi}\left(\mathrm{C}_{6} \mathrm{H}_{5}\right)_{5}: & \mathrm{Bi}-\mathrm{C}_{\mathrm{ax}} 222.1 \mathrm{pm} & \mathrm{Bi}-\mathrm{C}_{\mathrm{ba}} 233.6 \mathrm{pm} & \mathrm{C}_{\mathrm{ax}}-\mathrm{Bi}-\mathrm{C}_{\mathrm{ba}} 101.6^{\circ} \\
\mathrm{Sb}\left(\mathrm{C}_{6} \mathrm{H}_{5}\right)_{5}: & \mathrm{Sb}-\mathrm{C}_{\mathrm{ax}} 211.5 \mathrm{pm} & \mathrm{Sb}-\mathrm{C}_{\mathrm{ba}} 221.6 \mathrm{pm} & \mathrm{C}_{\mathrm{ax}}-\mathrm{Sb}-\mathrm{C}_{\mathrm{ba}} 105.4^{\circ}
\end{array}
$$

The molecules of $\mathrm{MX}_{5} \mathrm{E}$ type, such as $\mathrm{SbF}_{5}^{2-}, \mathrm{BiCl}_{5}^{2-}$, and some oligolymeric anions $\left(\mathrm{SbF}_{4}\right)_{4}^{4-}$ and $\left(\mathrm{BiCl}_{4}\right)_{2}^{2-}$, have square-pyramidal geometry at each M atom. In these cases, the four ligands in the base of the square pyramid lie in a plane slightly above the central M atom, and the bond angles are all less than $90^{\circ}$ caused by the greater lone-pair repulsions.

The anions of the type $\mathrm{MX}_{6}$, such as $\mathrm{SbF}_{6}^{-}, \mathrm{SbBr}_{6}^{-}$, and $\mathrm{Sb}(\mathrm{OH})_{6}^{-}$, have the expected octahedral geometry. The anions of the type $\mathrm{MX}_{6} \mathrm{E}$, such as $\mathrm{SbBr}_{6}^{3-}$ and $\mathrm{BiBr}_{6}^{3-}$, frequently also have a regular octahedral structure. The undistorted nature of the $\mathrm{SbBr}_{6}^{3-}$ octahedral suggests that the lonepair is predominantly $5 \mathrm{~s}^{2}$, but in a sense it is still stereochemically active since the $\mathrm{Sb}-\mathrm{Br}$ distance in $\mathrm{Sb}^{\mathrm{III}} \mathrm{Br}_{6}^{3-}$ is 279.5 pm , which is longer than the distance $256.4 \mathrm{pm}^{\text {in }} \mathrm{Sb}^{\mathrm{V}} \mathrm{Br}_{6}^{-}$.

The bismuthonium ylide 4,4-dimethyl-2,6-dioxo-1-triphenylbismuthoniocyclohexane exhibits a distorted tetrahedral geometry with a $\mathrm{Bi}-\mathrm{C}_{\text {ylide }}$ bond length of $215.6 \mathrm{pm}, \mathrm{Bi}-\mathrm{C}_{\mathrm{Ph}}$ bond lengths in the range $221-2 \mathrm{pm}$, and a weak $\mathrm{Bi} \cdot$. O interaction of 301.9 pm with one of the carbonyl oxygen atoms (the other $\mathrm{Bi} \cdot$. O separation is 335.2 pm ). The X -ray data are consistent with the expectation that the negative charge resides mainly on a deprotonated enolic oxygen atom rather than on the ylidic carbon atom, whose 2 p orbital does not overlap effectively with the 6 d orbital of bismuth. Accordingly, formula I
is a faithful representation of the structure in preference to II, III, and IV, as displayed below:

I

II

III

IV

From 1995 onward, studies have led to the synthesis and structural characterization of stable tungsten complexes with a heavier Group 15 element functioning as a triple-bonded terminal ligand. In the series of complexes $\left[\left(\mathrm{CH}_{2} \mathrm{CH}_{2} \mathrm{NSiMe}_{3}\right)_{3} \mathrm{~N}\right] \mathrm{W} \equiv \mathrm{E}(\mathrm{E}=\mathrm{P}, \mathrm{As}, \mathrm{Sb})$, the tungsten atom exhibits a distorted trigonal bipyramidal coordination geometry with three equatorial N atoms and one N atom and the E atom occupying the axial positions. The molecular structure and $\mathrm{W} \equiv \mathrm{E}$ bond distances are shown below:

$$
\begin{array}{ll}
\mathrm{R}=\mathrm{SiMe}_{3} \\
\\
\mathrm{~W} \equiv \mathrm{P} & 216.2(4) \mathrm{pm} \\
\mathrm{~W} \equiv \mathrm{As} & 229.0(1) \mathrm{pm} \\
\mathrm{~W} \equiv \mathrm{Sb} & 252.6(2) \mathrm{pm}
\end{array}
$$

### 15.6.2 Metal-metal bonds and clusters

Many compounds containing M-M bonds or stable rings and clusters of Group 15 elements are known. Figures 15.6.2(a) to 15.6 .2(c) show the structures of some organometallic compounds of $\mathrm{As}, \mathrm{Sb}$, and Bi , which contain M-M bonds, and Figs. 15.6.2(d) to $15.6 .2(\mathrm{e})$ show the structures of naked cluster cations $\mathrm{Bi}_{n}^{m+}$, which are the components of some complex salts of bismuth. The structure of $\mathrm{As}_{6}\left(\mathrm{C}_{6} \mathrm{H}_{5}\right)_{6}$ illustrates the typical trigonal pyramidal environment of the As atom; the As-As bond length is 246 pm , in which the $\mathrm{As}_{6}$ ring adopts a chair conformation. In $\mathrm{Sb}_{4}\left(\eta^{1}-\mathrm{C}_{5} \mathrm{Me}_{4}\right)_{4}, \mathrm{Sb}_{4}$ forms a twisted ring, with $\mathrm{Sb}-\mathrm{Sb} 284 \mathrm{pm}$, and all $\mathrm{Sb}-\mathrm{Sb}-\mathrm{Sb}$ bond angles are acute. Tetrameric bis(trimethylsilyl)methylbismuthine $\left[\left(\mathrm{Me}_{3} \mathrm{Si}_{2}{ }_{2} \mathrm{CHBi}\right]_{4}\right.$ contains a folded four-membered metallacycle with fold angles of $112.6^{\circ}$ and $112.9^{\circ}$, $\mathrm{Bi}-\mathrm{Bi}$ bond lengths in the range $297.0-304.4 \mathrm{pm}$, and $\mathrm{Bi}-\mathrm{Bi}-\mathrm{Bi}$ angles in the range 79.0-79.9 . The discrete molecules $\mathrm{As}_{2} \mathrm{Ph}_{4}, \mathrm{Sb}_{2} \mathrm{Ph}_{4}$, and $\mathrm{Bi}_{2} \mathrm{Ph}_{4}$ all adopt the staggered conformation, and the bond lengths are $\mathrm{As}-\mathrm{As} 246 \mathrm{pm}, \mathrm{Sb}-\mathrm{Sb}$ 286 pm, and Bi-Bi 299 pm.

Dibismuthenes of the general formula $\mathrm{LBi}=\mathrm{BiL}$ can be synthesized when L is a bulky aryl ligand. The $\mathrm{LBi}=\mathrm{BiL}$ molecule is centrosymmetric and therefore exists in the trans configuration. For $\mathrm{L}=2,4$, 6-tris[bis(trimethylsilyl)methyl]phenyl, X-ray analysis of the dibismuthene
(a)

(b)

(c)

(d)

yielded a $\mathrm{Bi}=\mathrm{Bi}$ double-bond length of 282.1 pm and a $\mathrm{Bi}=\mathrm{Bi}-\mathrm{C}$ angle of $100.5^{\circ}$.

The structures of cationic bismuth clusters $\mathrm{Bi}_{5}^{3+}, \mathrm{Bi}_{8}^{2+}$, and $\mathrm{Bi}_{9}^{5+}$ are listed in Table 15.6.2.

Table 15.6.2. Cationic bismuth clusters

| Cation | Crystal | Structure | Symmetry |
| :--- | :--- | :--- | :--- |
| $\mathrm{Bi}_{5}^{3+}$ | $\mathrm{Bi}_{5}\left(\mathrm{AlCl}_{4}\right)_{3}$ | Trigonal bipyramidal | $D_{3 \mathrm{~h}}$ |
| $\mathrm{Bi}_{8}^{2+}$ | $\mathrm{Bi}_{8}\left(\mathrm{AlCl}_{4}\right)_{2}$ | Square antiprism | $D_{4 \mathrm{~h}}$ |
| $\mathrm{Bi}_{9}^{5+}$ | $\mathrm{Bi}_{24} \mathrm{Cl}_{28}$, or | Tricapped trigonal prism | $C_{3 \mathrm{~h}}\left(\sim D_{3 \mathrm{~h}}\right)$ |
|  | $\left(\mathrm{Bi}_{9}^{5+}\right)_{2}\left(\mathrm{BiCl}_{5}^{2-}\right)_{4}\left(\mathrm{Bi}_{2} \mathrm{Cl}_{8}^{2-}\right)$ |  |  |

Metalloid and intermetalloid clusters of Group 13 and 14 elements have been described in the two preceding chapters. For Group 15 elements, the ligandfree intermetalloid clusters $\left[\mathrm{As} @ \mathrm{Ni}_{12} @ \mathrm{As}_{20}\right]^{3-}$ and $\left[\mathrm{Zn} @ \mathrm{Zn}_{8} \mathrm{Bi}_{4} @ \mathrm{Bi}_{7}\right]^{5-}$ are known. In [As@ $\left.\mathrm{Ni}_{12} @ \mathrm{As}_{20}\right]^{3-}$, a central As atom is located inside a $\mathrm{Ni}_{12}$ icosahedron, which is in turn enclosed by a $\mathrm{As}_{20}$ pentagonal dodecahedron, as shown in Fig. 15.6.3(a).

The first example of an intermetalloid cluster that almagamates 11 Bi and 9 Zn atoms has been found in the complex $[\mathrm{K}(2.2 .2 \text {-crypt })]_{5}\left[\mathrm{Zn}_{9} \mathrm{Bi}_{11}\right]$. 2en•toluene (2.2.2-crypt $=4,7,13,16,21,24$-hexaoxa-1,10-diazabicyclo[8.8.8] hexacosane). The naked $\left[\mathrm{Zn} @ \mathrm{Zn}_{8} \mathrm{Bi}_{4} @ \mathrm{Bi}_{7}\right]^{5-}$ cluster consists of a central Zn atom trapped inside a distorted icosahedron whose vertices are 8 Zn atoms and 4 Bi atoms, with 7 of the 20 triangular faces each capped by a Bi atom, as shown in Fig. 15.6.3(b).

A simplified model may be used to rationalize the bonding in the heteroatomic species $\left[\mathrm{Zn} @ \mathrm{Zn}_{8} \mathrm{Bi}_{4} @ \mathrm{Bi}_{7}\right]^{5-}$. According to the electron counting theory proposed by Wade, the formation of a closo deltahedra of 12 vertices is stabilized by 13 skeletal electron pairs. The total of 26 electrons required for skeletal bonding may be considered to be provided as follows: 2 from the interstitial Zn atom, $(8 \times 0+4 \times 3=12)$ from the $\mathrm{Zn}_{8} \mathrm{Bi}_{4}$ icosahedral unit (each vertex atom carries an exo lone pair or bond pair), 7 from the capping Bi atoms, and 5 from

Fig. 15.6.3.

(b) Structure of the $\left[\mathrm{Zn} @ \mathrm{Zn}_{8} \mathrm{Bi}_{4} @ \mathrm{Bi}_{7}\right]^{5-}$ cluster; the shaded and open circles represent Zn and Bi atoms, respectively. Interatomic distrances: $\mathrm{Zn}_{\text {cent }}-\mathrm{Zn}_{\text {ico }}$ $283.2(2)-359.4(3), \mathrm{Zn}_{\text {cent }}-\mathrm{Bi}_{\text {ico }} 282.2(2)-292.8(2), \mathrm{Zn}_{\text {ico }}-\mathrm{Bi}_{\text {ico }} 287.6(2)-375.5(2), \mathrm{Bi}_{\text {ico }}-$ Bi $_{\text {ico }}$ $320.5(1), \mathrm{Zn}_{\text {ico }}-\mathrm{Zn}_{\text {ico }} 289.4(2)-376.2(2), \mathrm{Bi}_{\text {cap }}-\mathrm{Zn}_{\text {ico }} 259.8(1)-276.8(1), \mathrm{Bi}_{\text {cap }}-\mathrm{Bi}_{\text {ico }}$ $310.7(1)-331.2(1) \mathrm{pm}$; the subscripts cent, ico, and cap denote atoms occupying the central, icosahedral, and capping sites, respectively.
the negative charges. Note that each vertex Bi atom is considered to retain one lone pair, whereas each capping Bi atom withholds two lone pairs.

### 15.6.3 Intermolecular interactions in organoantimony and organobismuth compounds

Intermolecular interactions have long been known to exist in inorganic compounds of antimony and bismuth. For example, $\mathrm{SbCl}_{3}$ has three $\mathrm{Sb}-\mathrm{Cl}$ bonds of length 234 pm and five $\mathrm{Sb} \cdots \mathrm{Cl}$ distances in the range $346-74 \mathrm{pm}$, thus enlarging the coordination sphere from trigonal pyramidal to $(3+5)$ bicapped trigonal prismatic geometry.

The organoantimony and organobismuth compounds in oxidation states I-III also exhibit strong intermolecular interactions, which lead to secondary bonds between molecules in forming chain-like, layer-type, and threedimensional supramolecular structures. Figure 15.6.4 shows the structures of three organometallic compounds of Sb and Bi .

## (1) $\mathbf{M e S b C l}_{2}$

Crystalline $\mathrm{MeSbCl}_{2}$ contains alternating layers, each consisting of double chains of $\mathrm{MeSbCl}_{2}$ molecules. Along a $\mathrm{MeSbCl}_{2}$ chain, the bond lengths and angles are $\mathrm{Sb}-\mathrm{Cl}, 236.8$ and $243.0 \mathrm{pm} ; \mathrm{Sb} \cdots \mathrm{Cl}, 333.7$ and 386.5 pm ; $\mathrm{Sb}-\mathrm{Cl} \cdots \mathrm{Sb}$ (within chain), $102.9^{\circ}$.

## (2) $\mathbf{M e}_{2} \mathbf{S b I}$

In the $\mathrm{Me}_{2} \mathrm{SbI}$ chain, the bond lengths are $\mathrm{Sb}-\mathrm{I} 279.9 \mathrm{pm}$ and $\mathrm{Sb} \cdots \mathrm{I} 366.6 \mathrm{pm}$, so that the short and long $\mathrm{Sb}-\mathrm{I}$ bonds are clearly different. The chain atoms lie

(b)

almost in a plane, while the methyl groups are directed to one side of this plane. The reverse side is exposed to neighboring chains with very weak interchain $\mathrm{Sb} \cdots \mathrm{I}$ contacts ( $402.4-416.7 \mathrm{pm}$ ) close to the van der Waals separation. This type of chain packing leads to the formation of double layers.

## (3) $\mathbf{M e s B i B r}_{2}$

In the chain structure of $\mathrm{MesBiBr}_{2}$, the Bi and bridging Br atoms constitute a zigzag chain, with the nonbridging Br atoms lying on one side and the mesityl groups on the other side of the plane as defined by the positions of the chain atoms. The structure is stabilized by $\pi$ interaction between the Bi atom and the noncoordinated mesityl group. The bond lengths are $\mathrm{Bi}-\mathrm{Br}, 261.9$ and 281.8 pm ; $\mathrm{Bi} \cdots \mathrm{Bi}, 301.7$ and 302.2 pm ; Bi- mesityl ring centroid, 319.5 and 330.1 pm .

## 16

## Structural Chemistry of Group 16 Elements

### 16.1 Dioxygen and ozone

Oxygen is the most abundant element on the earth's surface. It occurs both in the free state and as a component in innumerable compounds. The common allotrope of oxygen is dioxygen $\left(\mathrm{O}_{2}\right)$ or oxygen gas; the other allotrope is ozone $\left(\mathrm{O}_{3}\right)$.

### 16.1.1 Structure and properties of dioxygen

Molecular oxygen (or dioxygen) $\mathrm{O}_{2}$ and related species are involved in many chemical reactions. The valence molecular orbitals and electronic configurations of the homonuclear diatomic species $\mathrm{O}_{2}$ and $\mathrm{O}_{2}^{-}$are shown in Fig. 16.1.1.

In the ground state of $\mathrm{O}_{2}$, the outermost two electrons occupy a doubly degenerate set of antibonding $\pi^{*}$ orbitals with parallel spins. Dioxygen is thus a paramagnetic molecule with a triplet ground state $\left({ }^{3} \Sigma\right)$, and its formal double bond has a length of 120.752 pm .

The first electronic excited state $\left({ }^{1} \Delta\right)$ is $94 \mathrm{~kJ} \mathrm{~mol}^{-1}$ above the ground state and is a singlet with no unpaired electrons. This very reactive species, commonly called singlet oxygen, has a half-life of $2 \mu$ s in water. Its bond length is 121.563 pm . Another singlet $\left({ }^{1} \Sigma\right)$ species, with paired electrons in the $\pi_{\mathrm{g}}$ orbitals, is higher in energy than the ground state by $158 \mathrm{~kJ} \mathrm{~mol}^{-1}$, and its bond length is 122.688 pm . Of the two singlet states only the lower ${ }^{1} \Delta$ survives long enough to participate in chemical reactions. The higher ${ }^{1} \Sigma$ state is deactivated to the $\mathrm{O}_{2}\left({ }^{1} \Delta\right)$ state so rapidly that it has no significant chemistry.

Simple reduction of dioxygen to the superoxide ion, $\mathrm{O}_{2}^{-}$, is thermodynamically unfavorable as it involves adding an electron to a half-filled antibonding orbital. Reduction to the peroxide ion, $\mathrm{O}_{2}^{2-}$, however, is favorable from either superoxide or dioxygen. Owing to the increased population of antibonding orbitals in the reduced $\mathrm{O}_{2}$ species $\left(\mathrm{O}_{2}^{-}\right.$and $\left.\mathrm{O}_{2}^{2-}\right)$, both the bond order and $\mathrm{O}-\mathrm{O}$ IR stretching frequency decrease, while the $\mathrm{O}-\mathrm{O}$ distance increases. Table 16.1.1 lists relevant data on the bond properties of dioxygen species.

Owing to its nonpolar nature, $\mathrm{O}_{2}$ is more soluble in organic solvents than in $\mathrm{H}_{2} \mathrm{O}$. Since the ${ }^{3} \Sigma$ ground state of dioxygen is a spin triplet, concerted oxygenation reaction is subject to spin restriction. As a result, many types of dioxygen reactions proceed slowly, even in cases where such reactions are

strongly favored thermodynamically, such as a mixture of $\mathrm{O}_{2}$ and $\mathrm{H}_{2}$. The reactivity of dioxygen with singlet molecules can be increased by exciting it to its ${ }^{1} \Delta$ singlet state, thereby removing the spin restriction. This energy corresponds to an infrared wavelength of 1270 nm . As singlet oxygen in solution deactivates by transferring its electronic energy to vibration of solvent molecules, its lifetime depends strongly on the medium. Solvents with high vibrational frequencies provide the most efficient relaxation. For this reason, the lifetime (about 2-4 $\mu \mathrm{s}$ ) is shortest in water, which has a strong OH vibration near $3600 \mathrm{~cm}^{-1}$. Solvents with CH groups ( $\approx 3000 \mathrm{~cm}^{-1}$ ) are the next most efficient, with lifetime in the range of $30-100 \mu \mathrm{~s}$.

Table 16.1.1. Bond properties of dioxygen species

| Species | Compound | Bond order | $\mathrm{O}-\mathrm{O}(\mathrm{pm})$ | Bond energy $\left(\mathrm{kJ} \mathrm{~mol}^{-1}\right)$ | $\nu(\mathrm{O}-\mathrm{O})\left(\mathrm{cm}^{-1}\right)$ |
| :---: | :---: | :---: | :---: | :---: | :---: |
| Oxygenyl $\mathrm{O}_{2}^{+}$ | $\mathrm{O}_{2}\left[\mathrm{AsF}_{6}\right]$ | 2.5 | 112.3 | 625.1 | 1858 |
| Triplet $\mathrm{O}_{2}\left({ }^{2} \Sigma\right)$ | $\mathrm{O}_{2}(\mathrm{~g})$ | 2 | 120.752 | 490.4 | 1554.7 |
| Singlet $\mathrm{O}_{2}\left({ }^{1} \Delta\right)$ | $\mathrm{O}_{2}(\mathrm{~g})$ | 2 | 121.563 | 396.2 | 1483.5 |
| Singlet $\mathrm{O}_{2}\left({ }^{1} \Sigma\right)$ | $\mathrm{O}_{2}(\mathrm{~g})$ | 2 | 122.688 | - | - |
| Superoxide $\mathrm{O}_{2}^{-}$ | $\mathrm{KO}_{2}$ | 1.5 | 128 | - | 1145 |
| Peroxide $\mathrm{O}_{2}^{2-}$ | $\mathrm{Na}_{2} \mathrm{O}_{2}$ | 1 | 149 | 204.2 | 842 |
| -O-O- | $\mathrm{H}_{2} \mathrm{O}_{2}$ (cryst.) | 1 | 145.8 | 213 | 882 |

There are two major sources of singlet oxygen $\mathrm{O}_{2}\left({ }^{1} \Delta\right)$ :
(1) Photochemical sources. One of the most common sources of singlet oxygen is energy transfer from an excited "sensitizer" (Sens), such as a dye or natural pigment, to the ground state of the oxygen molecule. The role of the sensitizer is to absorb irradiation and be converted to an electronically excited state (Sens*). This state, normally a triplet, then transfers its

Fig. 16.1.1.
MO diagrams for $\mathrm{O}_{2}$ and $\mathrm{O}_{2}^{-}$.

## Structural Chemistry of Selected Elements

energy to the oxygen molecule, producing singlet oxygen and regenerating the sensitizer, as indicated below:

$$
\text { Sens } \xrightarrow{h \nu} \text { Sens }^{*} \xrightarrow{\mathrm{O}_{2}} \operatorname{Sens}+\mathrm{O}_{2}\left({ }^{1} \Delta\right) .
$$

(2) Chemical sources. An early chemical source is the reaction of HOCl with $\mathrm{H}_{2} \mathrm{O}_{2}$, which produces singlet $\mathrm{O}_{2}\left({ }^{1} \Delta\right)$ in nearly quantitative yield:

$$
\mathrm{H}_{2} \mathrm{O}_{2}+\mathrm{HOCl} \rightarrow \mathrm{O}_{2}\left({ }^{1} \Delta\right)+\mathrm{H}_{2} \mathrm{O}+\mathrm{HCl} .
$$

Another source is derived from phosphite ozonides as in the reaction

In addition to the above sources, a number of other chemical reactions have been suggested for the production of singlet oxygen.

Singlet oxygen $\mathrm{O}_{2}\left({ }^{1} \Delta\right)$ is a useful synthetic reagent, which allows stereospecific and regiospecific introduction of $\mathrm{O}_{2}$ into organic substrates. Since singlet oxygen $\mathrm{O}_{2}\left({ }^{1} \Delta\right)$ has a vacant $\pi_{\mathrm{g}}$ orbital, similar to the frontier MO of ethylene, it behaves as an electrophilic reagent, with a reactivity pattern reminiscent of that exhibited by ethylene with electronegative substituents. For example, it undergoes $[4+2]$ cycloadditions with 1,3 -dienes, and $[2+2]$ cycloadditions and ene reactions with isolated double bonds. Some examples are given below:

### 16.1.2 Crystalline phases of solid oxygen

X-ray studies of solid oxygen began in the 1920s, and at present six distinct crystallographic forms have been unequivocally identified. The $\alpha, \beta$, and $\gamma$ phases exist at ambient pressure and low temperature. At $T=295 \mathrm{~K}$, oxygen solidifies to form the $\beta$ phase at 5.4 GPa , which transforms into the orange $\delta$

phase at 9.6 GPa , which in turn is converted to the red $\varepsilon$ phase at 10 GPa . Above 96 GPa , the $\varepsilon$ phase undergoes transformation to the metallic $\varsigma$ phase.

The monoclinic $\alpha$, rhombohedral $\beta$, and orthorhombic $\gamma$ phases all have layered structures composed of $\mathrm{O}_{2}$ molecules. Recently, single-crystal Xray analysis has established that in the crystal structure of the $\varepsilon$ phase at $13.2-17.6 \mathrm{GPa}$ (space group $C 2 / m$ with $Z=8$ ), four $\mathrm{O}_{2}$ molecules associate into a rhombohedral $\left(\mathrm{O}_{2}\right)_{4}$ cluster by serving as the short, parallel edges of a rhombic prism located at a site of symmetry $2 / m$, which is held together by weak chemical bonds. The layer-type crystal structure is shown in Fig. 16.1.2. The $\mathrm{O} \cdots \mathrm{O} \cdots \mathrm{O}$ angles at the rhombic face $\mathrm{O} 2-\mathrm{O} 3-\mathrm{O} 1 \mathrm{~A}-\mathrm{O} 3 \mathrm{~B}$ are $84.5^{\circ}$ and $95.8^{\circ}$. The two independently measured O-O bond lengths are 120 and 121 pm , which are in agreement with that in the gas phase. The shortest intracluster, intercluster, and interlayer $\mathrm{O} \cdots \mathrm{O}$ contacts are 218,259 , and 250 pm , respectively.

### 16.1.3 Dioxygen-related species and hydrogen peroxide

The oxygenyl cation, $\mathrm{O}_{2}^{+}$, is well characterized in both the gas phase and in salts with non-oxidizable anions. Removal of one of the antibonding $\pi_{\mathrm{g}}$ electrons from $\mathrm{O}_{2}$ gives $\mathrm{O}_{2}^{+}$with a bond order of 2.5 and, consequently, a shorter bond length of 112.3 pm . The chemistry of $\mathrm{O}_{2}^{+}$is quite limited in scope because of the high ionization potential of $\mathrm{O}_{2}\left(1163 \mathrm{~kJ} \mathrm{~mol}^{-1}\right)$.

The superoxide ion $\mathrm{O}_{2}^{-}$is formed by adding one electron into the antibonding orbital $\pi_{\mathrm{g}}$ of $\mathrm{O}_{2}$, thereby reducing the bond order to 1.5 and increasing the bond length to 128 pm , as shown in Table 16.1.1.

The peroxide ion, $\mathrm{O}_{2}^{2-}$, has two more electrons than neutral dioxygen, and these additional electrons completely fill the $\pi_{\mathrm{g}} \mathrm{MO}$, resulting in a diamagnetic molecule with an $\mathrm{O}-\mathrm{O}$ bond order of 1 . The single-bond character is evident from the longer bond length (about 149 pm ) and from the lower rotational barrier of the peroxide bond. The peroxide anion is found in ionic salts with the alkali metals and heavier alkaline-earth metals such as calcium, strontium, and barium. These ionic peroxides are powerful oxidants, and hydrogen peroxide, $\mathrm{H}_{2} \mathrm{O}_{2}$, is formed when they are dissolved in water. Figure 16.1.3 shows the molecular structure of $\mathrm{H}_{2} \mathrm{O}_{2}$.

Fig. 16.1.2.
Molecular packing in the crystal structure of $\varepsilon$-oxygen; the solid and open lines indicate covalent and weak bonds, respectively. (a) $C$-centered layer of $\left(\mathrm{O}_{2}\right)_{4}$ clusters viewed along the $c$ axis; (b) the same layer viewed along the $b$ axis. Symmetry codes: A $\bar{x}, y, \bar{z} ; \mathrm{B} x, \bar{y}, z$; C $\bar{x}, \bar{y}, \bar{z}$.

## 614

Structural Chemistry of Selected Elements

(a)

(b)

Table 16.1.2 lists the values of the dihedral angle of $\mathrm{H}_{2} \mathrm{O}_{2}$ in some crystalline phases (a value of $180^{\circ}$ corresponds to a planar trans configuration). This large range of values indicates that the rotational barrier is low and the molecular configuration of $\mathrm{H}_{2} \mathrm{O}_{2}$ is very sensitive to its surroundings.

Table 16.1.2. Dihedral angle of $\mathrm{H}_{2} \mathrm{O}_{2}$ in some crystalline phases

| Compound | Dihedral angle | Compound | Dihedral angle |
| :--- | :--- | :--- | :--- |
| $\mathrm{H}_{2} \mathrm{O}_{2}(\mathrm{~s})$ | $90.2^{\circ}$ | $\mathrm{Li}_{2} \mathrm{C}_{2} \mathrm{O}_{4} \cdot \mathrm{H}_{2} \mathrm{O}_{2}$ | $180^{\circ}$ |
| $\mathrm{K}_{2} \mathrm{C}_{2} \mathrm{O}_{4} \cdot \mathrm{H}_{2} \mathrm{O}_{2}$ | $101.6^{\circ}$ | $\mathrm{Na}_{2} \mathrm{C}_{2} \mathrm{O}_{4} \cdot \mathrm{H}_{2} \mathrm{O}_{2}$ | $180^{\circ}$ |
| $\mathrm{Rb}_{2} \mathrm{C}_{2} \mathrm{O}_{4} \cdot \mathrm{H}_{2} \mathrm{O}_{2}$ | $103.4^{\circ}$ | $\mathrm{NH}_{4} \mathrm{~F} \cdot \mathrm{H}_{2} \mathrm{O}_{2}$ | $180^{\circ}$ |
| $\mathrm{H}_{2} \mathrm{O}_{2} \cdot 2 \mathrm{H}_{2} \mathrm{O}$ | $129^{\circ}$ | theoretical | $90^{\circ}-120^{\circ}$ |

Hydrogen peroxide has a rich and varied chemistry which arises from its versatility:
(a) It can act either as an oxidizing or a reducing agent in both acid and alkaline media.
(b) It undergoes proton acid/base reactions to form peroxonium salts $\left(\mathrm{H}_{2} \mathrm{OOH}\right)^{+}$, hydroperoxides $(\mathrm{OOH})^{-}$, and peroxides $\left(\mathrm{O}_{2}^{2-}\right)$.
(c) It gives rise to peroxometal complexes and peroxoacid anions.
(d) It can form crystalline addition compounds with other molecules through hydrogen bonding, such as $\mathrm{Na}_{2} \mathrm{C}_{2} \mathrm{O}_{4} \cdot \mathrm{H}_{2} \mathrm{O}_{2}, \mathrm{NH}_{4} \mathrm{~F} \cdot \mathrm{H}_{2} \mathrm{O}_{2}$, and $\mathrm{H}_{2} \mathrm{O}_{2} \cdot 2 \mathrm{H}_{2} \mathrm{O}$.

The $\mathrm{O}-\mathrm{O}$ bond length of 134 pm for the superoxide ion, $\mathrm{O}_{2}^{-}$, was determined accurately for the first time in its $\left[1,3-\left(\mathrm{Me}_{3} \mathrm{~N}\right)_{2} \mathrm{C}_{6} \mathrm{H}_{4}\right]\left[\mathrm{O}_{2}\right]_{2} \cdot 3 \mathrm{NH}_{3}$ salt. Orientational disorder of the $\mathrm{O}_{2}^{-}$ion that often occurs in crystals is avoided by using the bulky, nonspherical organic counter cation, which imposes order on the anionic sites.

### 16.1.4 Ozone

Ozone is a diamagnetic gas with a distinctive strong odor. The $\mathrm{O}_{3}$ molecule [Fig. 16.1.4(a)] is angular, with an $\mathrm{O}-\mathrm{O}$ bond length of 127.8 pm , which is longer than that of $\mathrm{O}_{2}(120.8 \mathrm{pm})$; the bond energy of $297 \mathrm{~kJ} \mathrm{~mol}^{-1}$ is lesser than that of $\mathrm{O}_{2}\left(490 \mathrm{~kJ} \mathrm{~mol}^{-1}\right)$. The central O atom uses its $\mathrm{sp}^{2}$ hybrid orbitals to form $\sigma$ bonds with the terminal O atoms and to accommodate a lone pair, leaving the remaining $p$ orbital for $\pi$ bonding, as shown in Fig. 16.1.4(b). Each $\mathrm{O}-\mathrm{O}$ bond has a bond order of 1.5 . Ozone has a measured dipole moment of
$1.73 \times 10^{-30} \mathrm{C} \cdot \mathrm{m}(0.52$ Debye) due to the uneven electron distribution over the central and terminal O atoms.

(a)

(b)

Fig. 16.1.4.
The $\mathrm{O}_{3}$ molecule: (a) geometry and (b) bonding.

The deep red ozonide ion $\mathrm{O}_{3}^{-}$has a bent structure, and sodium ozonide is isostructural with sodium nitrite $\left(\mathrm{NaNO}_{2}\right)$. The X-ray structural data of the alkali metal ozonides show that an increase in cationic size corresponds to a decrease in $\mathrm{O}-\mathrm{O}$ bond length and an increase in $\mathrm{O}-\mathrm{O}-\mathrm{O}$ angle, as summarized in the following table:

| $\mathrm{MO}_{3}$ | $\mathrm{O}-\mathrm{O}(\mathrm{pm})$ | $\mathrm{O}-\mathrm{O}-\mathrm{O}\left({ }^{\circ}\right)$ |
| :--- | :--- | :--- |
| $\mathrm{NaO}_{3}$ | $135.3(3)$ | $113.0(2)$ |
| $\mathrm{KO}_{3}$ | $134.6(2)$ | $113.5(1)$ |
| $\mathrm{RbO}_{3}$ | $134.3(7)$ | $113.7(5)$ |
| $\mathrm{CsO}_{3}$ | $133.3(9)$ | $114.6(6)$ |

Since the additional electron enters an antibonding $\pi^{*}$ orbital, the bond order of $\mathrm{O}-\mathrm{O}$ in $\mathrm{O}_{3}^{-}$is 1.25 and the bond length increases. Ionic ozonides such as $\mathrm{KO}_{3}$ are thermodynamically metastable and extremely sensitive to moisture and carbon dioxide.

Ozone is a major atmospheric pollutant in urban areas. In addition to its damaging effect on lung tissue and even on exposed skin surfaces, ozone attacks the rubber of tires, causing them to become brittle and crack. But in the stratosphere, where ozone absorbs much of the short-wavelength UV radiation from the sun, it provides a vital protective shield for life forms on earth.

Ozone has proven to be useful as a reagent to oxygenate organic compounds, a good example being the conversion of olefins to cleaved carbonyl products (Fig. 16.1.5). When $\mathrm{O}_{3}$ reacts with olefins, the first product formed

Fig. 16.1.5.
Mechanism of reaction between $\mathrm{O}_{3}$ and an olefin.

Fig. 16.1.6.
Structure of the molecule $\mathrm{FC}(\mathrm{O}) \mathrm{OOOC}(\mathrm{O}) \mathrm{F}$ showing (a) its $C_{2}$ symmetry axis and (b) left-handed chiral conformation.

is a molozonide which in turn undergoes an $\mathrm{O}-\mathrm{O}$ bond cleavage to give an aldehyde or a ketone plus a carbonyl oxide. The carbonyl oxide then decomposes to yield the products. But under appropriate conditions, the aldehyde or ketone will recombine with the carbonyl oxide to generate an ozonide, which then decomposes in the presence of $\mathrm{H}_{2} \mathrm{O}$ to give two carbonyl compounds and hydrogen peroxide.

There exist only a few compounds which contain a linear chain of three oxygen atoms. The unstable compound bis(fluoroformyl)trioxide, $\mathrm{F}-\mathrm{C}(\mathrm{O})-\mathrm{O}-$ $\mathrm{O}-\mathrm{O}-\mathrm{C}(\mathrm{O})-\mathrm{F}$, exists as the trans-syn-syn rotamer with $C_{2}$ symmetry in the crystalline state (with respect to the central $\mathrm{O}_{3}$ fragment, the $\mathrm{C}-\mathrm{O}$ bonds are trans and both $\mathrm{C}=\mathrm{O}$ bonds are cis). The $\mathrm{C}-\mathrm{O}-\mathrm{O}-\mathrm{O}$ torsion angle and $\mathrm{O}-\mathrm{O}-\mathrm{O}$ bond angle are $99.0(1)^{\circ}$ and $104.0(1)^{\circ}$, respectively, as shown in Fig. 16.1.6. In the stable molecule bis(trifluoromethyl)trioxide $\mathrm{F}_{3} \mathrm{C}-\mathrm{O}-\mathrm{O}-\mathrm{O}-\mathrm{CF}_{3}$, the corresponding values are $95.9(8)$ and $106.4(1)^{\circ}$, respectively.

### 16.2 Oxygen and dioxygen metal complexes

### 16.2.1 Coordination modes of oxygen in metal-oxo complexes

The structures of inorganic crystals are usually described by the packing of anions and metal coordination geometries. In this section, we place particular emphasis on the coordination environment of the oxygen atom. The oxygen atom (oxo ligand) exhibits various ligation modes in binding to metal centers, as shown in Table 16.2.1.

### 16.2.2 Ligation modes of dioxygen in metal complexes

In general, dioxygen metal complexes can be classified in terms of their mode of binding. With nonbridging $\mathrm{O}_{2}$ ligands, both $\eta^{1}$ (superoxo) and $\eta^{2}$ (peroxo) complexes are known. Bridging dioxygen groups can adopt $\eta^{1}: \eta^{1}, \eta^{1}: \eta^{2}$, and $\eta^{2}: \eta^{2}$ configurations. Figure 16.2 . 1 shows the observed coordination modes in dioxygen metal complexes.

Another commonly adopted classification of dioxygen metal complexes is based on $\mathrm{O}-\mathrm{O}$ bond lengths (referring to Table 16.2.2): superoxo complexes of types $\mathrm{I} a$ and $\mathrm{I} b$, in which the $\mathrm{O}-\mathrm{O}$ distance is roughly constant and close to the value reported for the superoxide anion ( $\sim 130 \mathrm{pm}$ ); and types IIa and IIb , in which the $\mathrm{O}-\mathrm{O}$ distance is close to the values reported for $\mathrm{H}_{2} \mathrm{O}_{2}$ and $\mathrm{O}_{2}^{2-}(\sim 148 \mathrm{pm})$. The $a$ or $b$ classification distinguishes complexes in which the dioxygen is bound to one metal atom (type $a$ ) or bridging two metal atoms (type $b$ ).

| :---: | :---: | :---: | :---: | :---: | :---: |
| Superoxo | I $a$ | 1:1 |  | $125-135$ | 1130-1195 |
| Superoxo | I $b$ | 1:2 |  | 126-136 | 1075-1122 |
| Peroxo | II $a$ | 1:1 |  | $130-155$ | 800-932 |
| Peroxo | II $b$ | 1:2 |  | 144-149 | $790-884$ |

The stretching frequencies attributed to the $\mathrm{O}-\mathrm{O}$ vibration are closely related to the structural type. Type I complexes show $\mathrm{O}-\mathrm{O}$ stretching vibrations around $1125 \mathrm{~cm}^{-1}$ and type II around $860 \mathrm{~cm}^{-1}$. This sharp difference enables the $\mathrm{O}-$ O stretching frequency as measured by infrared or Raman spectroscopy to be used for structure type classification. Table 16.2.2 lists the structural data of dioxygen metal complexes.

### 16.2.3 Biological dioxygen carriers

The proteins hemoglobin $(\mathrm{Hb})$ and myoglobin $(\mathrm{Mb})$ serve to transport and to store oxygen, respectively, in all vertebrates. The active site in both proteins is a planar heme group (Fig. 16.2.2). Myoglobin is composed of one globin (globular protein molecule) and one heme group. Hemoglobin consists of four myoglobin-like subunits, two $\alpha$ and two $\beta$. In each subunit, the heme group is partially embedded in the globin, and an oxygen molecule can bond to the iron atom on the side of the porphyrin opposite the proximal histidine, thus forming a hexa-coordinate iron complex, as shown in Fig. 16.2.3.

Myoglobin contains $\mathrm{Fe}^{2+}$ ( $\mathrm{d}^{6}$ configuration) in a high-spin state, which has a radius of about 78 pm in a pseudo-octahedral environment. $\mathrm{The}_{\mathrm{Fe}}{ }^{2+}$ ion is too large to fit into the central cavity of the porphyrin ring, and lies some 42 pm above the plane of the N donor atoms. When a dioxygen molecule binds to $\mathrm{Fe}^{2+}$, the $\mathrm{Fe}^{2+}$ becomes low-spin $\mathrm{d}^{6}$ with a shrunken radius of only 61 pm , which enables it to slip into the porphyrin cavity.

In hemoglobin, $\mathrm{O}_{2}$ binding to $\mathrm{Fe}^{2+}$ does not oxidize it to $\mathrm{Fe}^{3+}$, as it is protected by protein units around the heme group. A nonaqueous environment is required for reversible $\mathrm{O}_{2}$ binding.

The $\mathrm{O}_{2}\left({ }^{3} \Sigma\right)$ and the high-spin $\mathrm{Fe}^{2+}$ atom of the heme combine to form a spin-paired diamagnetic system. The resulting $\mathrm{Fe}-\mathrm{O}-\mathrm{O}$ is bent, with a bond angle varying from $115^{\circ}$ to $153^{\circ}$. The stronger $\sigma$ interaction is between the $\mathrm{d}_{z^{2}}(\mathrm{Fe})$ and $\pi_{\mathrm{g}}\left(\mathrm{O}_{2}\right)$ orbitals, and the weak $\pi$ interaction is between $\mathrm{d}_{x z}(\mathrm{Fe})$ and $\pi_{\mathrm{g}}^{*}\left(\mathrm{O}_{2}\right)$. The increased ligand effect results in pairing of electrons and a weakened $\mathrm{O}-\mathrm{O}$ bond.

Oxygen enters the blood in the lungs, where the partial pressure of $\mathrm{O}_{2}$ is relatively high $\left(2.1 \times 10^{4} \mathrm{~Pa}\right)$ under ideal conditions; in the lungs with mixing of inhaled and nonexhaled gases, the $\mathrm{O}_{2}$ partial pressure is $\sim 1.3 \times 10^{4} \mathrm{~Pa}$. It is then carried by red blood cells to the tissues where the $\mathrm{O}_{2}$ partial pressure is lowered to $\sim 4 \times 10^{3} \mathrm{~Pa}$. The reactions that occur are represented as follows:

$$
\begin{aligned}
& \text { Lungs: } \mathrm{Hb}+4 \mathrm{O}_{2} \rightarrow \mathrm{Hb}\left(\mathrm{O}_{2}\right)_{4} \\
& \text { Tissues: } \mathrm{Hb}\left(\mathrm{O}_{2}\right)_{4}+4 \mathrm{Mb} \rightarrow 4 \mathrm{Mb}\left(\mathrm{O}_{2}\right)+\mathrm{Hb} \text {. }
\end{aligned}
$$

The four subunits $(2 \alpha+2 \beta)$ of hemoglobin function cooperatively. When one $\mathrm{O}_{2}$ is bound to one heme group, the conformation of Hb subtly changes to make binding of additional oxygen molecules easier. Thus the four irons can each carry one $\mathrm{O}_{2}$ with steadily increasing equilibrium constants. As a result, as soon as some $\mathrm{O}_{2}$ has been bound to the molecule, all four irons readily become oxygenated ( oxyHb ). In a similar fashion, initial removal of oxygen triggers the release of the remainder, and the entire load of $\mathrm{O}_{2}$ is delivered at the required site. This effect is also facilitated by pH changes caused by increased $\mathrm{CO}_{2}$ concentration in the capillaries. As the $\mathrm{CO}_{2}$ concentration increases, the pH decreases due to formation of $\mathrm{HCO}_{3}^{-}$, and the increased acidity favors release of $\mathrm{O}_{2}$ from oxyHb. This is known as the Bohr effect.

Hemoglobin carries oxygen via the circulatory system from the lungs to body tissues. There the oxygen can be transferred to myoglobin, where it is stored for oxidation of foodstuffs. The properties of Hb and Mb can be represented by the oxygen-binding curves of Fig. 16.2.4. At high oxygen concentrations, Hb and Mb bind $\mathrm{O}_{2}$ with approximately equal affinity. However, at low oxygen concentrations, such as in muscle tissue during or immediately after muscular activity, Hb is a poor oxygen binder and therefore can deliver its oxygen to Mb . The difference in $\mathrm{O}_{2}$-binding ability between Mb and Hb is accentuated at low pH values; hence the transfer from Hb to Mb has a great driving force where it is most needed, viz., in tissues where oxygen has been converted to $\mathrm{CO}_{2}$.

### 16.3 Structure of water and ices

Water is the most common substance on the earth's surface, and it constitutes about $70 \%$ of the human body and the food it consumes. It is also the smallest molecule with the greatest potential for hydrogen bonding. Water is the most

important species in chemistry because a majority of chemical reactions can be carried out in its presence.

### 16.3.1 Water in the gas phase

The $\mathrm{H}_{2} \mathrm{O}$ molecule has a bent structure, with $\mathrm{O}-\mathrm{H}$ bond length 95.72 pm and bond angle $\mathrm{H}-\mathrm{O}-\mathrm{H} 104.52^{\circ}$; the $\mathrm{O}-\mathrm{H}$ bonds and the lone pairs form a tetrahedral configuration, as shown in Fig. 16.3.1(a). They are capable of forming donor O$\mathrm{H} \cdots \mathrm{X}$ and acceptor $\mathrm{O} \cdots \mathrm{H}-\mathrm{X}$ hydrogen bonds ( X is a highly electronegative atom).

(a)

(b)

In the gas phase, the adducts of $\mathrm{H}_{2} \mathrm{O}$ with $\mathrm{HF}, \mathrm{HCl}, \mathrm{HBr}, \mathrm{HCN}, \mathrm{HC} \equiv \mathrm{CH}$, and $\mathrm{NH}_{3}$ have been studied by microwave spectroscopy to determine the relationship of hydrogen-bond donor and acceptor. The structures of the adducts are $\mathrm{H}_{2} \mathrm{O}: \cdots \mathrm{H}-\mathrm{F}, \mathrm{H}_{2} \mathrm{O}: \cdots \mathrm{H}-\mathrm{Cl}$, and $\mathrm{H}_{2} \mathrm{O}: \cdots \mathrm{H}-\mathrm{CN}$. Only with $\mathrm{NH}_{3}$ is water a H donor: $\mathrm{H}_{3} \mathrm{~N}: \cdots \mathrm{H}-\mathrm{OH}$.
Water forms a hydrogen-bonded dimer, the structure of which has been determined by microwave spectroscopy, as shown in Fig. 16.3.1(b). The experimental value of the binding energy of this dimeric system is $22.6 \mathrm{~kJ} \mathrm{~mol}^{-1}$.

### 16.3.2 Water in the solid phase: ices

Solid $\mathrm{H}_{2} \mathrm{O}$ has 11 known crystalline forms, as listed in Table 16.3.1.
Ordinary hexagonal ice $\mathrm{I}_{\mathrm{h}}$ and cubic ice $\mathrm{I}_{\mathrm{c}}$ are formed at normal pressures, the latter being stable below $-120^{\circ} \mathrm{C}$. Their hydrogen bonding patterns are

*No. of nearest neighbors closer than 300 pm.
very similar, and only the arrangements of the oxygen atoms differ. In $I_{c}$, the oxygens are arranged like the carbon atoms in cubic diamond, whereas in $\mathrm{I}_{\mathrm{h}}$ the atomic arrangement corresponds to that in hexagonal diamond. Figure 16.3.2 shows the structure of $\mathrm{I}_{\mathrm{h}}$.

In both $\mathrm{I}_{\mathrm{h}}$ and $\mathrm{I}_{\mathrm{c}}$, the hydrogen-bonded systems contain cyclohexane-like buckled hexagonal ring motifs: chair form in $I_{c}$ and boat form in $I_{h}$. An important distinction is that in $I_{c}$ all four hydrogen bonds are equivalent by symmetry. In $\mathrm{I}_{\mathrm{h}}$, the hydrogen bond in the direction of the hexagonal axis can be differentiated from the other three.

A neutron diffraction analysis of $\mathrm{H}_{2} \mathrm{O}$ and $\mathrm{D}_{2} \mathrm{O}$ ice $\mathrm{I}_{\mathrm{h}}$ at different temperatures has shown that, in addition to the disordered hydrogens, the oxygen atoms are also disordered about sites 6 pm off the hexagonal axis.

In the high-pressure ices the hydrogen-bonding patterns become progressively more complex with increasing pressure until the ultra-high-pressure ice polymorphs VII and VIII are formed. Ice II contains nearly planar hexagonal rings of hydrogen-bond O atoms arranged in columns. The $\mathrm{O} \cdots \mathrm{O} \cdots \mathrm{O}$

Fig. 16.3.2.
Structure of ice $\mathrm{I}_{\mathrm{h}}$. (Large circle represents O atom, small black circle represents H atom, and broken line represents a disordered hydrogen bond, for which only one of the two arrangements, $\mathrm{O}-\mathrm{H} \cdots \mathrm{O}$ and $\mathrm{O} \cdots \mathrm{H}-\mathrm{O}$, is shown).

angles are greatly distorted from tetrahedral, with some close nonbonded $\mathrm{O} \cdots \mathrm{O}$ separation of 324 pm .
Ice III is composed mainly from hydrogen-bonded pentagons with some heptagons, but with no hexagonal rings. Ice IX has the same structure as ice III, except that the hydrogen atoms are ordered in IX and disordered in III. The transformation III $\rightarrow$ IX occurs between 208 and 165 K .

Ice IV, which is metastable, is even more distorted with $\mathrm{O} \cdots \mathrm{O} \cdots \mathrm{O}$ angles between $88^{\circ}$ and $128^{\circ}$ and a large number of non-hydrogen-bonded $\mathrm{O} \cdots \mathrm{O}$ contacts between 314 and 329 pm . Some oxygen atoms lie at the centers of hexagonal rings. Ice V contains quadrilaterals, pentagons, and hexagons, in which respect it resembles some of the clathrate hydrate host frameworks.

It is of interest to note that ice VI is the first of the ice structures composed of two independent interpenetrating hydrogen-bonded frameworks (e.g., it is a self-clathrate).

Ice VII and VIII are constructed from much more regular interpenetrating frameworks, each with the $I_{c}$ structure with little distortion from tetrahedral bonding configuration. In ice VII, each oxygen has eight nearest neighbors, four hydrogen-bonded at $\mathrm{O} \cdots \mathrm{O}=288 \mathrm{pm}$, and four nonbonded at a shorter distance of 274 pm , demonstrating that it is easier to compress a van der Waals $\mathrm{O} \cdots \mathrm{O}$ distance than a $\mathrm{O}-\mathrm{H} \cdots \mathrm{O}$ distance. Until the formation of interpenetrating frameworks, the principal effect of increasing pressure is to produce more complex hydrogen-bond patterns with large departures from tetrahedral coordination around the oxygen atoms; with the interpenetrating hydrogen bond frameworks, the patterns become much simpler.

A very-high-pressure form, ice X , which was predicated to have a H atom located midway between every pair of hydrogen-bonded O atoms, was identified by infrared spectroscopy with a transition at 44 GPa .

In addition to the various forms of ice, there are a large number of ice-like structures with four-coordinated water molecules that constitute a host framework, which are only stable when voids in the host framework are occupied by other guest molecules. Such compounds are known as clathrate hydrates.

### 16.3.3 Structural model of liquid water

Water is a unique substance in view of its unusual physical and chemical properties:
(a) The density of liquid water reaches a maximum at $4^{\circ} \mathrm{C}$.
(b) Water has a high dielectric constant associated with the distortion or breaking of hydrogen bonds.
(c) Water has relatively high electrical conductivity associated with the transfer of $\mathrm{H}_{3} \mathrm{O}^{+}$and $\mathrm{OH}^{-}$ions through the hydrogen-bonded structure.
(d) Water can be super-cooled and its fluidity increases under pressure.
(e) Water is an essential chemical for all life processes.

Many models for the structure of liquid water have been proposed. One of the most useful is the polyhedral model.

In liquid water, the thermal motions of molecules are perpetual, and the relative positions of the molecules are changing all the time. Although the structure of liquid water has no definite pattern, the hydrogen bonds between molecules still exist in large numbers. Thus liquid water is a dynamic system in which the $\mathrm{H}_{2} \mathrm{O}$ molecules self-assemble in perfect, imperfect, isolated, linked and fused polyhedra (Fig. 16.3.3), among which the pentagonal dodecahedron takes precedence.

The ideal process of the melting of ice may be visualized as a partial ( $\sim 15 \%$ ) breakage of hydrogen bonds to form "ice fragments," which are then converted into a polyhedral system, as indicated in Fig. 16.3.4.

The polyhedral model is useful for understanding the properties of liquid water.

## (1) Hydrogen bonds in liquid water

The geometry of a pentagonal dodecahedron is well suited to the formation of hydrogen bonds between molecules. The interior angle of a five-membered ring

(b)

ice crystal

dodecahedron

Fig. 16.3.3.
Structures of some polyhedra for liquid water: (a) pentagonal dodecahedron ( $5^{12}$ ), (b) 14-hedron $\left(5^{12} 6^{2}\right)$, and (c) 15-hedron $\left(5^{12} 6^{3}\right)$.

Fig. 16.3.4.
Schematic diagram for melting of ice to form water.

## Structural Chemistry of Selected Elements

$\left(108^{\circ}\right)$ is close to the $\mathrm{H}-\mathrm{O}-\mathrm{H}$ bond angle $\left(104.5^{\circ}\right)$ of the water molecule and its tetrahedral charge distribution.

## (2) Density of water

When "ice fragments" convert to the dodecahedral form, the packing of molecules becomes compact, so liquid water is denser than solid ice. In other circumstances, the density of water decreases when the temperature is raised. Water has its highest density at $4^{\circ} \mathrm{C}$.

## (3) X-ray diffraction of liquid water

The " $g(r)$ vs $r$ " diagrams from X-ray diffraction of ice and liquid water are shown in Fig. 16.3.5, in which $g(r)$ represents the oxygen atom-pair correlation function and $r$ represents the distance between an oxygen atom-pair. The diagram of liquid water shows that the strongest peak occurs at $r=280 \mathrm{pm}$, which corresponds to the distance of the hydrogen bond in the dodecahedral system. The next peak is at 450 pm , and the others lie in the range of 640 to 780 pm . There is no peak in the ranges of $280-450 \mathrm{pm}$ and $450-640 \mathrm{pm}$. In the pentagonal dodecahedron the distances between a vertex and its neighbors are 1 (length of the edge, which is taken as the unit length), $\tau,(2)^{1 / 2} \tau, \tau^{2},(3)^{1 / 2} \tau$, with $\tau=1.618$. The calculated distances of oxygen atom-pairs are 280, 450, 640,730 , and 780 pm , which fit the X-ray diffraction data of liquid water.

The diagram of ice $\mathrm{I}_{\mathrm{h}}$ has a distinct peak at $r=520 \mathrm{pm}$, which does not occur in liquid water. At 77 K , the " $g(r)$ vs $r$ " diagrams of amorphous water solid and liquid water are very similar to each other.

## (4) Thermal properties

The relations between the thermal properties of ice, liquid water, and steam are indicated below:

These properties show that in liquid water there still exist a large number of intermolecular hydrogen bonds, thus lending support to the polyhedral model.

## (5) Formation of clathrate hydrates

Many gases, such as $\mathrm{Ar}, \mathrm{Kr}, \mathrm{Xe}, \mathrm{N}_{2}, \mathrm{O}_{2}, \mathrm{Cl}_{2}, \mathrm{CH}_{4}$ and CO , can be crystallized with water to form ice-like clathrate hydrates. The basic structural components of these hydrates are the $\left(\mathrm{H}_{2} \mathrm{O}\right)_{20}$ pentagonal dodecahedron and other larger polyhedra bounded by five- and six-membered hydrogen-bonded rings, which can accommodate the small neutral molecules. The inclusion properties of water imply that such polyhedra are likely to be present in liquid water as its structural components.

Recently there have been extensive studies on the structure and property of water. In December, 2004, upon assessing the major achievements of the past twelve months, Science declared that the study of water as one of the Breakthroughs of the Year. (Specifically, it was listed as No. 8.)

In the structural study of gaseous protonated water clusters, $\mathrm{H}^{+}\left(\mathrm{H}_{2} \mathrm{O}\right)_{n}$, with $n=6-27$, it was found that the mass peak with $n=21$ is particularly intense, signifying a "magic number" in the spectrum. Furthermore, infrared spectroscopic studies revealed that this cluster resembles the pentagonal dodecahedral cage that encapsulates a methane molecule in a Type I clathrate hydrate. In the $\mathrm{H}^{+}\left(\mathrm{H}_{2} \mathrm{O}\right)_{21}$ cluster, the hydronium ion $\mathrm{H}_{3} \mathrm{O}^{+}$can either occupy the (methane) position inside the clathrate cage or take up a site on the cage's surface, thereby pushing a neutral water molecule to the center of the cage.

Another ongoing debate is concerned with the structure of liquid water. In the conventional century-old picture, liquid water is simply an extended network where each water molecule is linked (or hydrogen-bonded) to four others in a tetrahedral pattern. Contrary to this, there are recent synchrotron X-ray results which suggest that many water molecules are linked to only two neighbors. Yet there are also more-recent X-ray data which support the "original" structure, and so this controversy is by no means resolved. Water clearly plays indispensable roles in essentially all fields of science, most notably in chemistry and the life

## Structural Chemistry of Selected Elements

sciences. These roles will be better understood once the structure of liquid water is unequivocally determined.

### 16.3.4 Protonated water species, $\mathrm{H}_{3} \mathrm{O}^{+}$and $\mathrm{H}_{5} \mathrm{O}_{2}^{+}$

The oxonium (or hydronium) ion $\mathrm{H}_{3} \mathrm{O}^{+}$is a stable entity with a pyramidal structure, in which the $\mathrm{O}-\mathrm{H}$ bond has the same length as that in ice, and the apical angle lies between $110^{\circ}$ and $115^{\circ}$. Figure 16.3.6(a) shows the structure of $\mathrm{H}_{3} \mathrm{O}^{+}$.

The $\mathrm{H}_{5} \mathrm{O}_{2}^{+}$ion is a well-documented chemical entity in many crystal structures. Some relevant data are listed in Table 16.3.2. The common characteristic of these compounds is a very short $\mathrm{O}-\mathrm{H} \cdots \mathrm{O}$ hydrogen bond ( $240-5 \mathrm{pm}$ ). Figure 16.3.6(b) shows the structure of $\mathrm{H}_{5} \mathrm{O}_{2}^{+}$in the crystalline dihydrate of hydrochloric acid $\mathrm{H}_{5} \mathrm{O}_{2}^{+} \cdot \mathrm{Cl}^{-}$.

Besides $\mathrm{H}_{3} \mathrm{O}^{+}$and $\mathrm{H}_{5} \mathrm{O}_{2}^{+}$, several other hydronium ion complexes have been proposed, for example $\mathrm{H}_{7} \mathrm{O}_{3}^{+}, \mathrm{H}_{9} \mathrm{O}_{4}^{+}, \mathrm{H}_{13} \mathrm{O}_{6}^{+}$and $\mathrm{H}_{14} \mathrm{O}_{6}^{2+}$. If 245 pm is taken as the upper limit for the $\mathrm{O}-\mathrm{H} \cdots \mathrm{O}$ distance within a hydronium ion, longer $\mathrm{O}-\mathrm{H} \cdots \mathrm{O}$ distances represent hydrogen bonds between a hydronium ion and neighboring water molecules. According to this criterion, reasonable and unambiguous structural formulas can be assigned to many acid hydrates, as listed in Table 16.3.3.

(b)

### 16.4 Allotropes of sulfur and polyatomic sulfur species

### 16.4.1 Allotropes of sulfur

The allotropy of sulfur is far more extensive and complex than that of any other element. This arises from the following factors.
(1) A great variety of molecules can be generated by $-\mathrm{S}-\mathrm{S}-$ catenation. This becomes evident by comparing the experimental bond enthalpies of $\mathrm{O}_{2}$ and $\mathrm{S}_{2}$, which are 498 and $431 \mathrm{~kJ} \mathrm{~mol}^{-1}$, respectively. On the other hand, the S-S single-bond enthalpy, $263 \mathrm{~kJ} \mathrm{~mol}^{-1}$, is much greater than the value of 142 kJ $\mathrm{mol}^{-1}$ for the $\mathrm{O}-\mathrm{O}$ single bond. In view of the difference in atomic size, the repulsion energies of lone pairs on two O atoms are larger than that on two S atoms. Thus elemental sulfur readily forms rings or chains with $\mathrm{S}-\mathrm{S}$ single bonds, whereas oxygen exists primarily as a diatomic molecule.
(2) The S-S bonds are very variable and flexible, generating large $S_{n}$ molecules or extended structures, and hence the relevant compounds are solids at room temperature. The interatomic distances cover the range of 198 to 218 pm , depending mainly on the extent of multiple bonding. Bond angles S-S-S are in the range $101^{\circ}$ to $111^{\circ}$ and the dihedral angles S-S-S-S vary from $74^{\circ}$ to $100^{\circ}$.
(3) The $S_{n}$ molecules can be packed in numerous ways in the crystal lattice.

All allotropic forms of sulfur that occur at room temperature consist of $S_{n}$ rings, with $n=6$ to 20 (Table 16.4.1). Many homocyclic sulfur allotropes have been characterized by X-ray crystallography: $\mathrm{S}_{6}, \mathrm{~S}_{7}$ (two modifications), $\mathrm{S}_{8}$ (three modifications), $\mathrm{S}_{9}, \mathrm{~S}_{10}, \mathrm{~S}_{6} \cdot \mathrm{~S}_{10}, \mathrm{~S}_{11}, \mathrm{~S}_{12}, \mathrm{~S}_{13}, \mathrm{~S}_{14}, \mathrm{~S}_{18}$ (two forms), $\mathrm{S}_{20}$, and polymer chain $S_{\infty}$. Their structural data are listed in Table 16.4.2, and the molecular structures are shown in Fig. 16.4.1.

The most common allotrope of sulfur is orthorhombic $\alpha-\mathrm{S}_{8}$. At about $95.3^{\circ} \mathrm{C}$, $\alpha-\mathrm{S}_{8}$ transforms to monoclinic $\beta$ - $\mathrm{S}_{8}$, such that the packing of $\mathrm{S}_{8}$ molecules is altered and their orientation becomes partly disordered. This leads to a lower density of 1.94 to $2.01 \mathrm{~g} \mathrm{~cm}^{-3}$, but the dimensions of $\mathrm{S}_{8}$ rings in the two allotropes are very similar. Monoclinic $\gamma$ - $\mathrm{S}_{8}$ also comprises cyclo$\mathrm{S}_{8}$ molecules, but the packing is more efficient and leads to a higher density of $2.19 \mathrm{~g} \mathrm{~cm}^{-3}$. It reverts slowly to $\alpha-\mathrm{S}_{8}$ at room temperature, but rapid heating gives a melting point of $106.8^{\circ} \mathrm{C}$.

Table 16.4.1. Some properties of sulfur allotropes

| Allotrope | Color | Density $(\mathrm{g} \mathrm{cm})^{-3}$ | $\mathrm{mp} \mathrm{or} \mathrm{dp}\left({ }^{\circ} \mathrm{C}\right)$ |
| :--- | :--- | :--- | :--- |

| $\mathrm{S}_{18}$ | Lemon yellow | 2.090 | $\mathrm{mp} \mathrm{124(dec)}$ |
| $\mathrm{~S}_{20}$ | Pale yellow | 2.016 | $104(\mathrm{dec})$ |
| $\mathrm{S}_{x}$ | Yellow | 2.01 |  |

$\mathrm{mp}=$ melting point; $\mathrm{dp}=$ decomposition temperature; dec $=$ with decomposition

Allotrope $\mathrm{S}_{7}$ is known in four crystalline modifications, one of which ( $\delta$ form) is obtained by crystallization from $\mathrm{CS}_{2}$ at $-78^{\circ} \mathrm{C}$. It features one long bond (bond $S^{6}-S^{7}$ in Fig. 16.4.1) of 218.1 pm , which probably arises from the virtually coplanar set of atoms $S^{4}-S^{6}-S^{7}-S^{5}$, which leads to maximum repulsion between nonbonding lone pairs on adjacent $S$ atoms. As a result of this weakening of the $S^{6}-S^{7}$ bond, the adjacent $S^{4}-S^{6}$ and $S^{5}-S^{7}$ bonds are strengthened ( 199.5 pm ), and there are further alternations of bond lengths (210.2 and 205.2 pm ) throughout the molecule.

Table 16.4.2. Structural data of $S_{n}$ molecules in the sulfur allotropes

| Molecule | Bond length $(\mathrm{pm})$ | Bond angle $\left({ }^{\circ}\right)$ | Torsion angle $\left({ }^{\circ}\right)$ |
| :--- | :--- | :--- | :--- |

$S_{\infty}$ (projection)
cell, but the molecular symmetry is approximately $C_{2}$, as shown in Fig. 16.4.1. The bond lengths lie between 203.2 and 206.9 pm . The bond angles vary in the range of $103.7^{\circ}$ to $109.7^{\circ}$, and torsion angles in the range of 59.7 to $115.6^{\circ}$. The conformation of a sulfur homocycle is best described by its "motif", i.e., the order of the signs of the torsion angles around the ring. The motif of $\alpha-\mathrm{S}_{9}$ is ++--++-+- .

A new allotrope of sulfur, cyclo- $\mathrm{S}_{14}$, has been isolated as yellow rod-like crystals ( $\mathrm{mp} 113^{\circ} \mathrm{C}$ ) from the reaction of $\left[(\mathrm{tmeda}) \mathrm{ZnS}_{6}\right]\left(\mathrm{tmeda}=\mathrm{N}, \mathrm{N}, \mathrm{N}^{\prime}, \mathrm{N}^{\prime}-\right.$ tetra-methylethylenediamine) with $\mathrm{S}_{8} \mathrm{Cl}_{2}$. The bond distances vary from 204.7 to 206.1 pm , the bond angles from $104.0^{\circ}$ to $109.3^{\circ}$, and the torsion angles in the range $72.5^{\circ}$ to $101.7^{\circ}$. The motif of cyclo- $\mathrm{S}_{14}$ is ++--++--++--+- , in which the first twelve signs are the same as those of cyclo- $\mathrm{S}_{12}$, as shown in Fig. 16.4.1. Hence the structure of $S_{14}$ can be obtained by opening a bond in $S_{12}$ and inserting an $S_{2}$ fragment (i.e., atoms $S^{9}$ and $S^{10}$ in the figure).

Solid polycatena sulfur comes in many forms as described by their names: rubbery $S$, plastic $S$, lamina $S$, fibrous $S$, polymeric $S$, and insoluble $S$ which is also termed $S_{\mu}$ or $S_{\omega}$. Fibrous $S$ consists of parallel helical chains of sulfur atoms whose axes are arranged on a hexagonal close-packed net 463 pm apart. The structure contains both left- and right-handed helices of radius 95 pm

## Structural Chemistry of Selected Elements

(Fig. 16.4.1, $\mathrm{S}_{\infty}$ ) with a repeat distance of 1380 pm comprising 10 S atoms in three turns. Within each helix the metric parameters are bond distance $\mathrm{S}-\mathrm{S}$ 206.6 pm , bond angle $\mathrm{S}-\mathrm{S}-\mathrm{S} 106.0^{\circ}$, and dihedral angle S-S-S-S $85.3^{\circ}$

$\mathrm{S}_{8}{ }^{2+}$

$\mathrm{S}_{19}{ }^{2+}$

### 16.4.2 Polyatomic sulfur ions

## (1) Cations

Sulfur may be oxidized by different oxidizing agents to yield a variety of polyatomic cations. The currently known species that have been characterized by X-ray diffraction are $\mathrm{S}_{4}^{2+}, \mathrm{S}_{8}^{2+}$, and $\mathrm{S}_{19}^{2+}$, the structures of which are shown in Fig. 16.4.2.

In crystalline $\left(\mathrm{S}_{4}^{2+}\right)\left(\mathrm{S}_{7} \mathrm{I}^{+}\right)_{4}\left(\mathrm{AsF}_{6}^{-}\right)_{6}$, the cation $\mathrm{S}_{4}^{2+}$ takes the form of a square-planar ring of edge 198 pm . As this is significantly shorter than a typical S-S single bond ( 206 pm ), the $\mathrm{S}-\mathrm{S}$ bonds in $\mathrm{S}_{4}^{2+}$ have some double-bond character.

In the salt $\left(\mathrm{S}_{8}^{2+}\right)\left(\mathrm{AsF}_{6}^{-}\right)_{2}$, the eight-membered ring of $\mathrm{S}_{8}^{2+}$ has an exo-endo conformation and a rather long transannular bond of 283 pm . This structure may be regarded as being halfway between those of the cage molecule $\mathrm{S}_{4} \mathrm{~N}_{4}$ and the crown-shaped ring of $\mathrm{S}_{8}$. Since $\mathrm{S}_{4} \mathrm{~N}_{4}$ has two electrons less than $\mathrm{S}_{8}^{2+}$ and is isoelectronic with the unknown $\mathrm{S}_{8}^{4+}$, it is conceivable that, as two electrons are removed from $\mathrm{S}_{8}$, one end folds up to generate a transannular bond. Then, with the removal of two more electrons, the other end also folds up and another bond is formed to give the $\mathrm{S}_{4} \mathrm{~N}_{4}$ structure, as shown in Fig. 16.4.3.

In crystalline $\left(\mathrm{S}_{19}^{2+}\right)\left(\mathrm{AsF}_{6}^{-}\right)_{2}$, the $\mathrm{S}_{19}^{2+}$ cation consists of two seven-membered rings joined by a five-atom chain. One of the rings has a boat conformation while the other is disordered, existing as a $4: 1$ mixture of chair and boat conformations. The S-S distances vary greatly from 187 to 239 pm , and S-S-S angles from $91.9^{\circ}$ to $127.6^{\circ}$.

## (2) Anions

The majority of polysulfide anions have acyclic structures. The configurations of $\mathrm{S}_{n}^{2-}$ species are in accord with their bond valence (b):

$$
\begin{aligned}
b & =\frac{1}{2}(8 n-g) \\
& =\frac{1}{2}[8 n-(6 n+2)] \\
& =n-1 .
\end{aligned}
$$

Figure 16.4.4 shows the puckered chain motifs of some $\mathrm{S}_{n}^{2-}$ species, and their structural data are listed in Table 16.4.3.

Table 16.4.3. Structural data of $\mathrm{S}_{n}^{2-}$

| $\mathrm{S}_{n}^{2-}$ | Compound | Bond length (pm) | Bond angle (central) | Symmetry |
| :--- | :--- | :--- | :--- | :--- |

### 16.5 Sulfide anions as ligands in metal complexes

Sulfur has an extensive coordination chemistry involving the $\mathrm{S}^{2-}$ and $\mathrm{S}_{n}^{2-}$ anions, which exhibit an extremely versatile variety of coordination modes.

### 16.5.1 Monosulfide $\mathrm{S}^{2-}$

Ligands in which S acts as a donor atom are usually classified as soft Lewis bases, in contrast to oxygen donor-atom ligands which tend to be hard Lewis bases. The large size of the S atom and its easily deformed electron cloud account for this difference, and the participation of metal $\mathrm{d} \pi$ orbitals in bonding to sulfur is well established. The monosulfide dianion $\mathrm{S}^{2-}$ can act either as a terminal or a bridging ligand. As a terminal ligand, $\mathrm{S}^{2-}$ donates a pair of electron to its

(c) $\left.\left(\mu_{2}-\mathrm{S}\right)_{2} \mathrm{Mo}(\mathrm{S})_{2} \mathrm{Fe}(\mathrm{SPh})_{2}\right]^{2-}$,
(d) $\left.\left(\mu_{2}-\mathrm{S}\right)_{2} \mathrm{Fe}_{2}(\mathrm{NO})_{4}\right]^{2-}$,
(e) $\left(\mu_{3}-\mathrm{S}\right)\left[\mathrm{Au}\left(\mathrm{PPh}_{3}\right)\right]_{3}$,
(f) $\left(\mu_{3}-\mathrm{S}\right)\left[\mathrm{Co}(\mathrm{CO})_{3}\right]_{3}$,
(g) $\left(\mu_{3}-\mathrm{S}\right)_{2}(\mathrm{CoCp})_{3}$,
(h) $\left(\mu_{3}-\mathrm{S}\right)_{4}[\mathrm{Fe}(\mathrm{NO})]_{4}$,
(i) $\left(\mu_{4}-\mathrm{S}\right)\left[\mathrm{Zn}_{4}\left(\mathrm{~S}_{2} \mathrm{AsMe}_{2}\right)_{6}\right]$, and
(j) $\left(\mu_{4}-\mathrm{S}\right)_{2} \mathrm{Co}_{4}(\mathrm{CO})_{10}$.
bonded atom. In the $\mu_{2}$ bridging mode $S$ is usually regarded as a two-electron donor.

Figures 16.5 .1 (a) to Fig. 16.5 .1 (d) shows four $\mu_{2}$ bridging modes. In the $\mu_{3}$ triply bridging mode S can be regarded as a four-electron donor, using both its two unpaired electrons and one lone pair. The pseudo-cubane structure adopted by some of the $\mu_{3}-S$ compounds is a crucial structural unit in many biologically important systems, e.g., the $[(\mathrm{RS}) \mathrm{MS}]_{4}(\mathrm{M}=\mathrm{Mo}, \mathrm{Fe})$ units which cross-link the polypeptide chains in nitrogenase and ferredoxins. Figures 16.5.1(e) to Fig. 16.5.1(h) shows four $\mu_{3}$ bridging modes. In the $\mu_{4}$ bridging mode S can be regarded as a four- or six-electron donor, depending on the geometry of the mode. Figures 16.5 .1 (i) to Fig. 16.5.1(j) show two $\mu_{4}$ bridging modes. As yet there is no molecular compound in which S bridges six or eight metal atoms, but interstitial sulfur is well known.

### 16.5.2 Disulfide $\mathrm{S}_{2}{ }^{2-}$

The coordination modes of disulfide $\mathrm{S}_{2}{ }^{2-}$ in some representative compounds are listed in Table 16.5.1. Their molecular structures are shown in Fig. 16.5.2.

### 16.5.3 Polysulfides $\mathrm{S}_{\mathrm{n}}{ }^{2-}$

The $S_{n}^{2-}(n=3-9)$ anions generally have a chain structure. The average $S-S$ bond length is smaller in $\mathrm{S}_{n}^{2-}$ ions $(n>2)$ than in $\mathrm{S}_{2}^{2-}$, and the length of the S-S terminal bond decreases from $S_{3}^{2-}(215 \mathrm{pm})$ to $S_{7}^{2-}$ (199.2 pm). These data indicate that the negative charge (filling a $\pi^{*}$ antibonding MO) is delocalized over the entire chain, but the delocalization along the chain is less in higher polysulfides. These considerations are important in comparing the $\mathrm{S}-\mathrm{S}$ bond lengths of the free ions with those of their metal complexes. Fig. 16.5.3 shows the structures of some polysulfide coordination compounds.

### 16.6 Oxides and oxoacids of sulfur

### 16.6.1 Oxides of sulfur

More than ten oxides of sulfur are known, and the most important industrially are $\mathrm{SO}_{2}$ and $\mathrm{SO}_{3}$. The six homocyclic polysulfur monoxides $\mathrm{S}_{n} \mathrm{O}(5 \leq n \leq 10)$ are prepared by oxidizing the appropriate $\mathrm{cyclo}-\mathrm{S}_{n}$ with trifluoroperoxoacetic

acid, $\mathrm{CF}_{3} \mathrm{C}(\mathrm{O}) \mathrm{OOH}$, at $-30^{\circ} \mathrm{C}$. The dioxides $\mathrm{S}_{7} \mathrm{O}_{2}$ and $\mathrm{S}_{6} \mathrm{O}_{2}$ are also known. In addition, there are the thermally unstable acylclic oxides $\mathrm{S}_{2} \mathrm{O}, \mathrm{S}_{2} \mathrm{O}_{2}$, SO and the elusive species SOO and $\mathrm{SO}_{4}$. The $\mathrm{S}_{2} \mathrm{O}$ molecule has a bent structure with $C_{\mathrm{S}}$ symmetry, and its structural parameters are $\mathrm{S}=\mathrm{O}$ bond length $145.6 \mathrm{pm}, \mathrm{S}=\mathrm{S}$ 188.4 pm , and bond angle $\mathrm{S}-\mathrm{S}-\mathrm{O}$ is $117.9^{\circ}$.

## (1) Sulfur dioxide, $\mathrm{SO}_{2}$

When sulfide ores (such as pyrite), sulfur-rich organic compounds, and fossil fuels (such as coal) are burned in air, the sulfur therein is mostly converted to $\mathrm{SO}_{2}$.

Sulfur dioxide is a colorless, toxic gas with a choking odor. Gaseous $\mathrm{SO}_{2}$ neither burns nor supports combustion. It is readily soluble in water ( $3927 \mathrm{~cm}^{3}$ $\mathrm{SO}_{2}$ in $100 \mathrm{~g} \mathrm{H}_{2} \mathrm{O}$ at $20^{\circ} \mathrm{C}$ ) and forms "sulfurous acid."

Sulfur dioxide is a component of air pollutants, and is capable of causing severe damage to human and other animal lungs, particularly in the sulfate form. It is also an important precursor to acid rain. The $\mathrm{SO}_{2}$ molecule survives for a few days in the atmosphere before it is oxidized to $\mathrm{SO}_{3}$. The direct reaction

$$
2 \mathrm{SO}_{2}(\mathrm{~g})+\mathrm{O}_{2}(\mathrm{~g}) \rightarrow 2 \mathrm{SO}_{3}(\mathrm{~g})
$$

is very slow, but it speeds up markedly in the presence of metal cations such as $\mathrm{Fe}^{3+}$.

Sulfur dioxide is a bent molecule with $C_{2 v}$ symmetry; the bond angle is $119^{\circ}$, and the bond length is 143.1 pm , which is shorter than the expected value of a single S-O ( 176 pm ) or $\mathrm{S}=\mathrm{O}$ double bond ( 154 pm ) calculated from the sum of covalent radii. The $\mathrm{S}-\mathrm{O}$ bond energy in $\mathrm{SO}_{2}$ is $548 \mathrm{~kJ} \mathrm{~mol}^{-1}$, which is larger than that of the unstable molecule $\mathrm{SO}\left(524 \mathrm{~kJ} \mathrm{~mol}^{-1}\right)$. These data indicate that the $\mathrm{S}-\mathrm{O}$ bond order in $\mathrm{SO}_{2}$ exceeds 2 , a consequence of the participation of the 3 d orbitals of S in bonding. Sulfur dioxide is homologous with $\mathrm{O}_{3}$. In the bent molecule $\mathrm{O}_{3}$ the $\mathrm{O}-\mathrm{O}$ bond length is 127.8 pm , which is longer than that in $\mathrm{O}_{2}$ ( 120.7 pm ).

There are lone pairs in the S and O atoms of $\mathrm{SO}_{2}$ molecule, which as a ligand forms many coordination modes with metal atoms, as shown in Fig. 16.6.1.

(b)

(c)

## (2) Sulfur trioxide, $\mathrm{SO}_{3}$

Sulfur trioxide is made on a huge scale by the catalytic oxidation of $\mathrm{SO}_{2}$. It is usually not isolated but is immediately converted to $\mathrm{H}_{2} \mathrm{SO}_{4}$.

In the gas phase, monomeric $\mathrm{SO}_{3}$ has a $D_{3 \mathrm{~h}}$ planar structure with bond length S-O 142 pm , as shown in Fig. 16.6.2(a). The cyclic trimer $\left(\mathrm{SO}_{3}\right)_{3}$ occurs in colorless orthorhombic $\gamma-\mathrm{SO}_{3}\left(\mathrm{mp} 16.9^{\circ} \mathrm{C}\right)$, and its structure is shown in Fig. 16.6.2(b). The helical chain structure of $\beta-\mathrm{SO}_{3}$ is shown in Fig. 16.6.2(c). A third and still more stable form, $\alpha-\mathrm{SO}_{3}\left(\mathrm{mp} 62^{\circ} \mathrm{C}\right.$ ), involves cross-linkage between the chains to give a complex layer structure. The standard enthalpies of formation of the four forms of $\mathrm{SO}_{3}$ at 298 K are listed below:

|  | $\mathrm{SO}_{3}(\mathrm{~g})$ | $\alpha-\mathrm{SO}_{3}$ | $\beta-\mathrm{SO}_{3}$ | $\gamma-\mathrm{SO}_{3}$ |
| :--- | :--- | :--- | :--- | :--- |
| $\Delta H_{f}^{0} / \mathrm{kJ} \mathrm{mol}^{-1}$ | -395.2 | -462.4 | -449.6 | -447.4 |

Sulfur trioxide reacts vigorously and extremely exothermically with water to give $\mathrm{H}_{2} \mathrm{SO}_{4}$. Anhydrous $\mathrm{H}_{2} \mathrm{SO}_{4}$ has an unusually high dielectric constant, and also a very high electrical conductivity which results from the ionic selfdissociation of the compound coupled with a proton-switch mechanism for the rapid conduction of current through the viscous hydrogen-bonded liquid:

$$
2 \mathrm{H}_{2} \mathrm{SO}_{4} \rightleftharpoons \mathrm{H}_{3} \mathrm{SO}_{4}^{-}+\mathrm{HSO}_{4}^{-} .
$$

Photolysis of $\mathrm{SO}_{3}$ and $\mathrm{O}_{3}$ mixtures yields monomeric $\mathrm{SO}_{4}$, which can be isolated by inert-gas matrix techniques at low temperatures ( 15 to 78 K ). Vibration spectroscopy indicates a sulfuryl group together with either an open SOO branch ( $C_{\mathrm{s}}$ structure) or a closed three-membered peroxo ring ( $C_{2 \mathrm{v}}$ structure), the latter being preferred on the basis of the infrared absorption bands. The structures of these two species are illustrated pictorially below.

(a)

(b)

(c)

(e)

## (3) Oxides of cyclic poly-sulfur, $\mathrm{S}_{n} \mathrm{O}$ and $\mathrm{S}_{n} \mathrm{O}_{2}$

When cyclo- $\mathrm{S}_{8},-\mathrm{S}_{9}$, and $-\mathrm{S}_{10}$ are dissolved in $\mathrm{CS}_{2}$ and oxidized by freshly prepared $\mathrm{CF}_{3} \mathrm{C}(\mathrm{O}) \mathrm{O}_{2} \mathrm{H}$ at temperatures below $-10^{\circ} \mathrm{C}$, modest yields (10-20\%) of the corresponding crystalline monoxides $\mathrm{S}_{n} \mathrm{O}$ are obtained. Of these compounds, $\mathrm{S}_{5} \mathrm{O}$ has not yet been isolated, but it has been prepared in solution by the same method. On the other hand, $\mathrm{S}_{6} \mathrm{O}$ has two crystalline modifications: orange $\alpha-\mathrm{S}_{6} \mathrm{O}$ with $\mathrm{mp} 39^{\circ} \mathrm{C}$ (dec) and dark orange $\beta-\mathrm{S}_{6} \mathrm{O}$ with $\mathrm{mp} 34^{\circ} \mathrm{C}$ (dec), and its molecular structure is shown in Fig. 16.6.3(a). Also, $\mathrm{S}_{7} \mathrm{O}$ is a orange crystal with $\mathrm{mp} 55^{\circ} \mathrm{C}$ (dec), and its molecular structure is shown in Fig. 16.6.3(b). Finally, $\mathrm{S}_{8} \mathrm{O}$ is a orange-yellow crystal with $\mathrm{mp} 78^{\circ} \mathrm{C}(\mathrm{dec})$, and its structure is shown in Fig. 16.6.3(c).

In the $\mathrm{S}_{n} \mathrm{O}_{2}$ compounds, $\mathrm{S}_{7} \mathrm{O}_{2}$ is a dark orange crystal which decomposes above room temperature. Its molecular structure is shown in Fig. 16.6.3(d). The structure of $\mathrm{S}_{12} \mathrm{O}_{2}$ as determined from the orange adduct $\mathrm{S}_{12} \mathrm{O}_{2} \cdot 2 \mathrm{SbCl}_{5} \cdot 3 \mathrm{CS}_{2}$ is shown in Fig. 16.6.3(e).

### 16.6.2 Oxoacids of sulfur

Sulfur forms many oxoacids, though few of them can be isolated in pure form. Most are prepared in aqueous solution or as crystalline salts of the corresponding oxoacid anions. Table 16.6.1 lists the common oxoacids of sulfur.

## (1) Sulfuric acid and disulfuric acid

Sulfuric acid is the most important chemical of all sulfur compounds. Anhydrous sulfuric acid is a dense, viscous liquid which is readily miscible with water in all proportions. Sulfuric acid forms hydrogen sulfate (also known as bisulfate, $\left.\mathrm{HSO}_{4}^{-}\right)$and sulfate $\left(\mathrm{SO}_{4}^{2-}\right)$ salts with many metals, which are frequently very stable and are important mineral compounds. Figures 16.6.4(a)-(c) shows the molecular structures of $\mathrm{H}_{2} \mathrm{SO}_{4}, \mathrm{HSO}_{4}^{-}$, and $\mathrm{SO}_{4}^{2-}$.

The crystal structure of sulfuric acid consists of layers of $\mathrm{O}_{2} \mathrm{~S}(\mathrm{OH})_{2}$ tetrahedra connected via hydrogen bonds involving the donor OH groups and acceptor O atoms. Figure 16.6 .5 shows a layer of hydrogen-bonded $\mathrm{H}_{2} \mathrm{SO}_{4}$ molecules.

Fig. 16.6.3.
Molecular structure of oxides of cyclic poly-sulfur: (a) $\mathrm{S}_{6} \mathrm{O}$, (b) $\mathrm{S}_{7} \mathrm{O}$, (c) $\mathrm{S}_{8} \mathrm{O}$, (d) $\mathrm{S}_{7} \mathrm{O}_{2}$, (e) $\mathrm{S}_{12} \mathrm{O}_{2}$.

Table 16.6.1. The common oxoacids of sulfur

| Formula | Name | Oxidation state of S | Schematic structure | Salt |
| :---: | :---: | :---: | :---: | :---: |
| $\mathrm{H}_{2} \mathrm{SO}_{4}$ | Sulfuric | 6 |  | Sulfate $\mathrm{SO}_{4}^{2-}$ |

<\mathrm{S}-\mathrm{O}_{t}>144 \mathrm{pm} \\
\mathrm{~S}-\mathrm{O}-\mathrm{S} 124^{\circ} \mathrm{pm}
\end{gathered}
$$

(d)

The $\mathrm{O}-\mathrm{H} \cdots \mathrm{O}$ hydrogen bond length is 264.8 pm and the bond angle $\mathrm{O}-\mathrm{H} \cdots \mathrm{O}$ is $170^{\circ}$.

The hydrogen sulfate (or bisulfate) anion $\mathrm{HSO}_{4}^{-}$exists in crystalline salts such as $\left(\mathrm{H}_{3} \mathrm{O}\right)\left(\mathrm{HSO}_{4}\right), \mathrm{K}\left(\mathrm{HSO}_{4}\right)$ and $\mathrm{Na}\left(\mathrm{HSO}_{4}\right)$. The bond lengths of $\mathrm{HSO}_{4}^{-}$ in $\left(\mathrm{H}_{3} \mathrm{O}\right)\left(\mathrm{HSO}_{4}\right)$ are $\mathrm{S}-\mathrm{O}=145.6 \mathrm{pm}$ and $\mathrm{S}-\mathrm{OH}=155.8 \mathrm{pm}$.

Disulfuric acid (also known as pyrosulfuric acid), $\mathrm{H}_{2} \mathrm{~S}_{2} \mathrm{O}_{7}$, which is the major constituent of "fuming sulfuric acid", is formed from sulfur trioxide and sulfuric acid:

$$
\mathrm{SO}_{3}+\mathrm{H}_{2} \mathrm{SO}_{4} \rightarrow \mathrm{H}_{2} \mathrm{~S}_{2} \mathrm{O}_{7}
$$

Figure 16.6.4(d) shows the structure of the $\mathrm{S}_{2} \mathrm{O}_{7}^{2-}$ anion.

## (2) Sulfurous acid and disulfurous acid

Sulfurous acid, $\mathrm{H}_{2} \mathrm{SO}_{3}$, and disulfurous acid, $\mathrm{H}_{2} \mathrm{~S}_{2} \mathrm{O}_{5}$, are examples of sulfur oxoacids that do not exist in the free state, although numerous salts derived from them containing the $\mathrm{HSO}_{3}^{-}, \mathrm{SO}_{3}^{2-}, \mathrm{HS}_{2} \mathrm{O}_{5}^{-}$, and $\mathrm{S}_{2} \mathrm{O}_{5}^{2-}$ anions are stable

Fig. 16.6.4.

(b) $\mathrm{HSO}_{4}^{-}$, (c) $\mathrm{SO}_{4}^{2-}$ and (d) $\mathrm{S}_{2} \mathrm{O}_{7}^{2-}$.

## Fig. 16.6.6.

Structure of (a) $\mathrm{SO}_{3}^{2-}$, (b) $\mathrm{S}_{2} \mathrm{O}_{5}^{2-}$, and (c) $\mathrm{S}_{2} \mathrm{O}_{4}^{2-}$ (bond lengths in pm).

Fig. 16.6.7.
The coordination modes of $\mathrm{S}_{2} \mathrm{O}_{3}^{2-}$.

solids. An aqueous solution of $\mathrm{SO}_{2}$, though acidic, contain negligible quantities of the free acid $\mathrm{H}_{2} \mathrm{SO}_{3}$. The apparent hexahydrate $\mathrm{H}_{2} \mathrm{SO}_{3} \cdot 6 \mathrm{H}_{2} \mathrm{O}$ is actually the gas hydrate $6 \mathrm{SO}_{2} \cdot 46 \mathrm{H}_{2} \mathrm{O}$, in which the $\mathrm{SO}_{2}$ molecules are enclosed in cages within a host framework constructed from hydrogen-bonded water molecules. Figure 16.6 .6 shows the structures of the anions $\mathrm{SO}_{3}^{2-}, \mathrm{S}_{2} \mathrm{O}_{5}^{2-}$, and $\mathrm{S}_{2} \mathrm{O}_{4}^{2-}$. The hydrogen sulfite (bisulfite) ion $\mathrm{HSO}_{3}^{-}$has been found to exist in two isomeric forms: $\mathrm{HO}-\mathrm{SO}_{2}^{-}$and $\mathrm{H}-\mathrm{SO}_{3}^{-}$.

## (3) Thiosulfate, $\mathrm{SSO}_{3}^{2-}$

In the thiosulfate ion, a terminal S atom replaces an O atom of the sulfate ion. The $\mathrm{S}-\mathrm{S}$ bond length is 201.3 pm , which indicates essentially single-bond character, while the mean S-O bond length is 146.8 pm , which indicates considerable $\pi$ bonding between the S and O atoms.

Single-crystal X-ray analysis has shown that the structure of $\mathrm{SeSO}_{3}^{2-}$ is isostructural with the $\mathrm{S}_{2} \mathrm{O}_{3}^{2-}$ ion with a $\mathrm{Se}-\mathrm{S}$ bond length of $217.5(1) \mathrm{pm}$.

The thiosulfate ion, in which the terminal S and O atoms can function as ligand sites, is a polyfunctional species in various coordination modes with metal atoms. Figure 16.6 .7 shows the coordination modes of $\mathrm{S}_{2} \mathrm{O}_{3}^{2-}$.

## (4) Peroxoacids of sulfur

The peroxoacids of sulfur and their salts all contain the -O-O- group. The salts of $\mathrm{S}_{2} \mathrm{O}_{8}^{2-}$, such as $\mathrm{K}_{2} \mathrm{~S}_{2} \mathrm{O}_{8}$, are very convenient and powerful oxidizing agents. Peroxomonosulfuric acid (Caro's acid), $\mathrm{H}_{2} \mathrm{SO}_{5}$, is a colorless, explosive solid ( $\mathrm{mp} 45^{\circ} \mathrm{C}$ ), and salts of $\mathrm{HSO}_{5}^{-}$are known. In $\mathrm{HSO}_{5}^{-}$and $\mathrm{S}_{2} \mathrm{O}_{8}^{2-}$, the $\mathrm{S}-\mathrm{O}$ (peroxo) and $\mathrm{S}-\mathrm{O}$ (terminal) bond distances are different. The $\mathrm{S}-\mathrm{O}$ (peroxo) bond length is about 160 pm , which corresponds to a single bond, and the $\mathrm{S}-\mathrm{O}$ (terminal) bond length is about 145 pm , which corresponds to a double bond.

The structural formulas of $\mathrm{HSO}_{5}^{-}$and $\mathrm{S}_{2} \mathrm{O}_{8}^{2-}$ are shown below:

$\mathrm{HSO}_{5}^{-}$

$\mathrm{S}_{2} \mathrm{O}_{8}{ }^{2-}$

### 16.7 Sulfur-nitrogen compounds

Sulfur and nitrogen are diagonally related elements in the Periodic Table and might therefore be expected to have similar electronic charge densities for similar coordination numbers, and to form cyclic, acyclic, and polycyclic molecules through extensive covalent bonding. Some sulfur-nitrogen compounds exhibit interesting chemical bonding and have unusual properties, as discussed below.

### 16.7.1 Tetrasulfur tetranitride, $\mathrm{S}_{4} \mathrm{~N}_{4}$

Nitride $\mathrm{S}_{4} \mathrm{~N}_{4}$ is an air-stable compound that can be prepared by passing $\mathrm{NH}_{3}$ gas into a warm solution of $\mathrm{S}_{2} \mathrm{Cl}_{2}$ in $\mathrm{CCl}_{4}$ or benzene. It is a thermochromic crystal: colorless at 83 K , pale yellow at 243 K , orange at room temperature, and deep red above 373 K .

The $D_{2 \mathrm{~d}}$ molecular structure of $\mathrm{S}_{4} \mathrm{~N}_{4}$ is shown in Fig. 16.7.1(a). The atoms of $\mathrm{S}_{4} \mathrm{~N}_{4}$ are arranged so that the electropositive S atoms occupy the vertices of a tetrahedron, while the electronegative N atoms constitute a square that intersects the tetrahedron. All the $\mathrm{S}-\mathrm{N}$ distances are equal; for gaseous $\mathrm{S}_{4} \mathrm{~N}_{4}$ they are 162.3 pm , which is intermediate between the distances of the $\mathrm{S}-\mathrm{N}$ single bond ( 174 pm ) and $\mathrm{S}=\mathrm{N}$ double bond ( 154 pm ). The $\mathrm{N}-\mathrm{S}-\mathrm{N}$ bond angle is $105.3^{\circ}, \mathrm{S}-\mathrm{N}-\mathrm{S}$ is $114.2^{\circ}$, and $\mathrm{S}-\mathrm{S}-\mathrm{N}$ is $88.4^{\circ}$. A peculiarity of the $\mathrm{S}_{4} \mathrm{~N}_{4}$ structure is the short distance between the two S atoms connected by a broken line in Fig. 16.7.1(a); at 258 pm , it lies between the $\mathrm{S}-\mathrm{S}$ single-bond length ( 208 pm ) and van der Waals contacting distance $\mathrm{S} \cdots \mathrm{S} 360 \mathrm{pm}$. This may imply that the S atom uses two electrons for two $\sigma \mathrm{S}-\mathrm{N}$ bonds, one electron for delocalized $\pi$ bonding, and one electron for $S \cdots S$ weak bonding.

Tetraselenium tetranitride, $\mathrm{Se}_{4} \mathrm{~N}_{4}$, forms red, hygroscopic crystals and is highly explosive. The structure of $\mathrm{Se}_{4} \mathrm{~N}_{4}$ resembles that of $\mathrm{S}_{4} \mathrm{~N}_{4}$ with $\mathrm{Se}-\mathrm{N}$ bond length of 180 pm and cross-cage $\mathrm{Se} \cdots$ Se distance of 276 pm (note that $\left.2 r_{\mathrm{cov}}(\mathrm{Se})=2 \times 117 \mathrm{pm}=234 \mathrm{pm}\right)$.

(a)

(b)

Fig. 16.7.1.
Molecular structure of (a) $\mathrm{S}_{4} \mathrm{~N}_{4}$ and (b) $\mathrm{As}_{4} \mathrm{~S}_{4}$.

Fig. 16.7.2.
Structure of (a) $\mathrm{S}_{2} \mathrm{~N}_{2}$ and (b) polymeric chains in one layer of $(\mathrm{SN})_{x}$ and the important structural parameters (bond lengths in pm ).

The homolog realgar, $\mathrm{As}_{4} \mathrm{~S}_{4}$, has an analogous but different structure with the electronegative $S$ atoms at the vertices of a square and the electropositive As atoms at the vertices of a tetrahedron. The As atoms are linked by normal single bonds, as shown by the solid lines between them in Fig. 16.7.1(b). The As-As distance is 249 pm , which is nearly equal to the calculated value of 244 pm (Table 3.4.3).

### 16.7.2 $\quad S_{2} \mathrm{~N}_{2}$ and $(\mathrm{SN})_{x}$

When the heated vapor of $\mathrm{S}_{4} \mathrm{~N}_{4}$ is passed over silver wool at 520 to 570 K , the unstable cyclic dimer $\mathrm{S}_{2} \mathrm{~N}_{2}$ is obtained. It forms large colorless crystals which are insoluble in water but soluble in many organic solvents.

The molecular structure of $\mathrm{S}_{2} \mathrm{~N}_{2}$, as shown in Fig. 16.7.2(a), is a $D_{2 \mathrm{~h}}$ squareplanar ring with S-N edge 165 pm , somewhat analogous to the isoelectronic cation $S_{4}^{2+}$ (Fig. 16.4.2). The valence-bond representations of the $\mathrm{S}_{2} \mathrm{~N}_{2}$ molecule are as follows:

When colorless $\mathrm{S}_{2} \mathrm{~N}_{2}$ crystals are allowed to stand at room temperature, golden (SN) $x_{x}$ crystals are gradually formed. The (SN) $)_{x}$ chain can conceivably be generated from adjacent square-planar $\mathrm{S}_{2} \mathrm{~N}_{2}$ molecules, and a free radical mechanism has been proposed. Since polymerization can take place with only minor movements of the atoms, the starting material and product are pseudomorphs without alteration of the crystallinity. Figure 16.7.2 shows the configuration of the $(\mathrm{SN})_{x}$ chains and the packing of the chains in the crystal.

Polymeric (SN) $)_{x}$ has some unusual properties. For example, it has a bronze color and metallic luster, and its electrical conductivity is about that of mercury metal. Values of the conductivity of $(\mathrm{SN})_{x}$ depend on the purity and crystallinity of the polymer and on the direction of measurement, being much greater along the fibers than across them. A conjugated single-bond/double-bond system can be formulated, in which every $\mathrm{S}-\mathrm{N}$ unit has one antibonding $\pi^{*}$ electron. The half-filled overlapping $\pi^{*}$ orbitals combine to form a half-filled conduction band, in much the same way as the half-filled $n$ s orbitals of alkali metal atoms

$\mathrm{S}_{4} \mathrm{~N}_{2}$

$\mathrm{S}_{3} \mathrm{~N}_{2}{ }^{2+}$

$\mathrm{S}_{3} \mathrm{~N}_{3}{ }^{-}$

form a conduction band. However, in $(\mathrm{SN})_{x}$, the conduction band lies only in the direction of the (SN) $)_{x}$ fibers, so the polymer behaves as an "one-dimensional metal".

### 16.7.3 Cyclic sulfur-nitrogen compounds

Many cyclic sulfur-nitrogen compounds are known, some of which are shown in Fig. 16.7.3. The general structural features of sulfur-nitrogen compounds are formulated as follows:
(a) The S atom has the ability to form various types of $\mathrm{S}-\mathrm{S}$ and $\mathrm{S}-\mathrm{N}$ bonds, some of which contain catenated $-S-S$ - chains that can insert into the cyclic chains as a fragment in molecules. For example, the $\mathrm{S}_{11} \mathrm{~N}_{2}$ molecule has two $S_{5}$ chain fragments, and $S_{4} \mathrm{~N}_{2}$ and $\mathrm{S}_{4} \mathrm{~N}^{-}$each has one $\mathrm{S}_{3}$ chain fragment. The $\mathrm{S} \cdots$ S interactions can vary in strength: 314 pm in $\mathrm{S}_{4} \mathrm{~N}^{-}$as compared to $271-5 \mathrm{pm}$ in $\mathrm{S}_{4} \mathrm{~N}_{5}^{-}$.
(b) The $\mathrm{S}-\mathrm{N}$ bond distances are in the range of 155 to 165 pm , which are shorter than the calculated single-bond length, so the S-N bonds have some double-bond character. The bond angles vary over a large range: for example,
in $\mathrm{S}_{5} \mathrm{~N}_{5}^{+}$the bond angles are between $138^{\circ}$ and $151^{\circ}$. The wide variations of bond distances and angles indicate that the bond types are quite complex.
(c) Normally the S and N atoms are each bonded to two adjacent atoms, but in some cases they are also three-connected to form polycyclic molecules. Some examples are as $\mathrm{S}_{5} \mathrm{~N}_{6}, \mathrm{~S}_{11} \mathrm{~N}_{2}, \mathrm{~S}_{4} \mathrm{~N}_{5}^{+}$and $\mathrm{S}_{4} \mathrm{~N}_{5}^{-}$, the structures of which are shown in Fig. 16.7.3.
(d) The conformations of the cyclic S-N molecules exhibit diversity. For example, $\mathrm{S}_{3} \mathrm{~N}_{2}^{2+}$ and $\mathrm{S}_{3} \mathrm{~N}_{3}^{-}$adopt planar conformations which are stabilized by delocalized $\pi$ bonding, while the majority of these cyclic molecules are nonplanar, in which the d orbitals of S atoms also participate in bonding.

### 16.8 Structural chemistry of selenium and tellurium

### 16.8.1 Allotropes of selenium and tellurium

Selenium forms several allotropes but tellurium forms only one. The thermodynamically stable form of selenium ( $\alpha$-selenium or gray selenium) and the crystalline form of tellurium are isostructural. In both Te and gray Se , the atoms form infinite, helical chains having three atoms in every turn, the axes of which lie parallel to each other in the crystal, as shown in Fig. 16.8.1.

The distance of two adjacent atoms within the chain are Se-Se 237 pm and Te-Te 283 pm . Each atom has four adjacent atoms from three different chains at an average distance of $\mathrm{Se} \cdots \mathrm{Se} 344 \mathrm{pm}, \mathrm{Te} \cdots \mathrm{Te} 350 \mathrm{pm}$. The interchain distance is significantly shorter than expected from the van der Waals separation ( 380 pm for Se and 412 pm for Te ).

Red monoclinic selenium exists in three forms, each containing $\mathrm{Se}_{8}$ rings with the crown conformation of $\mathrm{S}_{8}$ (Fig. 16.4.1). Vitreous black selenium, the ordinary commercial form of the element, comprises an extremely complex and irregular structure of large polymeric rings.

### 16.8.2 Polyatomic cations and anions of selenium and tellurium

Like their sulfur congener, selenium and tellurium can form polyatomic cations and anions in many compounds.

## (1) Polyatomic cations

Figure 16.8.2 show the structures of some polyatomic cations of Se and Te that exist in crystalline salts. Figure 16.8.2(a) shows the square-planar geometry of the $\mathrm{Se}_{4}^{2+}$ and $\mathrm{Te}_{4}^{2+}$ cations. In $\mathrm{Se}_{4}\left(\mathrm{HS}_{2} \mathrm{O}_{7}\right)_{2}$ the $\mathrm{Se}-\mathrm{Se}$ distance is 228 pm , and in $\mathrm{Te}_{4}\left(\mathrm{AsF}_{6}\right)_{2}$ the $\mathrm{Te}-\mathrm{Te}$ distance is 266 pm . These two distances are shorter than those in the respective elemental forms, 237 and 284 pm, respectively, being consistent with the effect of some multiple bonding.

The structure of $\mathrm{Te}_{6}^{4+}$ is shown in Fig. 16.8.2(c). In this trigonal prismatic cation, the average $\mathrm{Te}-\mathrm{Te}$ bond length within a triangular face is 268 pm , and the average $\mathrm{Te} \cdots \mathrm{Te}$ distance between the parallel triangular faces is 313 pm . The $\mathrm{Te}_{6}^{4+}$ cation can be considered as a dimer of two $\mathrm{Te}_{3}^{2+}$ units consolidated by a $\pi^{*}-\pi^{*} 6 c-4 e$ bonding interaction. As shown in Fig. 16.8.3, the tellurium $5 \mathrm{p}_{z}$ orbitals give rise to six molecular orbitals of $a_{1}^{\prime}, e^{\prime}, a_{2}^{\prime \prime}$, and $e^{\prime \prime}$ symmetry, the first three being used to accommodate eight valence electrons. The $e^{\prime}$ orbitals are nonbonding within the individual $\mathrm{Te}_{3}^{2+}$ units but form bonding interaction between them, and the bonding $a_{1}^{\prime}$ and antibonding $a_{2}^{\prime \prime}$ orbitals cancel each other. The formal bond order along each prism edge is therefore $2 / 3$.

Formal addition of two electrons to $\mathrm{Te}_{6}^{4+}$ gives $\mathrm{Te}_{6}^{2+}$, which takes the shape of a boat-shaped six-membered ring, as shown in Fig. 16.8.2(b). The average length of the pair of weak transannular interactions is 329 pm , which indicates that the two positive charges are delocalized over all four Te atoms in the rectangular base.

Fig. 16.8.2.

## Structural Chemistry of Selected Elements

Figure 16.8.2(d) shows the conformation of and weak central transannular interaction in the $\mathrm{Se}_{8}^{2+}$ and $\mathrm{Te}_{8}^{2+}$ cations, which are isostructural with $\mathrm{S}_{8}^{2+}$. Their common bicyclic structure can be regarded as being derived from a crownshaped eight-membered ring by flipping one atom from an exo to an endo position, with the formally positively charged atoms interacting in transannular linkage. $\mathrm{In}_{8}\left(\mathrm{ReCl}_{6}\right)_{2}$, the $\mathrm{Te}-\mathrm{Te}$ bond length indicates a normal single bond, and the $\mathrm{Te} \cdots \mathrm{Te}$ distance is 315 pm . In $\mathrm{Se}_{8}\left(\mathrm{AlCl}_{4}\right)_{2}$, the $\mathrm{Se}-\mathrm{Se}$ bond lengths lie in the range $229-36 \mathrm{pm}$, and $\mathrm{Se} \cdots$ Se is 284 pm .

Figures 16.8.2(e) and (f) show two other isomeric forms of $\mathrm{Te}_{8}^{2+}$. In $\mathrm{Te}_{8}\left(\mathrm{WCl}_{6}\right)_{2}$, the $\mathrm{Te}_{8}^{2+}$ cation is composed of two five-membered rings, each taking an envelope conformation, with an average $\mathrm{Te}-\mathrm{Te}$ bond length of 275 pm and a relatively short transannular $\mathrm{Te} \cdots \mathrm{Te}$ bond of 295 pm . In $\left(\mathrm{Te}_{6}\right)\left(\mathrm{Te}_{8}\right)\left(\mathrm{WCl}_{6}\right)_{4}, \mathrm{Te}_{8}^{2+}$ exhibits a bicyclo[2.2.2]octane geometry with two bridge-head Te atoms.

Figure $16.8 .2(\mathrm{~g})$ shows the structure of $\mathrm{Te}_{8}^{4+}$; this 44 valence electron cluster takes a cube shape with two cleaved edges, the positive charges being located on four three-coordinate Te atoms. The $\mathrm{Te}_{8}^{4+}$ cation can be viewed as two planar $\mathrm{Te}_{4}^{2+}$ ions that have dimerized via the formation of a pair of $\mathrm{Te}-\mathrm{Te}$ bonds with simultaneous loss of electronic delocalization and distortion from planarity.

Figures 16.8.2(h), (i), and (j) show the structures of $\mathrm{Se}_{10}^{2+}, \mathrm{Se}_{17}^{2+}$, and $\mathrm{Se}_{19}^{2+}$, respectively. They all consist of seven- or eight-membered rings connected by short chains. Each homopolyatomic cation has two three-coordinate atoms that formally carry the positive charges. $\mathrm{Se}_{10}^{2+}$ has a bicyclo[2.2.4]decane geometry. The Se-Se bond distances vary between 225 and 240 pm , and the $\mathrm{Se}-\mathrm{Se}-\mathrm{Se}$ angles range from $97^{\circ}$ to $106^{\circ} . \mathrm{Se}_{17}^{2+}$ and $\mathrm{Se}_{19}^{2+}$ comprise a pair of seven-membered rings connected by a three- and four-atom chain, respectively.

Figures 16.8.2(k), (l), and (m) show the structures of $\left(\mathrm{Te}_{2} \mathrm{Se}_{4}\right)^{2+},\left(\mathrm{Te}_{2} \mathrm{Se}_{6}\right)^{2+}$ and $\left(\mathrm{Te}_{2} \mathrm{Se}_{8}\right)^{2+}$, respectively. In these heteropolyatomic cations, the heavier Te atoms generally have a higher coordination number of three and serve as positive charge bearers, which is consistent with the lower electronegativity of Te compared to Se . As expected and confirmed by experiment, a weak transannular $\mathrm{Te} \cdots \mathrm{Te}$ bond exists in the boat-shaped $\left(\mathrm{Te}_{2} \mathrm{Se}_{4}\right)^{2+}$ cation. The $\left(\mathrm{Te}_{2} \mathrm{Se}_{6}\right)^{2+}$ and $\left(\mathrm{Te}_{2} \mathrm{Se}_{8}\right)^{2+}$ cations have bicyclo[2.2.2]octane and bicyclo[2.2.4]decane geometries, respectively, with the Te atoms located at the bridge-head positions.

Figure 16.8.4 shows the structures of some polymeric cations of Se and Te . In most of these systems, the $\mathrm{Te}-\mathrm{Te}$ bonds link the Te atoms to form an infinite polymeric chain. The coordination numbers of the Te atoms are normally two or three, but some may attain the value of four in forming hypervalent structures. Various polymeric cations contain four-, five-, or six-membered rings. The four-membered ring is planar, but the larger rings are nonplanar. The rings are directly connected or linked by short fragments of one, two, three atoms. In the heteroatom polymeric cations, the Te atoms invariably occupy the threecoordinate sites.

Figures 16.8.4(a) and (j) show the structures of the coexisting $\left(\mathrm{Te}_{4}^{2+}\right)_{\infty}$ and $\left(\mathrm{Te}_{10}^{2+}\right)_{\infty}$ in $\left(\mathrm{Te}_{4}\right)\left(\mathrm{Te}_{10}\right)\left(\mathrm{Bi}_{4} \mathrm{Cl}_{16}\right) .\left(\mathrm{Te}_{4}^{2+}\right)_{\infty}$ is composed of planar squares of Te atoms connected by $\mathrm{Te}-\mathrm{Te}$ bonds to form an infinite zigzag chain. There are
(a)

(d)

(f)

(h)

(i)

(j)

equal numbers of two- and three-coordinate Te atoms, so that the latter carry the positive charges. The bond lengths within each square ring are 275 and 281 pm , and the interring bond distance is 297 pm .
Figures 16.8.4(b) to (e) show the structures of $\left(\mathrm{Te}_{6}^{2+}\right)_{\infty}$ in $\left(\mathrm{Te}_{6}\right)\left(\mathrm{HfCl}_{6}\right)$, $\left(\mathrm{Te}_{7}^{2+}\right)_{\infty}$ in $\left(\mathrm{Te}_{7}\right)\left(\mathrm{AsF}_{6}\right)_{2}$, and $\left(\mathrm{Te}_{8}^{2+}\right)_{\infty}$ in $\left(\mathrm{Te}_{8}\right)\left(\mathrm{U}_{2} \mathrm{Br}_{10}\right)$ and $\left(\mathrm{Te}_{8}\right)\left(\mathrm{Bi}_{4} \mathrm{Cl}_{14}\right)$, respectively. These polymeric zigzag chains are composed of five- or sixmembered rings linked by one or two atoms.

Figures 16.8.4(f) and (g) show the structures of two related heteroatom polymeric cationic chains composed of Te and Se . In $\left(\mathrm{Te}_{3.15} \mathrm{Se}_{4.85}\right)\left(\mathrm{WOCl}_{4}\right)_{2}$, the non-stoichiometric, disordered $\left(\mathrm{Te}_{3.15} \mathrm{Se}_{4.85}^{2+}\right)_{\infty}$ cationic chains are constructed from the linkage of five-membered rings by nonlinear three-atom fragments. In $\left(\mathrm{Te}_{3} \mathrm{Se}_{4}\right)\left(\mathrm{WOCl}_{4}\right)_{2}$, the $\left(\mathrm{Te}_{3} \mathrm{Se}_{4}^{2+}\right)_{\infty}$ chain is composed of planar $\mathrm{Te}_{2} \mathrm{Se}_{2}$ rings connected by nonlinear $\mathrm{Se}-\mathrm{Te}-\mathrm{Se}$ fragments.

Figures 16.8.4(h) to ( j ) show the structures of polymeric cations that contain hypervalent Te atoms. Two kinds of $\left(\mathrm{Te}_{7}^{2+}\right)_{\infty}$ chains are found separately in $\left(\mathrm{Te}_{7}\right)\left(\mathrm{Bi}_{2} \mathrm{Cl}_{6}\right)$ and $\left(\mathrm{Te}_{7}\right)\left(\mathrm{NbOCl}_{4}\right)_{2}$, and $\left(\mathrm{Te}_{10}^{2+}\right)_{\infty}$ exists in $\left(\mathrm{Te}_{4}\right)\left(\mathrm{Te}_{10}\right)\left(\mathrm{Bi}_{4} \mathrm{Cl}_{16}\right)$. In these polymeric cations, the hypervalent Te atoms each exhibits square-planar coordination to form a $\mathrm{Te}_{\mathrm{T}}^{4} 4$ unit with $\mathrm{Te}-\mathrm{Te}$ bond lengths in the range 292-7 pm. In $\left(\mathrm{Te}_{7}^{2+}\right)_{\infty}$, the $\mathrm{TeTe}_{4}$ unit and a pair of terminal Te atoms constitute an enlarged $\mathrm{Te}_{7}$ unit composed of two planar squares sharing a common vertex. In $\left(\mathrm{Te}_{10}^{2+}\right)_{\infty}$, the basic $\mathrm{Te}_{10}$ structural unit consists of a linear arrangement of three corner-sharing planar squares, and such $\mathrm{Te}_{10}$

units are laterally connected by $\mathrm{Te}-\mathrm{Te}$ bonds to generate a corrugated polymeric ribbon that also contain chair-like six-membered rings.

## (2) Polyatomic anions

The chemistry of polyselenides, polytellurides, and their metal complexes is very well established. Typical structures of polyselenide dianions are shown in Fig. 16.8.5. In these species, the Se-Se bond distances vary from 227 to 236 pm, and the bond angles from $103^{\circ}$ to $110^{\circ}$. The tethered monocyclic structure of $\mathrm{Se}_{9}^{2-}$ in the complex $\operatorname{Sr}(15-\mathrm{C} 5)_{2}\left(\mathrm{Se}_{9}\right)$ has a three-connected Se atom forming two long and one normal Se-Se bonds at 295, 247, and 231 pm (anticlockwise in Fig. 16.8.5, with the longest bond represented by a broken line). The other $\mathrm{Se}-\mathrm{Se}$ bonds are in the range $227-39 \mathrm{pm}$.

$\mathrm{Te}_{3}{ }^{2-}$

$\mathrm{Te}_{7}{ }^{2-}$

$\mathrm{Te}_{4}{ }^{2-}$

The dianion $\mathrm{Se}_{11}^{2-}$ has a centrosymmetric spiro-bicyclic structure involving a central square-planar Se atom common to the two chair-shaped rings. The shared atom forms four long $\mathrm{Se}-\mathrm{Se}$ bonds of length $266-8 \mathrm{pm}$, and the structure may be described as a central $\mathrm{Se}^{2+}$ chelated by two $\eta^{2}-\mathrm{Se}_{5}^{2-}$ ligands.

Some typical structures of polytelluride dianions, $\mathrm{Te}_{x}^{2-}$, are shown in Fig. 16.8.6. In these species, the $\mathrm{Te}-\mathrm{Te}$ bond distances vary from 265 to 284 pm . In the bicyclic polytellurides $\mathrm{Te}_{7}^{2-}$ and $\mathrm{Te}_{8}^{2-}$, the central Te atom each has four long bonds with bond lengths from 292 to 311 pm .

The $\mathrm{Se}_{x}^{2-}$ and $\mathrm{Te}_{x}^{2-}$ are effective chelating ligands for both main group and transition metals, giving rise to complexes such as $\operatorname{Sn}\left(\eta^{2}-\mathrm{Se}_{4}\right)_{3}^{2-},\left[\mathrm{M}\left(\eta^{2}-\right.\right.$ $\left.\left.\mathrm{Se}_{4}\right)_{2}\right]^{2-}(\mathrm{M}=\mathrm{Zn}, \mathrm{Cd}, \mathrm{Hg}, \mathrm{Ni}, \mathrm{Pb}), \mathrm{Ti}\left(\eta^{5}-\mathrm{C}_{5} \mathrm{H}_{5}\right)_{2}\left(\eta^{2}-\mathrm{Se} 5\right),\left[\mathrm{Hg}\left(\eta^{3}-\mathrm{Te}_{7}\right)\right]^{2-}$, and $\mathrm{M}_{2}\left(\mu_{2}-\mathrm{Te}_{4}\right)\left(\eta^{2}-\mathrm{Te}_{4}\right)_{2}(\mathrm{M}=\mathrm{Cu}, \mathrm{Ag})$.

### 16.8.3 Stereochemistry of selenium and tellurium

Selenium and tellurium exhibit a great variety of molecular geometries as a consequence of the number of stable oxidation states. Various observed structures are summarized in Table 16.8.1, in which A is a central Se or Te atom, X is an atom bonded to A , and E represents a lone pair.

Table 16.8.1. Molecular geometries of Se and Te

| Type | Molecular geometry | Example (structure in Fig. 16.8.7) |
| :---: | :---: | :---: |
| $\mathrm{AX}_{2} \mathrm{E}$ | Bent | $\mathrm{SeO}_{2}$ |
| $\mathrm{AX}_{2} \mathrm{E}_{2}$ | Bent | $\mathrm{SeCl}_{2}, \mathrm{Se}\left(\mathrm{CH}_{3}\right)_{2}, \mathrm{TeCl}_{2}, \mathrm{Te}\left(\mathrm{CH}_{3}\right)_{2}$ |
| $\mathrm{AX}_{3}$ | Trigonal planar | $\mathrm{SeO}_{3}, \mathrm{TeO}_{3}$ |
| $\mathrm{AX}_{3} \mathrm{E}$ | Trigonal pyramidal | $\left(\mathrm{SeO}_{2}\right)_{x}$ (a), $\mathrm{OSeF}_{2}$ (b) |
| $\mathrm{AX}_{3} \mathrm{E}_{2}$ | T-shaped | $\left[\mathrm{SeC}\left(\mathrm{NH}_{2}\right)_{2}\right]_{3}^{2+}$ (c), $\mathrm{C}_{6} \mathrm{H}_{5} \mathrm{TeBr}\left(\mathrm{SC}_{3} \mathrm{~N}_{2} \mathrm{H}_{6}\right)$ (d) |
| $\mathrm{AX}_{4}$ | Tetrahedral | $\mathrm{O}_{2} \mathrm{SeF}_{2}$, $\left(\mathrm{SeO}_{3}\right)_{4}$ |
| $\mathrm{AX}_{4} \mathrm{E}$ | Disphenoidal | $\mathrm{Se}\left(\mathrm{C}_{6} \mathrm{H}_{5}\right)_{2} \mathrm{Cl}_{2}, \mathrm{Se}\left(\mathrm{C}_{6} \mathrm{H}_{5}\right)_{2} \mathrm{Br}_{2}, \mathrm{Te}\left(\mathrm{CH}_{3}\right)_{2} \mathrm{Cl}_{2}, \mathrm{Te}\left(\mathrm{C}_{6} \mathrm{H}_{5}\right)_{2} \mathrm{Br}_{2}$ |
| $\mathrm{AX}_{5} \mathrm{E}$ | Square pyramidal | $\mathrm{TeF}_{5}^{-}$(e), ( $\left.\mathrm{TeF}_{4}\right)_{x}$ (f) |
| $\mathrm{AX}_{6}$ | Octahedral | $\mathrm{SeF}_{6}, \mathrm{TeF}_{6},\left(\mathrm{TeO}_{3}\right)_{x}, \mathrm{~F}_{5} \mathrm{TeOTeF}_{5}$ (g) |
| $\mathrm{AX}_{6} \mathrm{E}$ | Octahedral | $\mathrm{SeCl}_{6}^{2-}, \mathrm{TeCl}_{6}^{2-}$ |
| $\mathrm{AX}_{7}$ | Pentagonal bipyramidal | $\mathrm{TeF}_{7}^{-}$(h) |

With reference to Table 16.8.1, the stereochemistries of Se and Te compounds are briefly described below.

## (1) $\quad \mathrm{AX}_{2} \mathrm{E}$ type

The $\mathrm{SeO}_{2}$ molecule in the vapor phase has a bent configuration with $\mathrm{Se}-\mathrm{O}$ 160.7 pm and $\mathrm{O}-\mathrm{Se}-\mathrm{O} 114^{\circ}$. Crystalline $\mathrm{SeO}_{2}$ is built of infinite chains, in which each Se atom is bonded to three oxygen atoms $\left(\mathrm{AX}_{3} \mathrm{E}\right.$ type) in a trigonal pyramidal configuration. The bond lengths are $\mathrm{Se}-\mathrm{O}_{\mathrm{b}} 178 \mathrm{pm}, \mathrm{Se}-\mathrm{O}_{\mathrm{t}} 173 \mathrm{pm}$, as shown in Fig. 16.8.7(a).

## (2) $\quad \mathrm{AX}_{2} \mathrm{E}_{2}$ type

Many $\mathrm{AX}_{2} \mathrm{E}_{2}$ type molecules, such as $\mathrm{Se}\left(\mathrm{CH}_{3}\right)_{2}, \mathrm{SeCl}_{2}, \mathrm{Te}\left(\mathrm{CH}_{3}\right)_{2}$, and $\mathrm{TeBr}_{2}$, all exhibit a bent configuration, in which repulsion of lone pairs makes the interbond angles smaller than the ideal tetrahedral angle:

|  | $\mathrm{Se}\left(\mathrm{CH}_{3}\right)_{2}$ | $\mathrm{SeCl}_{2}$ | $\mathrm{Te}\left(\mathrm{CH}_{3}\right)_{2}$ | $\mathrm{TeCl}_{2}$ |
| :--- | :--- | :--- | :--- | :--- |
| $\mathrm{~A}-\mathrm{X}(\mathrm{pm})$ | 194.5 | 215.7 | 214.2 | 232.9 |
| X-A-X | $96.3^{\circ}$ | $99.6^{\circ}$ | $94^{\circ}$ | $97^{\circ}$ |

## (3) AX ${ }_{3}$ type

Monomeric selenium trioxide $\left(\mathrm{SeO}_{3}\right)$ and tellurium trioxide $\left(\mathrm{TeO}_{3}\right)$ have a trigonal planar structure in the gas phase. In the solid state, $\mathrm{SeO}_{3}$ forms cyclic tetramers $\left(\mathrm{SeO}_{3}\right)_{4}$, in which each Se atom connects two bridging O atoms and two terminal O atoms, with $\mathrm{Se}-\mathrm{O}_{\mathrm{b}} 177 \mathrm{pm}$ and $\mathrm{Se}-\mathrm{O}_{\mathrm{t}} 155 \mathrm{pm}$ ( AX 4 type).

(a)

(c)

(e)

(g)

(b)

(d)

(f)

(h)

The solid-state structure of $\mathrm{TeO}_{3}$ is a three-dimensional framework, in which $\mathrm{Te}(\mathrm{VI})$ forms $\mathrm{TeO}_{6}$ octahedra ( $\mathrm{AX}_{6}$ type) sharing all vertices.

## (4) $\mathrm{AX}_{3}$ E type

Pyramidal molecule $\mathrm{SeOF}_{2}$ has bond lengths $\mathrm{Se}=\mathrm{O} 158 \mathrm{pm}$ and $\mathrm{Se}-\mathrm{F} 173 \mathrm{pm}$, bond angles $\mathrm{F}-\mathrm{Se}-\mathrm{F} 92^{\circ}$ and $\mathrm{F}-\mathrm{Se}-\mathrm{O} 105^{\circ}$, as shown in Fig. 16.8.7(b). Its dipole moment ( 2.62 D in benzene) and dielectric constant (46.2 at $20^{\circ} \mathrm{C}$ ) are both high, and accordingly it is a useful solvent.

## (5) $\quad \mathrm{AX}_{3} \mathrm{E}_{2}$ type

The cation $\left[\mathrm{SeC}\left(\mathrm{NH}_{2}\right)_{2}\right]_{3}^{2+}$ adopts T-shaped geometry, as shown in Fig. 16.8.7(c). In this structure, the central Se atom must bear a formal negative charge to have two lone pairs at the equatorial positions of a trigonal bipyramid.

The valence-bond structural formula of this cation is given below:

In the molecule $\mathrm{C}_{6} \mathrm{H}_{5} \mathrm{TeBr}\left(\mathrm{SC}_{3} \mathrm{~N}_{2} \mathrm{H}_{6}\right)$, the Te atom has a similar T -shaped configuration, as shown in Fig. 16.8.7(d). Bonding can be described in terms of resonance between a pair of valence-bond structures:

## (6) $\mathrm{AX}_{4}$ type

The molecule $\mathrm{SeO}_{2} \mathrm{~F}_{2}$ and analogous compounds have tetrahedral geometry with three different bond angles: $\mathrm{O}-\mathrm{Se}-\mathrm{O} 126.2^{\circ}$, $\mathrm{O}-\mathrm{Se}-\mathrm{F} 108.0^{\circ}$, and $\mathrm{F}-\mathrm{Se}-\mathrm{F}$ $94.1^{\circ}$.

## (7) $\quad \mathbf{A X}_{4}$ E type

The molecules $\mathrm{Se}\left(\mathrm{C}_{6} \mathrm{H}_{5}\right)_{2} \mathrm{Cl}_{2}, \mathrm{Se}\left(\mathrm{C}_{6} \mathrm{H}_{5}\right)_{2} \mathrm{Br}_{2}, \mathrm{Te}\left(\mathrm{CH}_{3}\right)_{2} \mathrm{Cl}_{2}$, and $\mathrm{Te}\left(\mathrm{C}_{6} \mathrm{H}_{5}\right)_{2} \mathrm{Br}_{2}$ constitute this structure type. In all these molecules, the halogen atoms occupy the axial positions, as shown below:

## (8) AX $\mathbf{S}_{5}$ type

The anion $\mathrm{TeF}_{5}^{-}$and polymeric $\left(\mathrm{TeF}_{4}\right)_{x}$ belong to the $\mathrm{AX}_{5} \mathrm{E}$ type with squarepyramidal configuration. In $\mathrm{TeF}_{5}^{-}$, the bonds in the square base ( 196 pm ) are longer than the axial bond ( 185 pm ), and the bond angles $\left(79^{\circ}\right)$ are smaller than $90^{\circ}$, as shown in Fig. 16.8.7(e). Crystalline $\left(\mathrm{TeF}_{4}\right)_{x}$ has a chain structure, in which $\mathrm{TeF}_{5}$ groups are linked by bridging F atoms in such a way that alternate pyramids are oriented in opposite directions, as shown in Fig. 16.8.7(f).

## (9) $\quad \mathrm{AX}_{6}$ type

The hexafluorides $\mathrm{SeF}_{6}$ and $\mathrm{TeF}_{6}$ have the expected regular octahedral configuration. In $\mathrm{F}_{5} \mathrm{SeOSeF}_{5}$ and $\mathrm{F}_{5} \mathrm{TeOTeF}_{5}$, the Se and Te atoms take the octahedral configuration, and the four equatorial bonds in each case are bent away from the bridging O atom, as shown in Fig. 16.8.7(g).

## (10) $\quad \mathbf{A X}_{6}$ E type

The anions $\mathrm{SeX}_{6}^{2-}$ and $\mathrm{TeX}_{6}^{2-}(\mathrm{X}=\mathrm{Cl}, \mathrm{Br})$ adopt regular octahedral geometry, apparently indicating that the lone pair in the valence shell is stereochemically inactive. The observed result can be explained as follows.
(a) With increasing size of the central atom the tendency for the lone pair to spread around the core is enhanced. It is drawn inside the valence shell, behaving like an s-type orbital and effectively becoming the outer shell of the core.
(b) This tendency is also enhanced by the presence of six bonding pairs in the valence shell, which leaves rather little space for the lone pair.
(c) With the addition of the nonbonding electron pair, the core size increases and the core charge decreases from +6 to +4 , with the result that the bond pairs move farther from the central nucleus, thus increasing the bond lengths. In accordance with this, the observed bond lengths of $\mathrm{SeX}_{6}^{2-}$, $\mathrm{TeX}_{6}^{2-}$, and $\mathrm{SbX}_{6}^{2-}(\mathrm{X}=\mathrm{Cl}, \mathrm{Br})$ ions are considerably longer than those expected from the sum of the covalent radii by about $20-5 \mathrm{pm}$.

## (11) $\quad \mathbf{A X}_{7}$ type

The $\mathrm{TeF}_{7}^{-}$ion, an isoelectronic and isostructural analog of $\mathrm{IF}_{7}$, has a pentagonal bipyramidal structure with $\mathrm{Te}-\mathrm{F}_{\mathrm{ax}} 179 \mathrm{pm}$ and $\mathrm{Te}-\mathrm{F}_{\mathrm{eq}} 183-90 \mathrm{pm}$, as shown in Fig. 16.8.5(h). The equatorial F atoms deviate slightly from the mean equatorial plane.

## 17

## Structural Chemistry of Group 17 and Group 18 Elements

### 17.1 Elemental halogens

### 17.1.1 Crystal structures of the elemental halogens

The halogens are diatomic molecules, whose color increases steadily with atomic number. Fluorine $\left(\mathrm{F}_{2}\right)$ is a pale yellow gas, bp 85.0 K . Chlorine $\left(\mathrm{Cl}_{2}\right)$ is a greenish-yellow gas, bp 239.1 K . Bromine $\left(\mathrm{Br}_{2}\right)$ is a dark-red liquid, bp 331.9 K. Iodine ( $\mathrm{I}_{2}$ ) is a lustrous black crystalline solid, mp 386.7 K , which sublimes and boils readily at 458.3 K . Actually solid iodine has a vapor pressure of 41 Pa at 298 K and $1.2 \times 10^{4} \mathrm{~Pa}$ at the melting point. In the solid state, the halogen molecules are aligned to give a layer structure. Fluorine exists in two crystalline modifications: a low-temperature $\alpha$-form and a higher temperature $\beta$-form, neither of which resembles the orthorhombic layer structure of the isostructural chlorine, bromine, and iodine crystals. Figure 17.1.1 shows the crystal structure of iodine. Table 17.1.1 gives the interatomic distances in gaseous and crystalline halogens.

The molecules $\mathrm{F}_{2}, \mathrm{Cl}_{2}$, and $\mathrm{Br}_{2}$ in the crystalline state have intramolecular distances ( $\mathrm{X}-\mathrm{X}$ ) which are nearly the same as those in the gaseous state. In crystalline iodine, the intramolecular I-I bond distance is longer than that in a gaseous molecule, and the lowering of the bond order is offset by the intermolecular bonding within each layer. The closest interatomic distance between neighboring $\mathrm{I}_{2}$ molecules is 350 pm , which is considerably shorter than twice the van der Waals radius ( 430 pm ). It therefore seems that appreciable secondary bonding interactions occur between the iodine molecules, giving rise to the semiconducting properties and metallic luster; under very high pressure iodine becomes a metallic conductor. The distance between layers in the iodine crystal (427 and 434 pm ) corresponds to the van der Waals distance.

### 17.1.2 Homopolyatomic halogen anions

The homopolyhalogen anions are formed mainly by iodine, which exhibits the highest tendency to form stable catenated anionic species. Numerous examples of small polyiodides, such as $\mathrm{I}_{3}^{-}, \mathrm{I}_{4}^{2-}$ and $\mathrm{I}_{5}^{-}$, and extended discrete oligomeric anionic polyiodides, such as $\mathrm{I}_{7}^{-}, \mathrm{I}_{8}^{2-}, \mathrm{I}_{9}^{-}, \mathrm{I}_{12}^{2-}, \mathrm{I}_{16}^{2-}, \mathrm{I}_{16}^{4-}, \mathrm{I}_{22}^{4-}$ and $\mathrm{I}_{29}^{3-}$, and polymeric $\left(\mathrm{I}_{7}^{-}\right)_{n}$ networks have been reported. These polyiodides are all formed by the relatively loose association of several $\mathrm{I}_{2}$ molecules with several $\mathrm{I}^{-}$and/or $\mathrm{I}_{3}^{-}$

Fig. 17.1.1.
Crystal structure of iodine.
anions. In order to assess the association of such species, the following equation between the bond length $(d)$ and bond order $(n)$ has been proposed:

$$
d=d_{\mathrm{o}}-c \log n=267 \mathrm{pm}-(85 \mathrm{pm}) \log n .
$$

In this equation, the reference I-I single-bond length $d_{0}$ is taken to be 267 pm ; when the distance $d$ between two iodine atoms is $\leq 293 \mathrm{pm}$, corresponding to bond order $n \geq 0.50$, there is a relatively strong bond between them, which is represented by a solid line. The distance $d$ between 293 and 352 pm corresponds to bond order $n$ between 0.50 and 0.10 , indicating a relatively weak bond, which is represented by a broken line. When the distance is longer than 352 pm , there is only van der Waals interaction between the two molecular/ionic species, and no discrete polyiodide is formed.

Table 17.1.1. Interatomic distances in gaseous and crystalline halogens

| X | X-X (pm) |  | $\mathrm{X} \cdots \mathrm{X}(\mathrm{pm})$ |  | Ratio | X $\cdots$ X (Shortest) |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: |
|  | Gas | Solid | Within layer | Between layers |  | X-X (Solid) |
| F | 143.5 | 149 | 324 | 284 |  | 1.91 |
| Cl | 198.8 | 198 | 332 | 374 |  | 1.68 |
| Br | 228.4 | 227 | 331 | 399 |  | 1.46 |
| I | 266.6 | 272 | 350 | 427 |  | 1.29 |

Figure 17.1.2 shows some polyiodides, which have been characterized structurally. All polyiodine anions consist of units of $\mathrm{I}^{-}, \mathrm{I}_{2}$, and $\mathrm{I}_{3}^{-}$. The bond length of the structural components of the polyiodides are often characteristic: 267 to 285 pm in $\mathrm{I}_{2}$ molecular fragments, whereas those of symmetrical triiodide $\mathrm{I}_{3}^{-}$ are about 292 pm .

The formation and stability of an extended polyiodide species are dependent on the size, shape, and charge of its accompanying cation. In the solid state, the polyiodide species are assembled around a central cation to form a discrete or one-, two-, or three-dimensional structure.

Fig. 17.1.2.
Structures of some polyiodides: (a) $\mathrm{I}_{3}^{-}$ (symmetric) in $\mathrm{Ph}_{4} \mathrm{AsI}_{3}$, (b) $\mathrm{I}_{3}^{-}$ (asymmetric) in $\mathrm{CsI}_{3}$, (c) $\mathrm{I}_{4}^{2-}$ in $\mathrm{Cu}\left(\mathrm{NH}_{3}\right)_{4} \mathrm{I}_{4}$, (d) $\mathrm{I}_{5}^{-}$in $\mathrm{Fe}\left(\mathrm{S}_{2} \mathrm{CNEt}_{2}\right)_{3} \mathrm{I}_{5}$, (e) $\mathrm{I}_{7}^{-}$in $\mathrm{Ph}_{4} \mathrm{PI}_{7}$, (f) $\mathrm{I}_{8}^{2-}$ in $\left[\left(\mathrm{CH}_{2}\right)_{6} \mathrm{~N}_{4}\right.$ $\mathrm{Me}_{2} \mathrm{I}_{8}$, (g) $\mathrm{I}_{9}^{-}$in $\mathrm{Me}_{4} \mathrm{NI}_{9}$, (h) $\mathrm{I}_{16}^{4-}$ in $\left[\left(\mathrm{C}_{7} \mathrm{H}_{8} \mathrm{~N}_{4} \mathrm{O}_{2}\right) \mathrm{H}\right]_{4} \mathrm{I}_{16}$, (i) $\mathrm{I}_{16}^{2-}$ in $\left(\mathrm{Cp}^{*}{ }_{2} \mathrm{Cr}_{2} \mathrm{I}_{3}\right)_{2} \mathrm{I}_{16}$, and (j) ( $\left.\mathrm{I}_{7}^{-}\right)_{n}$ network in a unit cell of the $\left\{\mathrm{Ag}[18] \mathrm{aneS}_{6}\right\} \mathrm{I}_{7}$ complex. Bond lengths are in pm.

### 17.1.3 Homopolyatomic halogen cations

The structures of the following homopolyatomic halogen cations have been determined by X-ray analysis:

```
\(\mathrm{X}_{2}^{+}: \quad \mathrm{Br}_{2}^{+}\)and \(\mathrm{I}_{2}^{+}\left(\right.\)in \(\mathrm{Br}_{2}^{+}\left[\mathrm{Sb}_{3} \mathrm{~F}_{16}\right]^{-}\)and \(\left.\mathrm{I}_{2}^{+}\left[\mathrm{Sb}_{2} \mathrm{~F}_{11}\right]^{-}\right)\)
\(\mathrm{X}_{3}^{+}: \mathrm{Cl}_{3}^{+}, \mathrm{Br}_{3}^{+}\)and \(\mathrm{I}_{3}^{+}\left(\right.\)in \(\left.\mathrm{X}_{3} \mathrm{AsF}_{6}\right)\)
\(\mathrm{X}_{4}^{2+}: \mathrm{I}_{4}^{2+}\left(\mathrm{in} \mathrm{I}_{4}^{2+}\left[\mathrm{Sb}_{3} \mathrm{~F}_{16}\right]^{-}\left[\mathrm{SbF}_{6}\right]^{-}\right)\)
\(\mathrm{X}_{5}^{+}\): \(\quad \mathrm{Br}_{5}^{+}\)and \(\mathrm{I}_{5}^{+}\)(in \(\mathrm{X}_{5} \mathrm{AsF}_{6}\) )
\(\mathrm{X}_{15}^{+}: \quad \mathrm{I}_{15}^{+}\left(\right.\)in \(\left.^{15} \mathrm{I}_{15} \mathrm{AsF}_{6}\right)\)
```

$\mathrm{X}_{2}^{+}$: The bond lengths of $\mathrm{Br}_{2}^{+}$and $\mathrm{I}_{2}^{+}$, with a formal bond order of $1 \frac{1}{2}$, are 215 and 258 pm , respectively, which are shorter than the bond lengths of
molecular $\mathrm{Br}_{2}(228 \mathrm{pm})$ and $\mathrm{I}_{2}(267 \mathrm{pm})$. This is consistent with the loss of an electron from an antibonding orbital.
$\mathrm{X}_{3}^{+}$: These cations have a bent structure (Fig. 17.1.3(a)). The $\mathrm{X}-\mathrm{X}$ bond lengths are similar to those in gaseous $\mathrm{X}_{2}$, being consistent with their single-bond character. The bond angles are between the $101^{\circ}$ and $104^{\circ}$.
$\mathrm{X}_{4}^{2+}$ : Compound $\mathrm{I}_{4}\left[\mathrm{Sb}_{3} \mathrm{~F}_{16}\right]\left[\mathrm{SbF}_{6}\right]$ contains an $\mathrm{I}_{4}^{2+}$ cation, which has the shape of a planar rectangle with I-I bond lengths of 258 and 326 pm , as shown in Fig. 17.1.3(b).
$\mathrm{X}_{5}^{+}$: Cations $\mathrm{Br}_{5}^{+}$and $\mathrm{I}_{5}^{+}$are iso-structural, as shown in Fig. 17.1.3(c).
$\mathrm{X}_{15}^{+}$: Compound $\mathrm{I}_{15} \mathrm{AsF}_{6}$ contains an $\mathrm{I}_{15}^{+}$cation, which has the shape of a centrosymmetric zigzag chain. This cation may be considered to be a finite zigzag chain composed of three connected $\mathrm{I}_{5}^{-}$units, as shown in Fig. 17.1.3(d).

### 17.2 Interhalogen compounds and ions

The halogens form many compounds and ions that are binary or ternary combinations of halogen atoms. There are three basic types: (a) neutral interhalogen compounds, (b) interhalogen cations, and (c) interhalogen anions.

### 17.2.1 Neutral interhalogen compounds

The halogens react with each other to form binary interhalogen compounds XY , $\mathrm{XY}_{3}, \mathrm{XY}_{5}$ and $\mathrm{XY}_{7}$, where X is the heavier halogen. A few ternary compounds are also known, e.g., $\mathrm{IFCl}_{2}$ and $\mathrm{IF}_{2} \mathrm{Cl}$. All interhalogen compounds contain an even number of halogen atoms. Table 17.2.1 lists the physical properties of some $\mathrm{XY}_{n}$ compounds.

XY: All six possible diatomic interhalogen compounds between $\mathrm{F}, \mathrm{Cl}, \mathrm{Br}$ and I are known, but IF is unstable, and BrCl cannot be isolated free from $\mathrm{Br}_{2}$ and $\mathrm{Cl}_{2}$. In general, the diatomic interhalogens exhibit properties intermediate

Table 17.2.1. Physical properties of some interhalogen compounds

| Compound | Appearance at 298 K | $\mathrm{mp}(\mathrm{K})$ | $\mathrm{bp}(\mathrm{K})$ | Bond length*(pm) |  |
| :--- | :--- | :--- | :--- | :--- | :--- |
| ClF | Colorless gas | 117 | 173 | 163 |  |
| BrF | Pale brown gas | 240 | 293 | 176 |  |
| BrCl | Red brown gas | - | - | 214 |  |
| $\mathrm{ICl}(\alpha)$ | Ruby red crystal | 300 | $\sim 373$ | 237,244 |  |
| $\mathrm{ICl}(\beta)$ | Brownish red crystal | 287 | - | 235,244 |  |
| IBr | Black crystal | 314 | $\sim 389$ | 249 |  |
| $\mathrm{ClF}_{3}$ | Colorless gas | 197 | 285 | $160(\mathrm{eq})$ | $170(\mathrm{ax})$ |
| $\mathrm{BrF}_{3}$ | Yellow liquid | 282 | 399 | $172(\mathrm{eq})$ | $181(\mathrm{ax})$ |
| $\mathrm{IF}_{3}$ | Yellow solid | $245(\mathrm{dec})$ | - |  | - |
| $\left(\mathrm{ICl}_{3}\right)_{2}$ | Orange solid | $337(\mathrm{sub})$ | - | $238(\mathrm{t})$ | $268(\mathrm{~b})$ |
| $\mathrm{ClF}_{5}$ | Colorless gas | 170 | 260 | $172(\mathrm{ba})$ | $162(\mathrm{ap})$ |
| $\mathrm{BrF}_{5}$ | Colorless liquid | 212.5 | 314 | $172(\mathrm{ba})$ | $168(\mathrm{ap})$ |
| $\mathrm{IF}_{5}$ | Colorless liquid | 282.5 | 378 | $189(\mathrm{ba})$ | $186(\mathrm{ap})$ |
| $\mathrm{IF}_{7}$ | Colorless gas | $278(\mathrm{sub})$ | - | $186(\mathrm{eq})$ | $179(\mathrm{ax})$ |

* The $\mathrm{XY}_{3}$ molecule has a T-shaped structure: axial (ax), equatorial (eq); $\left(\mathrm{ICl}_{3}\right)_{2}$ is a dimer: bridging (b), terminal ( t ); $\mathrm{XY}_{5}$ forms a square-based pyramid: apical (ap), basal (ba); $\mathrm{XY}_{7}$ has the shape of a pentagonal bipyramid: equatorial (eq), axial (ax).
between their parent halogens. However, the electronegativities of X and Y differ significantly, so the $\mathrm{X}-\mathrm{Y}$ bond is stronger than the mean of the $\mathrm{X}-\mathrm{X}$ and $\mathrm{Y}-\mathrm{Y}$ bond strengths, and the $\mathrm{X}-\mathrm{Y}$ bond lengths are shorter than the mean of $d(\mathrm{X}-\mathrm{X})$ and $d(\mathrm{Y}-\mathrm{Y})$. The dipole moments for polar XY molecules in the gas phase are ClF $0.88 \mathrm{D}, \mathrm{BrF} 1.29 \mathrm{D}, \mathrm{BrCl} 0.57 \mathrm{D}, \mathrm{ICl} 0.65 \mathrm{D}$, and IBr 1.21 D .

Iodine monochloride ICl is unusual in forming two modifications: the stable $\alpha$-form and the unstable $\beta$-form, both of which have infinite chain structures and significant I $\cdots \mathrm{Cl}$ intermolecular interactions of 294 to 308 pm . Figure 17.2.1(a) shows the chain structure of $\beta-\mathrm{ICl}$.
$\mathrm{XY}_{3}$ : Both $\mathrm{ClF}_{3}$ and $\mathrm{BrF}_{3}$ have a T-shaped structure, being consistent with the presence of 10 electrons in the valence shell of the central atom, as shown in Fig. 17.2.1(b). The relative bond lengths of $d\left(\mathrm{X}-\mathrm{Y}_{\mathrm{ax}}\right)>d\left(\mathrm{X}-\mathrm{Y}_{\text {eq }}\right)$ and the bond angle of $\mathrm{Y}_{\mathrm{ax}}-\mathrm{X}-\mathrm{Y}_{\mathrm{eq}}<90^{\circ}\left(\mathrm{ClF}_{3} 87.5^{\circ}\right.$ and $\left.\mathrm{BrF}_{3} 86^{\circ}\right)$ reflect the greater electronic repulsion of the nonbonding pair of electrons in the equatorial plane of the molecule.

Iodine trichloride is a fluffy orange powder that is unstable above room temperature. Its dimer $\left(\mathrm{ICl}_{3}\right)_{2}$ has a planar structure, as shown in Fig. 17.2.1(c), that contains two I-Cl-I bridges (I-Cl distances in the range of 268-272 pm) and four terminal $\mathrm{I}-\mathrm{Cl}$ bonds ( $238-9 \mathrm{pm}$ ).
$\mathrm{XY}_{5}$ : The three fluorides $\mathrm{ClF}_{5}, \mathrm{BrF}_{5}$, and $\mathrm{IF}_{5}$ are the only known interhalogens of the $\mathrm{XY}_{5}$ type, and they are extremely vigorous fluorinating reagents. All three compounds occur as a colorless gas or liquid at room temperature. Their structure has been shown to be square pyramidal with the central atom slightly below the plane of the four basal F atoms [Fig. 17.2.1(d)]. The bond angles $\mathrm{F}_{(\mathrm{ap})}-\mathrm{X}-\mathrm{F}_{(\mathrm{ba})}$ are $\sim 90^{\circ}\left(\mathrm{ClF}_{5}\right), 85^{\circ}\left(\mathrm{BrF}_{5}\right)$ and $81^{\circ}\left(\mathrm{IF}_{5}\right)$.
$\mathrm{XY}_{7}: \mathrm{IF}_{7}$ is the sole representative of this structural type. Its structure, as shown in Fig. 17.2.1(e), exhibits a slight deformation from pentagonal

(a)

Fig. 17.2.1.
Structures of some interhalogen molecules: (a) $\beta-\mathrm{ICl}$, (b) $\mathrm{ClF}_{3}$, (c) $\mathrm{I}_{2} \mathrm{Cl}_{6}$, (d) $\mathrm{IF}_{5}$, and (e) $\mathrm{IF}_{7}$.
bipyramidal $D_{5 \mathrm{~h}}$ symmetry due to a $7.5^{\circ}$ puckering and a $4.5^{\circ}$ axial bending displacement. Bond length $\mathrm{I}-\mathrm{F}_{(\mathrm{eq})}$ is 185.5 pm and $\mathrm{I}-\mathrm{F}_{(\mathrm{ax})}$ is 178.6 pm .

### 17.2.2 Interhalogen ions

These ions have the general formulas $\mathrm{XY}_{n}^{+}$and $\mathrm{XY}_{n}^{-}$, where $n$ can be $2,4,5$, 6 , and 8 , and the central halogen X is usually heavier than Y . Table 17.2.2 lists many of the known interhalogen ions.

Table 17.2.2. Some interhalogen ions

|  | $\mathrm{XY}_{2}$ |  |  | $\mathrm{XY}_{4}$ | $\mathrm{XY}_{5}$ | $\mathrm{XY}_{6}$ | $\mathrm{XY}_{8}$ |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| Cations | $\mathrm{ClF}_{2}^{+}$ | $\mathrm{I}_{2} \mathrm{Cl}^{+}$ |  | $\begin{gathered} \mathrm{ClF}_{4}^{+} \\ \mathrm{BrF}_{4}^{+} \\ \mathrm{IF}_{4}^{+} \\ \mathrm{I}_{3} \mathrm{Cl}_{2}^{+} \end{gathered}$ | - | $\begin{aligned} & \mathrm{ClF}_{6}^{+} \\ & \mathrm{BrF}_{6}^{+} \end{aligned}$ | - |
|  | $\mathrm{Cl}_{2} \mathrm{~F}^{+}$ | $\mathrm{IBr}_{2}^{+}$ |  |  |  |  |  |
|  | $\mathrm{BrF}_{2}^{+}$ | $\mathrm{I}_{2} \mathrm{Br}^{+}$ |  |  |  | $\mathrm{IF}_{6}^{+}$ |  |
|  | $\mathrm{IF}_{2}^{+}$ | $\mathrm{IBrCl}^{+}$ |  |  |  |  |  |
|  | $\mathrm{ICl}_{2}^{+}$ |  |  |  |  |  |  |
| Anions | $\mathrm{BrCl}_{2}^{-}$ | $\begin{aligned} & \mathrm{ClICl}^{-} \\ & \mathrm{ClIBr}^{-} \\ & \mathrm{BrIBr}^{-} \end{aligned}$ | $\begin{aligned} & \mathrm{ClF}_{4}^{-} \\ & \mathrm{BrF}_{4}^{-} \\ & \mathrm{IF}_{4}^{-} \end{aligned}$ | $\mathrm{I}_{2} \mathrm{Cl}_{3}^{-}$ | $\mathrm{IF}_{5}^{2-}$ | $\begin{aligned} & \mathrm{ClF}_{6}^{-} \\ & \mathrm{BrF}_{6}^{-} \\ & \mathrm{IF}_{6}^{-} \end{aligned}$ | $\mathrm{IF}_{8}^{-}$ |
|  | $\mathrm{Br}_{2} \mathrm{Cl}^{-}$ |  |  | $\mathrm{I}_{2} \mathrm{BrCl}_{2}^{-}$ |  |  |  |
|  | $\mathrm{I}_{2} \mathrm{Cl}^{-}$ |  |  | $\mathrm{I}_{2} \mathrm{Br}_{2} \mathrm{Cl}^{-}$ |  |  |  |
|  | $\mathrm{FClF}^{-}$ |  | $\mathrm{ICl}_{3} \mathrm{~F}^{-}$ | $\mathrm{I}_{2} \mathrm{Br}_{3}^{-}$ |  |  |  |
|  | $\mathrm{FIBr}^{-}$ |  | $\mathrm{ICl}_{4}^{-}$ | $\mathrm{I}_{4} \mathrm{Cl}^{-}$ |  |  |  |
|  |  |  | $\mathrm{IBrCl}_{3}^{-}$ |  |  |  |  |

The structures of these ions normally conform to those predicted by the VSEPR theory, as shown in Fig. 17.2.2. Since the anion $\mathrm{XY}_{n}^{-}$has two more electrons than the cation $\mathrm{XY}_{n}^{+}$, they have very different shapes. The anion $\mathrm{IF}_{5}^{2-}$ is planar with lone pairs occupying the axial positions of a pentagonal bipyramid. In $\left[\mathrm{Me}_{4} \mathrm{~N}\right]\left(\mathrm{IF}_{6}\right), \mathrm{IF}_{6}^{-}$is a distorted octahedron $\left(C_{3 \mathrm{v}}\right.$ symmetry) with a sterically active lone pair, whereas both $\mathrm{BrF}_{6}^{-}$and $\mathrm{ClF}_{6}^{-}$are octahedral. The anion $\mathrm{IF}_{8}^{-}$has the expected square antiprismatic structure.

### 17.3 Charge-transfer complexes of halogens

A charge-transfer (or donor-acceptor) complex is one in which a donor and an acceptor species interact weakly with some net transfer of electronic charge, usually facilitated by the acceptor. The diatomic halogen molecule $\mathrm{X}_{2}$ has HOMO $\pi^{*}$ and LUMO $\sigma^{*}$ molecular orbitals, and the $\sigma^{*}$ orbital is antibonding and acts as an acceptor. If the $\mathrm{X}_{2}$ molecule is dissolved in a solvent such as $\mathrm{ROH}, \mathrm{H}_{2} \mathrm{O}$, pyridine, or $\mathrm{CH}_{3} \mathrm{CN}$ that contains $\mathrm{N}, \mathrm{O}, \mathrm{S}, \mathrm{Se}$, or $\pi$ electron pairs, the solvent molecule can function as a donor through the interaction of one of its $\sigma$ or $\pi$ electron pairs with the $\sigma^{*}$ orbital of $\mathrm{X}_{2}$. This donor-acceptor interaction leads to the formation of a charge-transfer complex between the solvent (donor) and $X_{2}$ (acceptor) and alters the optical transition energy of $X_{2}$, as shown in Fig. 17.3.1.

Let us take $\mathrm{I}_{2}$ as an example. The normal violet color of gaseous iodine is attributable to the allowed $\pi^{*} \rightarrow \sigma^{*}$ transition. When iodine is dissolved in a solvent, the interaction of $\mathrm{I}_{2}$ with a donor solvent molecule causes an increase in the energy separation of the $\pi^{*}$ to $\sigma^{*}$ orbitals from $E_{1}$ to $E_{2}$, as shown in Fig. 17.3.1. The color of this solution is then changed to brown. (The absorption maximum for the violet solution occurs at 520 to 540 nm , and that of a typical brown solution at 460 to 480 nm .) The electron transition in these $\mathrm{I}_{2}$. solvent complexes is called a charge-transfer transition. However, the most direct evidence for the formation of a charge-transfer complex in solution comes from the appearance of an intense new charge-transfer band occurring in the near ultraviolet spectrum in the range $230-330 \mathrm{~nm}$.

The structures of many charge-transfer complexes have been determined. All the examples shown in Fig. 17.3.2 share the following common structural characteristics:

(a) The donor atom (D) or $\pi$ orbital ( $\pi$ ) and $\mathrm{X}_{2}$ molecule are essentially linear: $\mathrm{D} \cdots \mathrm{X}-\mathrm{X}$ or $\pi \cdots \mathrm{X}-\mathrm{X}$.
(b) The bond lengths of the $\mathrm{X}-\mathrm{X}$ groups in the complexes are all longer than those in the corresponding free $\mathrm{X}_{2}$ molecules; the $\mathrm{D} \cdots \mathrm{X}$ distance is invariably shorter than the sum of their van der Waals radii.
(c) Each $\mathrm{X}_{2}$ molecule in an infinite chain structure is engaged by donors (D) at both ends, and the $\mathrm{D} \cdots \mathrm{X}-\mathrm{X} \cdots \mathrm{D}$ unit is essentially linear, as expected for a $\sigma$-type acceptor orbital.

Fig. 17.3.2.
Structures of some charge-transfer complexes (bond lengths in pm). (a) $\left(\mathrm{H}_{3} \mathrm{CCN}\right)_{2} \cdot \mathrm{Br}_{2}$, (b) $\mathrm{C}_{6} \mathrm{H}_{6} \cdot \mathrm{Br}_{2}$, (c) $\mathrm{C}_{4} \mathrm{H}_{8} \mathrm{O}_{2} \cdot \mathrm{X}_{2}(\mathrm{X}=\mathrm{Cl}, \mathrm{Br}, \mathrm{X}-\mathrm{X}$ distance: 202 pm for $\mathrm{X}=\mathrm{Cl}$ and 231 pm for $\mathrm{X}=$ Br ), (d) $\mathrm{C}_{4} \mathrm{H}_{8} \mathrm{Se} \cdot \mathrm{I}_{2}$, and (e) $\mathrm{Me}_{3} \mathrm{~N} \cdot \mathrm{I}_{2}$.

In the extreme case, complete transfer of charge may occur, as in the formation of $\left[\mathrm{I}(\mathrm{py})_{2}\right]^{+}$:

$$
\left.2 \mathrm{I}_{2}+2\left(\prod_{\mathrm{N}}^{-}\right) \longrightarrow \stackrel{\square}{\mathrm{I}} \mathrm{~N}^{+} \mathrm{N}^{\prime \prime}\right\rangle+\mathrm{I}_{3}^{-}
$$

## Structural Chemistry of Selected Elements

### 17.4 Halogen oxides and oxo compounds

### 17.4.1 Binary halogen oxides

The structures of some binary halogen oxides are listed in Table 17.4.1.

## (1) $\mathrm{X}_{2} \mathrm{O}$ molecules

(a) Since fluorine is more electronegative than oxygen, the binary compounds of $\mathrm{F}_{2}$ and $\mathrm{O}_{2}$ are named oxygen fluorides, rather than fluorine oxides. $\mathrm{F}_{2} \mathrm{O}$ is a colorless, highly toxic, and explosive gas. The molecule has $C_{2 \mathrm{v}}$ symmetry, as expected for a molecule with 20 valence electrons and two normal single bonds.
(b) Dichlorine monoxide $\mathrm{Cl}_{2} \mathrm{O}$ is a yellow-brown gas that is stable at room temperature. There are two linkage isomers, $\mathrm{Cl}-\mathrm{Cl}-\mathrm{O}$ and $\mathrm{Cl}-\mathrm{O}-\mathrm{Cl}$, but

Table 17.4.1. Structure of halogen oxides
Oxide
only the latter is stable. The stable form $\mathrm{Cl}-\mathrm{O}-\mathrm{Cl}$ is bent $\left(111^{\circ}\right)$ with $\mathrm{Cl}-\mathrm{O}$ 169 pm .
(c) Dibromine monoxide $\mathrm{Br}_{2} \mathrm{O}$ is a dark-brown crystalline solid stable at 213 K (mp 255.6 K with decomposition). The molecule has $C_{2 \mathrm{v}}$ symmetry in both the solid and vapor phases with $\mathrm{Br}-\mathrm{O} 185 \mathrm{pm}$ and angle $\mathrm{Br}-\mathrm{O}-\mathrm{Br} 112^{\circ}$.

## (2) $\mathbf{X}_{2} \mathbf{O}_{2}$ molecules

Only $\mathrm{F}_{2} \mathrm{O}_{2}$ is known. This is a yellow-orange solid (mp 119 K ) that decomposes above 223 K . Its molecular shape resembles that of $\mathrm{H}_{2} \mathrm{O}_{2}$, although the internal dihedral angel is smaller $\left(87^{\circ}\right)$. The long $\mathrm{O}-\mathrm{F}$ bond ( 157.5 pm ) and short $\mathrm{O}-\mathrm{O}$ bond ( 121.7 pm ) in $\mathrm{F}_{2} \mathrm{O}_{2}$ can be rationalized by resonance involving the following valence bond representations:

## (3) $\mathbf{X O}_{2}$ molecule

Only $\mathrm{ClO}_{2}$ is known. Chlorine dioxide is an odd-electron molecule. Theoretical calculations suggest that the odd electron is delocalized throughout the molecule, and this probably accounts for the fact that there is no evidence of dimerization in solution, or even in the liquid or solid phase. Its important Lewis structures are shown below:

## (4) $\mathrm{X}_{2} \mathrm{O}_{\mathbf{3}}$ molecules

(a) $\mathrm{Cl}_{2} \mathrm{O}_{3}$ is a dark-brown solid which explodes even below 273 K . Its structure has not been determined.
(b) $\mathrm{Br}_{2} \mathrm{O}_{3}$ is an orange crystalline solid and has been shown by X -ray analysis to be syn- $\mathrm{BrOBrO}_{2}$ with $\mathrm{Br}^{\mathrm{I}}-\mathrm{O} 184.5 \mathrm{pm}, \mathrm{Br}^{\mathrm{V}}-\mathrm{O} 161.3 \mathrm{pm}$, and angle $\mathrm{Br}-\mathrm{O}-\mathrm{Br} 111.6^{\circ}$. It is thus, formally, the anhydride of hypobromous and bromic acid.

## (5) $\quad \mathrm{X}_{2} \mathrm{O}_{4}$ molecules

(a) Chlorine perchlorate, $\mathrm{Cl}_{2} \mathrm{O}_{4}$, is most likely $\mathrm{ClOClO}_{3}$. Little is known of the structure and properties of this pale-yellow liquid; it is even less stable than $\mathrm{ClO}_{2}$ and decomposes at room temperature to $\mathrm{Cl}_{2}, \mathrm{O}_{2}$, and $\mathrm{Cl}_{2} \mathrm{O}_{6}$.
(b) $\mathrm{Br}_{2} \mathrm{O}_{4}$ is a pale yellow crystalline solid, whose structure has been shown by EXAFS to be bromine perbromate, $\mathrm{BrOBrO}_{3}$, with $\mathrm{Br}^{\mathrm{I}}-\mathrm{O} 186.2 \mathrm{pm}$, $\mathrm{Br}^{\text {VII }}-\mathrm{O} 160.5 \mathrm{pm}$ and angle $\mathrm{Br}-\mathrm{O}-\mathrm{Br} 110^{\circ}$.

## Structural Chemistry of Selected Elements

## (6) $\mathrm{X}_{2} \mathrm{O}_{5}$ molecules

(a) Ozonization of $\mathrm{Br}_{2}$ generates $\mathrm{Br}_{2} \mathrm{O}_{3}$ and eventually $\mathrm{Br}_{2} \mathrm{O}_{5}$ :

The end product can be crystallized from propionitrile as $\mathrm{Br}_{2} \mathrm{O}_{5} \cdot \mathrm{EtCN}$, and crystal structure analysis has shown that $\mathrm{Br}_{2} \mathrm{O}_{5}$ is $\mathrm{O}_{2} \mathrm{BrOBrO}_{2}$ with each Br atom pyramidally surrounded by three O atoms, and the terminal O atoms are eclipsed with respect to each other.
(b) $\mathrm{I}_{2} \mathrm{O}_{5}$ is the most stable oxide of the halogens. Crystal structure analysis has shown that the molecule consists of two pyramidal $\mathrm{IO}_{3}$ groups sharing a common oxygen. The terminal O atoms have a staggered conformation, as shown in Table 17.4.1.

## (7) $\quad \mathbf{X}_{2} \mathrm{O}_{6}$ molecule

$\mathrm{Cl}_{2} \mathrm{O}_{6}$ is actually a mixed-valence ionic compound $\mathrm{ClO}_{2}^{+} \mathrm{ClO}_{4}^{-}$, in which the angular $\mathrm{ClO}_{2}^{+}$and tetrahedral $\mathrm{ClO}_{4}^{-}$ions are arranged in a distorted CsCl-type crystal structure. Cation $\mathrm{ClO}_{2}^{+}$has $\mathrm{Cl}-\mathrm{O} 141 \mathrm{pm}$, angle $\mathrm{O}-\mathrm{Cl}-\mathrm{O} 119^{\circ} ; \mathrm{ClO}_{4}^{-}$ has $\mathrm{Cl}-\mathrm{O}$ (av) 144 pm .

## (8) $\quad \mathbf{X}_{2} \mathrm{O}_{7}$ molecule

$\mathrm{Cl}_{2} \mathrm{O}_{7}$ is a colorless liquid at room temperature. The molecule has $C_{2}$ symmetry in both gaseous and crystalline states, the $\mathrm{ClO}_{3}$ groups being twisted from the staggered ( $C_{2 \mathrm{v}}$ ) configuration, with $\mathrm{Cl}-\mathrm{O}$ (bridge) 172.3 pm and $\mathrm{Cl}-\mathrm{O}$ (terminal) 141.6 pm .

In addition to the compounds mentioned above, other unstable binary halogen oxides are known. The structures of the short-lived gaseous XO radicals have been determined. For ClO , the interatomic distance $d=156.9 \mathrm{pm}$, dipole moment $\mu=1.24 \mathrm{D}$, and bond dissociation energy $D_{\mathrm{o}}=264.9 \mathrm{~kJ} \mathrm{~mol}^{-1}$. For $\mathrm{BrO}, d=172.1 \mathrm{pm}, \mu=1.55 \mathrm{D}$, and $D_{\mathrm{o}}=125.8 \mathrm{~kJ} \mathrm{~mol}^{-1}$. For IO, $d=186.7$ pm and $D_{\mathrm{o}}=175 \mathrm{~kJ} \mathrm{~mol}^{-1}$.

The structures of the less stable oxides $\mathrm{I}_{4} \mathrm{O}_{9}$ and $\mathrm{I}_{2} \mathrm{O}_{4}$ are still unknown, but $\mathrm{I}_{4} \mathrm{O}_{9}$ has been formulated as $\mathrm{I}^{3+}\left(\mathrm{I}^{5+} \mathrm{O}_{3}\right)_{3}$, and $\mathrm{I}_{2} \mathrm{O}_{4}$ as $(\mathrm{IO})^{+}\left(\mathrm{IO}_{3}\right)^{-}$.

### 17.4.2 Ternary halogen oxides

The ternary halogen oxides are mainly compounds in which a heavier X atom ( $\mathrm{Cl}, \mathrm{Br}, \mathrm{I}$ ) is bonded to both O and F . These compounds are called halogen oxide fluorides. The structures of the ternary halogen oxides are summarized in Fig. 17.4.1.

The geometries of these molecules are consistent with the VSEPR model. (a) FClO is bent with $C_{\mathrm{s}}$ symmetry (two lone pairs). (b) $\mathrm{FXO}_{2}$ is pyramidal with $C_{\mathrm{s}}$ symmetry (one lone pair). (c) $\mathrm{FXO}_{3}$ has $C_{3 \mathrm{v}}$ symmetry. (d) $\mathrm{F}_{3} \mathrm{XO}$ is an incomplete trigonal bipyramid with $\mathrm{F}, \mathrm{O}$, and a lone pair in the equatorial plane, having $C_{\mathrm{s}}$ symmetry. (e) $\mathrm{F}_{3} \mathrm{ClO}_{2}$ is a trigonal bipyramid with one fluorine and both oxygens in the equatorial plane; owing to the strong repulsion from two

$\mathrm{Cl}=\mathrm{O}$ double bonds in the equatorial plane, the axial $\mathrm{Cl}-\mathrm{F}$ bonds are longer than the equatorial Cl-F bonds, as confirmed by experimental data. (f) $\mathrm{F}_{5} \mathrm{IO}$ has $C_{4 \mathrm{v}}$ symmetry, in which the bond lengths are I-F $\mathrm{F}_{\mathrm{ax}} 186.3 \mathrm{pm}$, $\mathrm{I}-\mathrm{F}_{\mathrm{eq}} 181.7 \mathrm{pm}$, and $\mathrm{I}=\mathrm{O} 172.5 \mathrm{pm}$. Also, the I atom lies above the plane of four equatorial F atoms, and bond angle $\mathrm{O}-\mathrm{I}-\mathrm{F}_{\text {eq }}$ is $97.2^{\circ}$. (g) $\mathrm{F}_{3} \mathrm{IO}_{2}$ forms oligomeric species, and the dimer $\left(\mathrm{F}_{3} \mathrm{IO}_{2}\right)_{2}$ has $C_{2 \mathrm{~h}}$ symmetry. (h) $\mathrm{O}_{3} \mathrm{ClOX}$ are "halogen perchlorate salts".

A variety of cations and anions are derived from some of the above neutral molecules by gaining or losing one $\mathrm{F}^{-}$, as shown in Fig. 17.4.2. Their structures are again in accord with predictions by the VSEPR model.

* Isolated as pure compounds; others are stable only in aqueous solutions.

### 17.4.3 Halogen oxoacids and anions

Numerous halogen oxoacids are known, though most of them cannot be isolated as pure species and are stable only in aqueous solution or in the form of their salts. Anhydrous hypofluorous acid (HOF), perchloric acid $\left(\mathrm{HClO}_{4}\right)$, iodic acid $\left(\mathrm{HIO}_{3}\right)$, orthoperiodic acid $\left(\mathrm{H}_{3} \mathrm{IO}_{6}\right)$, and metaperiodic acid $\left(\mathrm{HIO}_{4}\right)$ have been isolated as pure compounds. Table 17.4.2 lists the halogen oxoacids.

## (1) Hypofluorous and other hypohalous acids

At room temperature hypofluorous acid HOF is a gas. Its colorless solid ( $\mathrm{mp}=$ 156 K ) melts to a pale yellow liquid. In the crystal structure, $\mathrm{O}-\mathrm{F}=144.2 \mathrm{pm}$, angle $\mathrm{H}-\mathrm{O}-\mathrm{F}=101^{\circ}$, and the HOF molecules are linked by $\mathrm{O}-\mathrm{H} \cdots \mathrm{O}$ hydrogen bonds (bond length 289.5 pm and bond angle $\mathrm{O}-\mathrm{H} \cdots \mathrm{O} 163^{\circ}$ ) to form a planar zigzag chain, as shown below:

In general, fluorine has a formal oxidation state of -1 , but in HOF and other hypohalous acids HOX, the formal oxidation state of F and X is +1 .

Hypochlorous acid HOCl is more stable than HOBr and HOI , with $\mathrm{Cl}-\mathrm{O}$ 169.3 pm and angle $\mathrm{H}-\mathrm{O}-\mathrm{Cl} 103^{\circ}$ in the gas phase.

## (2) Chlorous acid $\mathbf{H O C l O}$ and chlorite ion $\mathrm{ClO}_{2}^{-}$

Chlorous acid, HOClO , is the least stable of the oxoacids of chlorine. It cannot be isolated in pure form, but exists in dilute aqueous solution. Likewise, HOBrO and HOIO are even less stable, showing only a transient existence in aqueous solution.

The chlorite ion $\left(\mathrm{ClO}_{2}^{-}\right)$in $\mathrm{NaClO}_{2}$ and other salts has a bent structure $\left(C_{2 \mathrm{v}}\right.$ symmetry) with Cl-O $156 \mathrm{pm}, \mathrm{O}-\mathrm{Cl}-\mathrm{O} 111^{\circ}$.

## (3) Halic acids $\mathrm{HOXO}_{2}$ and halate ions $\mathrm{XO}_{3}^{-}$

Iodic acid, $\mathrm{HIO}_{3}$, is a stable white solid at room temperature. In the crystal structure, trigonal $\mathrm{HIO}_{3}$ molecules are connected by extensive hydrogen bonding with I-O 181 pm , I-OH 189 pm , angle O-I-O $101^{\circ}$, O-I-(OH) $97^{\circ}$.

Halate ions are trigonal pyramidal, with $C_{3 \mathrm{v}}$ symmetry, as shown below:

$$
\left[\begin{array}{rl}
\mathrm{O}^{-} \mathrm{X} \\
\mathrm{~T} \\
\mathrm{O}
\end{array}\right]^{-} \quad \begin{aligned}
& \mathrm{X}=\mathrm{Cl}, \mathrm{Cl}-\mathrm{O} 149 \mathrm{pm} \\
& \mathrm{X}=\mathrm{Br}, \mathrm{Br}-\mathrm{O} 165 \mathrm{pm} \\
& \mathrm{X}=\mathrm{I}, \mathrm{I}-\mathrm{O} 184 \mathrm{pm} \\
& \text { Angles O-X-O } 106^{\circ} \text { to } 107^{\circ}
\end{aligned}
$$

Note that in the solid state, some metal halates do not consist of discrete ions. For example, in the iodates there are three short I-O distances $177-90 \mathrm{pm}$ and three longer distances 251-300 pm, leading to distorted pseudo-sixfold coordination and piezoelectric properties.

## (4) Perchloric acid $\mathrm{HClO}_{4}$ and perhalates $\mathrm{XO}_{4}^{-}$

Perchloric acid is the only oxoacid of chlorine that can be isolated. The crystal structure of $\mathrm{HClO}_{4}$ at 113 K exhibits three $\mathrm{Cl}-\mathrm{O}$ distances of 142 pm and a $\mathrm{Cl}-\mathrm{OH}$ distance of 161 pm . The structure of $\mathrm{HClO}_{4}$, as determined by electron diffraction in the gas phase, shows $\mathrm{Cl}-\mathrm{O} 141 \mathrm{pm}, \mathrm{Cl}-\mathrm{OH} 163.5 \mathrm{pm}$, and angles $\mathrm{O}-\mathrm{Cl}-(\mathrm{OH}) 106^{\circ}, \mathrm{O}-\mathrm{Cl}-\mathrm{O} 113^{\circ}$.

The hydrates of perchloric acid exist in at least six crystalline forms. The monohydrate is composed of $\mathrm{H}_{3} \mathrm{O}^{+}$and $\mathrm{ClO}_{4}^{-}$connected by hydrogen bonds.

All perhalate ions $\mathrm{XO}_{4}^{-}$are tetrahedral, with $T_{\mathrm{d}}$ symmetry, as shown below:

$$
\begin{aligned}
& \mathrm{X}=\mathrm{Cl}, \mathrm{Cl}-\mathrm{O} 144 \mathrm{pm} \\
& \mathrm{X}=\mathrm{Br}, \mathrm{Br}-\mathrm{O} 161 \mathrm{pm} \\
& \mathrm{X}=\mathrm{I}, \mathrm{I}-\mathrm{O} 179 \mathrm{pm}
\end{aligned}
$$

## (5) Periodic acids and periodates

Several different periodic acids and periodates are known.
(a) Metaperiodic acid $\mathrm{HIO}_{4}$

Acid $\mathrm{HIO}_{4}$ consists of one-dimensional infinite chains built up of distorted cis-edge-sharing $\mathrm{IO}_{6}$ octahedra, as shown in Fig. 17.4.3. Until now no discrete $\mathrm{HIO}_{4}$ molecule has been found.
(b) Orthoperiodic (or paraperiodic) acid ( HO$)_{5} \mathrm{IO}$

The crystal structure of orthoperiodic acid, commonly written as $\mathrm{H}_{5} \mathrm{IO}_{6}$, consists of axially distorted octahedral $(\mathrm{HO})_{5} \mathrm{IO}$ molecules linked into a threedimensional array by $\mathrm{O}-\mathrm{H} \cdots \mathrm{O}$ hydrogen bonds ( 10 for each molecule,

(e)

(f)
$260-78 \mathrm{pm})$. The $(\mathrm{HO})_{5} \mathrm{IO}$ molecule has the maximum number of -OH groups surrounding the $\mathrm{I}(+7)$ atom and hence it is called orthoperiodic acid:

The structure of $\mathrm{H}_{7} \mathrm{I}_{3} \mathrm{O}_{14}$ does not show any new type of catenation, because this compound exists in the solid state as a stoichiometric phase containing orthoperiodic and metaperiodic acids according to the formula $(\mathrm{HO})_{5} \mathrm{IO} \cdot 2 \mathrm{HIO}_{4}$.

The structures of several periodates and hydrogen periodates are shown in Fig. 17.4.4.

### 17.4.4 Structural features of polycoordinate iodine compounds

Iodine differs in many aspects from the other halogens. Because of the large atomic size and the relatively low ionization energy, it can easily form stable polycoordinate, multivalent compounds. Interest in polyvalent organic iodine compounds arises from several factors: (a) the similarity of the chemical properties and reactivity of $\mathrm{I}(\mathrm{III})$ species to those of $\mathrm{Hg}(+2), \mathrm{Tl}(+3)$, and $\mathrm{Pb}(+4)$, but without the toxic and environmental problems of these heavy metal congeners; (b) the recognition of similarities between organic transition-metal complexes and polyvalent main-group compounds such as organoiodine species; and (c) the commercial availability of key precursors, such as $\mathrm{PhI}(\mathrm{OAc})_{2}$.

Six structural types of polyvalent iodine species are commonly encountered, as shown below:

(a)

(b)

(c)

(d)

(e)

(f)

The first two types, (a) and (b), called iodanes, are conventionally considered as derivatives of trivalent iodine $\mathrm{I}(+3)$. The next two, (c) and (d), periodanes, represent the most typical structural types of pentavalent iodine $I(+5)$. The structural types (e) and (f) are typical of heptavalent iodine $I(+7)$.

The most important structural features of polyvalent iodine compounds may be summarized as follows:
(1) The iodonium ion (type a) generally has a distance of $260-80 \mathrm{pm}$ between iodine and the nearest anion, and may be considered as having pseudotetrahedral geometry about the central iodine atom.
(2) Species of type (b) has an approximately T-shaped structure with a collinear arrangement of the most electronegative ligands. Including the nonbonding electron pairs, the geometry about iodine is a distorted trigonal bipyramid with the most electronegative groups occupying the axial positions and the least electronegative group and both electron pairs residing in equatorial positions.
(3) The I-C bond lengths in both iodonium salts (type a) and iodoso derivatives (type b) are approximately equal to the sum of the covalent radii of I and C atoms, ranging generally from 200 to 210 pm .
(4) For type (b) species with two heteroligands of the same electronegativity, both I-L bonds are longer than the sum of the appropriate covalent radii, but shorter than purely ionic bonds. For example, the I-Cl bond lengths in $\mathrm{PhICl}_{2}$ are 245 pm , whereas the sum of the covalent radii of I and Cl is 232 pm . Also, the $\mathrm{I}-\mathrm{O}$ bond lengths in $\mathrm{PhI}(\mathrm{OAc})_{2}$ are $215-16 \mathrm{pm}$, whereas the sum of the covalent radii of I and O is 199 pm .

(5) The geometry of the structural types (c) and (d) can be square pyramidal, pesudo-trigonal bipyramidal, and pesudo-octahedral. The bonding in $\mathrm{I}(+5)$ compounds $\mathrm{IL}_{5}$ with a square-pyramidal structure may be described in terms of a normal covalent bond between iodine and the ligand in the apical position, and two orthogonal, hypervalent $3 c-4 e$ bonds accommodating four ligands. The carbon ligand and unshared electron pair in this case should occupy the apical positions, with the most electronegative ligands residing at equatorial positions.
(6) The typical structures of $\mathrm{I}(+7)$ involve a distorted octahedral configuration (type e) about iodine in most periodates and oxyfluoride, $\mathrm{IOF}_{5}$, and the heptacoordinated, pentagonal bipyramidal species (type f) for the $\mathrm{IF}_{7}$ and $\mathrm{IOF}_{6}^{-}$anions. The pentagonal bipyramidal structure can be described as two covalent collinear axial bonds between iodine and ligands in the apical positions and a coplanar, hypervalent $6 c-10 e$ bond system for the five equatorial bonds.

Structural Chemistry of Selected Elements

### 17.5 Structural chemistry of noble gas compounds

### 17.5.1 General survey

All the Group 18 elements ( $\mathrm{He}, \mathrm{Ne}, \mathrm{Ar}, \mathrm{Kr}, \mathrm{Xe}$, and Rn ; rare gases or noble gases) have the very stable electronic configurations ( $1 \mathrm{~s}^{2}$ or $n \mathrm{~s}^{2} n \mathrm{p}^{6}$ ) and are monoatomic gases. The nonpolar, spherical nature of the atoms leads to physical properties that vary regularly with atomic number. The only interatomic interactions are weak van der Waals forces, which increase in magnitude as the polarizabilities of the atoms increase and the ionization energies decrease. In other words, interatomic interactions increase with atomic size.

In Section 5.8, we have encountered the noble gas compound HArF and complexes NgMX. The discussion there is mainly concerned with the electronic structures of these linear triatomic species. In recent years, the use of matrixisolation techniques has led to the generation of a wide range of compounds of the general formula HNgY , where $\mathrm{Ng}=\mathrm{Kr}$ or Xe , and Y is an electronegative atom or group such as H , halides, pseudohalides, $\mathrm{OH}, \mathrm{SH}, \mathrm{C} \equiv \mathrm{CH}$, and $\mathrm{C} \equiv \mathrm{C}-\mathrm{C} \equiv \mathrm{CH}$. These molecules can be easily detected by the extremely strong intensity of the $\mathrm{H}-\mathrm{Ng}$ stretching vibration. The observed $\nu(\mathrm{H}-\mathrm{Ng})$ values for some HXeY molecules are $\mathrm{Y}=\mathrm{H}, 1166,1181 ; \mathrm{Y}=\mathrm{Cl}, 1648 ; \mathrm{Y}=\mathrm{Br}, 1504$; $\mathrm{Y}=\mathrm{I}, 1193 ; \mathrm{Y}=\mathrm{CN}, 1623.8, \mathrm{Y}=\mathrm{NC}, 1851.0 \mathrm{~cm}^{-1}$. The electronic structure of HNgY is best described in terms of the ion pair $\mathrm{HNg}^{+} \mathrm{Y}^{-}$, in which the HNg fragment is held by a covalent bond, and the interaction between Ng and Y is mostly ionic.

In this section, we turn our attention to the structural chemistry of those noble gas compounds that can be isolated in bulk quantities.

Xenon compounds with direct bonds to the electronegative main-group elements F, O, N, C, and Cl are well established. The first noble gas compound, a yellow-orange solid formulated as $\mathrm{XePtF}_{6}$, was prepared by Neil Bartlett in 1962. Noting that the first ionization energy of $\mathrm{Xe}\left(1170 \mathrm{~kJ} \mathrm{~mol}^{-1}\right)$ is very similar to that of $\mathrm{O}_{2}\left(1175 \mathrm{~kJ} \mathrm{~mol}^{-1}\right)$, and that $\mathrm{PtF}_{6}$ and $\mathrm{O}_{2}$ can combine to form $\mathrm{O}_{2} \mathrm{PtF}_{6}$, Bartlett replaced $\mathrm{O}_{2}$ by a molar quantity of Xe in the reaction with $\mathrm{PtF}_{6}$ and produced $\mathrm{XePtF}_{6}$. It is now established that the initial product he obtained was a mixture containing diamagnetic $\mathrm{Xe}^{\mathrm{II}} \mathrm{Pt}^{\mathrm{IV}} \mathrm{F}_{6}$ as the major product, which is most likely a $\mathrm{XeF}^{+}$salt of $\left(\mathrm{PtF}_{5}^{-}\right)_{n}$ with a polymeric chain structure, as illustrated below, by analogy with the known crystal structure of $\mathrm{XeCrF}_{6}$.

Fig. 17.5.1.
Structures of $\mathrm{CUO}(\mathrm{Ne})_{4-n}(\operatorname{Ar})_{n}(n=0$, $1,2,3,4$ )

If xenon is mixed with a large excess of $\mathrm{PtF}_{6}$ vapor, further reactions proceed as follows:

$$
\begin{gathered}
\mathrm{XePtF}_{6}+\mathrm{PtF}_{6} \rightarrow \mathrm{XeF}^{+} \mathrm{PtF}_{6}^{-}+\mathrm{PtF}_{5} \text { (non-crystalline) } \\
\mathrm{XeF}^{+} \mathrm{PtF}_{6}^{-}+\mathrm{PtF}_{5}\left(\text { warmed } \geq 60^{\circ} \mathrm{C}\right) \rightarrow \mathrm{XeF}^{+} \mathrm{Pt}_{2} \mathrm{~F}_{11}^{-} \text {(orange }- \text { red solid) } .
\end{gathered}
$$

Evidently the $\mathrm{Xe}(\mathrm{I})$ oxidation state is not a viable one, and $\mathrm{Xe}(\mathrm{II})$ is clearly favored.

Until now, no compound of helium has been discovered, and as radon has intense $\alpha$-radioactivity, information about its chemistry is very limited. Compounds of the other rare gas elements, $\mathrm{Ne}, \mathrm{Ar}, \mathrm{Kr}$, and Xe , have been reported. For example, experimental investigation of $\mathrm{CUO}(\mathrm{Ng})_{n}(\mathrm{Ng}=\mathrm{Ar}, \mathrm{Kr}, \mathrm{Xe} ; n=$ $1,2,3,4)$ complexes in solid neon have provided evidence of their formation. The computed structures of $\mathrm{CUO}(\mathrm{Ne})_{4-n}(\mathrm{Ar})_{n}(n=0,1,2,3,4)$ complexes are illustrated in Fig.17.5.1.

### 17.5.2 Stereochemistry of xenon

Xenon reacts directly with fluorine to form fluorides. Other compounds of Xe can be prepared by reactions using xenon fluorides as starting materials, which fall into four main types:
(1) In combination with $\mathrm{F}^{-}$acceptors, yielding fluorocations of xenon, as in the formation of $\left(\mathrm{XeF}_{5}\right)\left(\mathrm{AsF}_{6}\right)$ and $\left(\mathrm{XeF}_{5}\right)\left(\mathrm{PtF}_{6}\right)$;
(2) In combination with $\mathrm{F}^{-}$donors, yielding fluoroanions of xenon, as in the formation of $\mathrm{Cs}\left(\mathrm{XeF}_{7}\right)$ and $\left(\mathrm{NO}_{2}\right)\left(\mathrm{XeF}_{8}\right)$;
(3) $\mathrm{F} / \mathrm{H}$ metathesis between $\mathrm{XeF}_{2}$ and an anhydrous acid, such as

$$
\mathrm{XeF}_{2}+\mathrm{HOClO}_{3} \rightarrow \mathrm{~F}-\mathrm{Xe}-\mathrm{OClO}_{3}+\mathrm{HF} ;
$$

(4) Hydrolysis, yielding oxofluorides, oxides, and xenates, such as

$$
\mathrm{XeF}_{6}+\mathrm{H}_{2} \mathrm{O} \rightarrow \mathrm{XeOF}_{4}+2 \mathrm{HF} .
$$

Xenon exhibits a rich variety of stereochemistry. Some of the more important compounds of xenon are listed in Table 17.5.1, and their structures are shown in Fig. 17.5.2. The structural description of these compounds depends on whether

Table 17.5.1. Structures of some compounds of xenon with fluorine and oxygen

| Compound | Geometry/ symmetry | $\begin{aligned} & \mathrm{Xe}-\mathrm{F} \\ & (\mathrm{pm}) \end{aligned}$ | $\begin{aligned} & \mathrm{Xe}-\mathrm{O} \\ & (\mathrm{pm}) \end{aligned}$ | Arrangement in the bonded and nonbonded electron pairs in Fig. 17.5.2 |  |

| $\begin{aligned} & \mathrm{XeF}_{8}^{2-} \text { in } \\ & (\mathrm{NO})_{2} \mathrm{XeF}_{8} \end{aligned}$ | Square antiprismatic, $D_{4 \mathrm{~d}}$ | 196-208 |  | Square antiprismatic | (o) |

only nearest neighbor atoms are considered or whether the electron lone pairs are also taken into consideration.

Figure 17.5.2 shows that the known formal oxidation state of xenon ranges from $+2\left(\mathrm{XeF}_{2}\right)$ to $+8\left(\mathrm{XeO}_{4}, \mathrm{XeO}_{3} \mathrm{~F}_{2}\right.$ and $\left.\mathrm{XeO}_{6}^{4-}\right)$, and the structures of the xenon compounds are all consistent with the VSEPR model.

### 17.5.3 Chemical bonding in xenon fluorides

## (1) Xenon difluoride and xenon tetrafluoride

The $\mathrm{XeF}_{2}$ molecule is linear. A simple bonding description takes the $5 \mathrm{p}_{z} \mathrm{AO}$ of the xenon atom and the $2 \mathrm{p}_{z} \mathrm{AO}$ of each fluorine atom to construct the MOs of $\mathrm{XeF}_{2}$ : bonding $(\sigma)$, nonbonding $\left(\sigma^{n}\right)$, and antibonding $\left(\sigma^{*}\right)$, as shown in Fig. 17.5.3. The four valence electrons fill $\sigma$ and $\sigma^{n}$, forming a $3 c-4 e \sigma$ bond extending over the entire $\mathrm{F}-\mathrm{Xe}-\mathrm{F}$ system. Hence the formal bond order of the $\mathrm{Xe}-\mathrm{F}$ bond can be taken as 0.5 . The remaining $5 \mathrm{~s}, 5 \mathrm{p}_{x}$ and $5 \mathrm{p}_{y} \mathrm{AOs}$ of the Xe

(g)

(I)

(o)
atom are hybridized to form $\mathrm{sp}^{2}$ hybrid orbitals to accommodate the three lone pairs, as shown in Fig. 17.5.2(a).

A similar treatment, involving two $3 c-4 e$ bonds located in X and Y directions, accounts satisfactorily for the planar structure of $\mathrm{XeF}_{4}$. The remaining 5 s and $5 \mathrm{p}_{z}$ AOs of Xe are hybridized to form sp hybrid orbitals that accommodate the two lone-pair electrons, as shown in Fig. 17.5.2(e). The crystal structure of $\mathrm{XeF}_{2}$ is analogous to that of $\alpha-\mathrm{KrF}_{2}$, which is illustrated in Fig. 17.5.8(a) (see below).

## (2) Xenon hexafluoride

There are two possible theoretical models for the isolated $\mathrm{XeF}_{6}$ molecule: (i) regular octahedral ( $O_{\mathrm{h}}$ symmetry), with three $3 c-4 e$ bonds and a sterically inactive lone pair of electrons occupying a spherically symmetric s orbital, or (ii) distorted octahedral ( $C_{3 \mathrm{v}}$ symmetry), where the lone pair is sterically active and lies above the center of one face, but the molecule is readily converted into other configurations. All known experimental data are consistent with the

Fig. 17.5.2.
Structures of xenon compounds (small shaded circles represent the O atoms):
(a) $\mathrm{XeF}_{2}$, (b) $\mathrm{XeO}_{3}$, (c) $\mathrm{XeF}_{3}^{+}$, (d)
$\mathrm{XeOF}_{2}$, (e) $\mathrm{XeF}_{4}$, (f) $\mathrm{XeO}_{4}$, (g)
$\mathrm{XeO}_{2} \mathrm{~F}_{2}$, (h) $\mathrm{XeOF}_{4}$, (i) $\mathrm{XeO}_{3} \mathrm{~F}_{2}$, (j) $\mathrm{XeF}_{5}^{+}$, (k) $\mathrm{XeF}_{5}^{-}$, (l) $\mathrm{XeF}_{6}$, (m) $\mathrm{XeO}_{6}^{4-}$, (n) $\mathrm{XeF}_{7}^{-}$, and (o) $\mathrm{XeF}_{8}^{2-}$. The electron lone pairs in $\mathrm{XeF}_{7}^{-}$and $\mathrm{XeF}_{8}^{2-}$ are not shown in the figure. The $\mathrm{XeF}_{6}$ molecule (1) has no static structure but is continually interchanging between eight possible $C_{3 v}$ structures in which the lone pair caps a triangular face of the octahedron, but in the figure the lone pair is shown in only one possible position.
Also, connecting these $C_{3 \mathrm{v}}$ structures are the transition states with $C_{2 \mathrm{v}}$ symmetry in which the lone pair pokes out from an edge of the octahedron.

Fig. 17.5.3.
Molecular orbitals of the $3 c-4 e \mathrm{~F}-\mathrm{Xe}-\mathrm{F}$ $\sigma$ bond of $\mathrm{XeF}_{2}$ : (a) the possible combinations of the AOs of Xe and F atoms, and (b) the schematic energy levels of $\mathrm{XeF}_{2}$ molecule.
following nonrigid model. Starting from the $C_{3 \mathrm{v}}$ structure, the electron pair can move across an edge between two F atoms ( $C_{2 \mathrm{v}}$ symmetry for the intermediate configuration) to an equivalent position surrounded by three F atoms. This continuous molecular rearrangement, designated as a $C_{3 \mathrm{v}} \rightarrow C_{2 \mathrm{v}} \rightarrow C_{3 \mathrm{v}}$ transformation, involves only modest changes in bond angles and virtually no change in bond lengths.

## (3) Perfluoroxenates $\mathrm{XeF}_{8}^{2-}$ and $\mathrm{XeF}_{7}^{-}$

There are nine electron pairs in $\mathrm{XeF}_{8}^{2-}$, which are to be accommodated around the Xe atom. From experimental data, the $\mathrm{XeF}_{8}^{2-}$ ion has a square antiprismatic structure [Fig. 17.5.2(o)] showing no distortion that could reveal a possible position for the nonbonding pair of electrons. The lone pair presumably resides in the spherical 5 s orbital.

There are eight electron pairs to be placed around the Xe atom in $\mathrm{XeF}_{7}^{-}$. Six F atoms are arranged octahedrally around the central Xe atom. The approach of the seventh F atom [labelled "a" for this F atom in Fig. 17.5.2(n)] towards the midpoint of one of the faces causes severe distortion of the basic octahedral shape. Such a distortion could easily mask similar effects arising from a nonspherical, sterically active lone pair. The bond between Xe atom and the capping fluorine atom $\mathrm{F}_{(\mathrm{a})}$ has the length $\mathrm{Xe}-\mathrm{F}_{(\mathrm{a})} 210 \mathrm{pm}$, or about 17 pm longer than the other $\mathrm{Xe}-\mathrm{F}$ bonds, which might suggest some influence of a lone pair in the $\mathrm{F}_{(\mathrm{a})}$ direction.

### 17.5.4 Structures of some inorganic xenon compounds

The structure and bonding of the $\left[\mathrm{AuXe}_{4}\right]^{2+}$ cation in $\left(\mathrm{AuXe}_{4}\right)\left(\mathrm{Sb}_{2} \mathrm{~F}_{11}\right)_{2}$ have been discussed in Section 2.4.3. Some other interesting inorganic xenon compounds are described below.

## (1) $\mathbf{X e}_{2} \mathbf{S b}_{4} \mathbf{F}_{21}$

Although the $\mathrm{Xe}_{2}^{+}$cation is known to exist from Raman spectroscopy, with $v(\mathrm{Xe}-\mathrm{Xe})=123 \mathrm{~cm}^{-1}$, its bond length was only determined in 1997 from the crystal structure of $\mathrm{Xe}_{2} \mathrm{Sb}_{4} \mathrm{~F}_{21}$. The $\mathrm{Xe}-\mathrm{Xe}$ bond length is 309 pm , the longest recorded homonuclear bond between main-group elements.

## (2) Complexes of xenon fluorides

The pentafluoride molecules, such as $\mathrm{AsF}_{5}$ and $\mathrm{RuF}_{5}$, act essentially as fluoride ion acceptors, so that their complexes with xenon fluorides can be formulated as salts containing cationic xenon species, e.g., $[\mathrm{XeF}]\left[\mathrm{AsF}_{6}\right],[\mathrm{XeF}]\left[\mathrm{RuF}_{6}\right]$, $\left[\mathrm{Xe}_{2} \mathrm{~F}_{3}\right]\left[\mathrm{AsF}_{6}\right],\left[\mathrm{XeF}_{3}\right]\left[\mathrm{Sb}_{2} \mathrm{~F}_{11}\right]$, and $\left[\mathrm{XeF}_{5}\right]\left[\mathrm{AgF}_{4}\right]$.

In a number of adducts of $\mathrm{XeF}_{2}$ with metal complexes, the configuration at the Xe atom remains virtually linear, with one F atom lying in the coordination sphere of the metal atom. The ion $\mathrm{Xe}-\mathrm{F}^{+}$does not ordinarily occur as a discrete ion, but rather is attached covalently to a fluorine atom on the anion. Figure 17.5.4(a) shows the structure of $[\mathrm{XeF}]\left[\mathrm{RuF}_{6}\right]$. The terminal $\mathrm{Xe}-\mathrm{F}_{(t)}$ bond is appreciably shorter than that in $\mathrm{XeF}_{2}(200 \mathrm{pm})$, while the bridging $\mathrm{Xe}-\mathrm{F}_{(b)}$ bond is longer. Table 17.5.2 lists the $\mathrm{Xe}-\mathrm{F}$ bond lengths in some adducts of this type.
(a)

(b)

Fig. 17.5.4.
Structure of (a) $[\mathrm{XeF}]\left[\mathrm{RuF}_{6}\right]$ and (b) $\left[\mathrm{Xe}_{2} \mathrm{~F}_{11}\right]_{2}\left[\mathrm{NiF}_{6}\right]$.

In the crystal structure of $\left[\mathrm{XeF}_{3}\right]\left[\mathrm{Sb}_{2} \mathrm{~F}_{11}\right]$, the T-shaped $\mathrm{XeF}_{3}^{+}$cation is nearly coplanar with a F atom of a $\mathrm{Sb}_{2} \mathrm{~F}_{11}^{-}$group in a close $\mathrm{Xe} \cdots \mathrm{F}$ contact, as shown below. The terminal $\mathrm{Sb}-\mathrm{F}$ bond lengths of the anion lie in the range $183-9 \mathrm{pm}$.

The crystal structure of $\left[\mathrm{XeF}_{5}\right]\left[\mathrm{AgF}_{4}\right]$ consists of alternate stacks of double layers of square-pyramidal $\mathrm{XeF}_{5}^{+}$cations and approximately square-planar $\mathrm{AgF}_{4}^{-}$anions (site symmetry $D_{2 \mathrm{~h}}, \mathrm{Ag}-\mathrm{F}=190.2 \mathrm{pm}$ ). The $\mathrm{XeF}_{5}^{+}$ion has $C_{4 \mathrm{v}}$ symmetry with $\mathrm{Xe}-\mathrm{F}(\mathrm{ax})=185.2$, $\mathrm{Xe}-\mathrm{F}(\mathrm{eq})=182.6 \mathrm{pm}$, and $\mathrm{F}(\mathrm{ax})-\mathrm{Xe}-$ $\mathrm{F}(\mathrm{eq})=77.7^{\circ}$. Each cation lying on a 4 -axis interacts with one bridging F ligand of each of four anions at 263.7 pm , as illustrated below:

Table 17.5.2. $\mathrm{Xe}-\mathrm{F}$ bond lengths in some complexes containing $\mathrm{XeF}^{+}$

| Compound | $\mathrm{Xe}^{2}-\mathrm{F}_{(t)}(\mathrm{pm})$ | $\mathrm{Xe}-\mathrm{F}_{(b)}(\mathrm{pm})$ |
| :--- | :--- | :--- |
| $\mathrm{F}-\mathrm{Xe}-\mathrm{FAsF}_{5}$ | 187 | 214 |
| $\mathrm{~F}-\mathrm{Xe}-\mathrm{FRuF}_{5}$ | 187 | 218 |
| $\mathrm{~F}-\mathrm{Xe}-\mathrm{FWOF}_{4}$ | 189 | 204 |
| $\mathrm{~F}-\mathrm{Xe}-\mathrm{Sb}_{2} \mathrm{~F}_{10}$ | 184 | 235 |

The $\left[\mathrm{Xe}_{2} \mathrm{~F}_{3}\right]^{+}$cation in $\left[\mathrm{Xe}_{2} \mathrm{~F}_{3}\right]\left[\mathrm{AsF}_{6}\right]$ is V -shaped, as shown below:

The $\left[\mathrm{Xe}_{2} \mathrm{~F}_{11}\right]^{+}$cation can be considered as $\left[\mathrm{F}_{5} \mathrm{Xe} \cdots \mathrm{F} \cdots \mathrm{XeF}_{5}\right]^{+}$by analogy to $\left[\mathrm{Xe}_{2} \mathrm{~F}_{3}\right]^{+}$. The compounds $\left[\mathrm{Xe}_{2} \mathrm{~F}_{11}^{+}\right]_{2}\left[\mathrm{NiF}_{6}^{2-}\right]$ and $\left[\mathrm{Xe}_{2} \mathrm{~F}_{11}^{+}\right]\left[\mathrm{AuF}_{6}^{-}\right]$ contain $\mathrm{Ni}(\mathrm{IV})$ and $\mathrm{Au}(\mathrm{V})$, respectively. Figure 17.5.4(b) shows the structure of $\left[\mathrm{Xe}_{2} \mathrm{~F}_{11}\right]_{2}\left[\mathrm{NiF}_{6}\right]$.

## (3) $\mathrm{FXeOSO}_{2} \mathrm{~F}$

When $\mathrm{XeF}_{2}$ reacts with an anhydrous acid, such as $\mathrm{HOSO}_{2} \mathrm{~F}$, elimination of HF occurs to yield $\mathrm{FXeOSO}_{2} \mathrm{~F}$, which contains a linear $\mathrm{F}-\mathrm{Xe}-\mathrm{O}$ group, as shown in Fig. 17.5.5(a).

## (4) $\quad \mathrm{FXeN}\left(\mathrm{SO}_{2} \mathrm{~F}\right)_{2}$

This compound is produced by the replacement of a F atom in $\mathrm{XeF}_{2}$ by a $\mathrm{N}\left(\mathrm{SO}_{2} \mathrm{~F}\right)_{2}$ group from $\mathrm{HN}\left(\mathrm{SO}_{2} \mathrm{~F}\right)_{2}$. Its molecular structure has a linear $\mathrm{F}-\mathrm{Xe}-\mathrm{N}$ fragment and a planar configuration at the N atom, as shown in Fig. 17.5.5(b).

## (5) $\mathbf{C s}_{2}\left(\mathrm{XeO}_{3} \mathrm{Cl}_{2}\right)$

This salt is obtained from the reaction of $\mathrm{XeO}_{3}$ with CsCl in aqueous HCl solution, and contains an anionic infinite chain. Figure 17.5.5(c) shows the structure of the chain $\left[\mathrm{Xe}_{2} \mathrm{O}_{6} \mathrm{Cl}_{4}\right]_{n}^{4 n-}$.

## (6) $\quad \mathbf{M}(\mathbf{C O})_{5} \mathrm{E}(\mathrm{M}=\mathbf{C r}, \mathrm{Mo}, \mathrm{W} ; \mathbf{E}=\mathbf{A r}(\mathbf{W}$ only), $\mathrm{Kr}, \mathrm{Xe})$

These complexes are transient species generated from photolysis of $\mathrm{M}(\mathrm{CO})_{6}$ in supercritical noble gas solution at room temperature. Their octahedral structure (symmetry $C_{4 v}$ ) has been characterized by IR spectroscopy and solution NMR. The noble gas atom E can be formally considered as a neutral two-electron donor ligand, and the bonding involves interactions between the $p$ orbitals of $E$ and orbitals on the equatorial CO groups. The stabilities of the complexes decrease in the order $\mathrm{W}>\mathrm{Mo} \sim \mathrm{Cr}$ and $\mathrm{Xe}>\mathrm{Kr}>$ Ar. Organometallic noble gas complexes

that can be generated using matrix isolation techniques include $\mathrm{Fe}(\mathrm{CO})_{4} \mathrm{Xe}$, $\operatorname{Rh}\left(\eta^{5}-\mathrm{C}_{5} \mathrm{R}_{5}\right)(\mathrm{CO}) \mathrm{E}(\mathrm{R}=\mathrm{H}, \mathrm{Me} ; \mathrm{E}=\mathrm{Kr}, \mathrm{Xe}), \mathrm{M}\left(\eta^{5}-\mathrm{C}_{5} \mathrm{R}_{5}\right)(\mathrm{CO})_{2} \mathrm{E}(\mathrm{M}=\mathrm{Mn}$, $\mathrm{Re} ; \mathrm{R}=\mathrm{H}, \mathrm{Me}, \mathrm{Et}$ ( Mn only); $\mathrm{E}=\mathrm{Ar}$ (only with Re and $\mathrm{C}_{5} \mathrm{H}_{5}$ ), $\mathrm{Kr}, \mathrm{Xe}$ ), and $\mathrm{M}\left(\eta^{5}-\mathrm{C}_{5} \mathrm{H}_{5}\right)(\mathrm{CO})_{3} \mathrm{Xe}(\mathrm{M}=\mathrm{Nb}, \mathrm{Ta})$.

### 17.5.5 Structures of some organoxenon compounds

More than ten organoxenon compounds which contain $\mathrm{Xe}-\mathrm{C}$ bonds have been prepared and characterized. The first structural characterization of a $\mathrm{Xe}-\mathrm{C}$ bond was performed on $\left[\mathrm{MeCN}-\mathrm{Xe}-\mathrm{C}_{6} \mathrm{H}_{5}\right]^{+}\left[\left(\mathrm{C}_{6} \mathrm{H}_{5}\right)_{2} \mathrm{BF}_{2}\right]^{-} \cdot \mathrm{MeCN}$. The structure of the cation $\left[\mathrm{MeCN}-\mathrm{Xe}-\mathrm{C}_{6} \mathrm{H}_{5}\right]^{+}$is shown in Fig. 2.4.4. The $\mathrm{Xe}-\mathrm{C}$ bond length is 209.2 pm , and the $\mathrm{Xe}-\mathrm{N}$ bond length is 268.1 pm , with the Xe atom in a linear environment. This compound has no significant fluorine bridge between cation and anion, as the shortest intermolecular $\mathrm{Xe} \cdots \mathrm{F}$ distance is 313.5 pm .

Other examples of compounds containing $\mathrm{Xe}-\mathrm{C}$ bonds are shown in Fig. 17.5.6 and described below.

## (1) $\quad \mathbf{X e}\left(\mathbf{C}_{6} \mathrm{~F}_{5}\right)_{\mathbf{2}}$

This is the first reported homoleptic organoxenon(II) compound with two Xe-C bonds of length 239 and 235 pm , longer than the corresponding bond in other compounds by about 30 pm . The $\mathrm{C}-\mathrm{Xe}-\mathrm{C}$ unit is almost linear (angle $178^{\circ}$ ) and the two $\mathrm{C}_{6} \mathrm{~F}_{5}$ rings are twisted by $72.5^{\circ}$ with respect to each other.

## (2) $\left[\left(\mathrm{C}_{6} \mathrm{~F}_{5} \mathrm{Xe}\right)_{2} \mathrm{Cl}\right]\left[\mathrm{AsF}_{6}\right]$

This is the first isolated and unambiguously characterized xenon(II) chlorine compound. The cation $\left[\left(\mathrm{C}_{6} \mathrm{~F}_{5} \mathrm{Xe}\right)_{2} \mathrm{Cl}\right]^{+}$consists of two $\mathrm{C}_{6} \mathrm{~F}_{5} \mathrm{Xe}$ fragments bridged through a chloride ion. Each linear $\mathrm{C}-\mathrm{Xe}-\mathrm{Cl}$ linkage can be considered to involve an asymmetric hypervalent $3 c-4 e$ bond. Thus a shorter Xe-C distance (mean value 211.3 pm ) occurs and is accompanied by a longer $\mathrm{Xe}-\mathrm{Cl}$ distance (mean value 281.6 pm ). The $\mathrm{Xe}-\mathrm{Cl}-\mathrm{Xe}$ angle is $117^{\circ}$.
(a)

(c)

(d)

Fig. 17.5.6.
Structures of some organoxenon compounds: (a) $\mathrm{Xe}\left(\mathrm{C}_{6} \mathrm{~F}_{5}\right)_{2}$, (b) the cation $\left[\left(\mathrm{C}_{6} \mathrm{~F}_{5} \mathrm{Xe}\right)_{2} \mathrm{Cl}\right]^{+}$, (c) the cation $\left(2,6-\mathrm{F}_{2} \mathrm{H}_{3} \mathrm{C}_{5} \mathrm{~N}-\mathrm{Xe}-\mathrm{C}_{6} \mathrm{~F}_{5}\right)^{+}$, and (d) $2,6-\mathrm{F}_{2} \mathrm{H}_{3} \mathrm{C}_{6}-\mathrm{Xe}-\mathrm{FBF}_{3}$.

## (3) $\left[\mathbf{2 , 6}-\mathrm{F}_{2} \mathrm{H}_{3} \mathrm{C}_{5} \mathrm{~N}-\mathrm{Xe}-\mathrm{C}_{6} \mathrm{~F}_{5}\right]\left[\mathrm{AsF}_{6}\right]$

In the structure of the cation $\left(2,6-\mathrm{F}_{2} \mathrm{H}_{3} \mathrm{C}_{5} \mathrm{~N}-\mathrm{Xe}-\mathrm{C}_{6} \mathrm{~F}_{5}\right)^{+}$, the Xe atom is (exactly) linearly bonded to C and N atoms; the bond lengths are $\mathrm{Xe}-\mathrm{C} 208.7 \mathrm{pm}$ and $\mathrm{Xe}-\mathrm{N} 269.5 \mathrm{pm}$.

## (4) $\mathbf{2 , 6}-\mathrm{F}_{2} \mathbf{H}_{\mathbf{3}} \mathrm{C}_{6}-\mathrm{Xe}^{2}-\mathrm{FBF}_{3}$

In this compound the Xe atom is linearly bonded to C and F atoms; bond lengths are $\mathrm{Xe}-\mathrm{C} 209.0 \mathrm{pm}$ and $\mathrm{Xe}-\mathrm{F} 279.36 \mathrm{pm}$ and the bond angle $\mathrm{C}-\mathrm{Xe}-\mathrm{F}$ is $167.8^{\circ}$.

The structural data of three other organoxenon compounds are listed below:

| Compound | Xe-C $(\mathrm{pm})$ | $\mathrm{Xe}-\mathrm{E}(\mathrm{pm})$ | $\mathrm{C}-\mathrm{Xe}-\mathrm{E}$ |
| :--- | ---: | :---: | :---: |
| $\left(\mathrm{C}_{6} \mathrm{~F}_{5}-\mathrm{Xe}\right)\left(\mathrm{AsF}_{6}\right)$ | (1) 207.9 | 271.4 | $170.5^{\circ}$ |
| $\prod_{1}$ | (2) 208.2 | 267.2 | $174.2^{\circ}$ |
| $\left(\mathrm{C}_{6} \mathrm{~F}_{5}-\mathrm{Xe}\right)\left(\mathrm{OCC}_{6} \mathrm{~F}_{5}\right)$ | 212.2 | 236.7 | $178.1^{\circ}$ |
| $\left(\mathrm{F}_{2} \mathrm{H}_{3} \mathrm{C}_{6}-\mathrm{Xe}\right)\left(\mathrm{OSO}_{2} \mathrm{CF}_{3}\right)$ | (1) 207.4 | 268.7 | $173.0^{\circ}$ |
|  | (2) 209.2 | 282.9 | $165.1^{\circ}$ |

In the known organoxenon compounds, the $\mathrm{C}-\mathrm{Xe}-\mathrm{E}$ angle $(\mathrm{E}=\mathrm{F}, \mathrm{O}, \mathrm{N}$, $\mathrm{Cl})$ deviates only slightly from $180^{\circ}$, indicating a hypervalent $3 c-4 e$ bond in all cases. The $\mathrm{Xe}-\mathrm{C}$ bond lengths, except in the compound $\mathrm{Xe}\left(\mathrm{C}_{6} \mathrm{~F}_{5}\right)_{2}$, vary within the range $208-12 \mathrm{pm}$. All $\mathrm{Xe} \cdots$ E contacts are significantly shorter than the sum of the van der Waals radii of Xe and E, indicating at least a weak secondary $\mathrm{Xe} \cdots$ E interaction.

### 17.5.6 Gold-xenon complexes

Xenon can act as a complex ligand to form M-Xe bonds, especially with gold, which exhibits significant relativistic effects in view of its electronic structure, as discussed in Section 2.4.3. Some gold-xenon complexes have been prepared and characterized, and their structures are shown in Fig. 17.5.7.

The compound $\left[\mathrm{AuXe}_{4}^{2+}\right]\left[\mathrm{Sb}_{2} \mathrm{~F}_{11}^{-}\right]_{2}$ is mentioned in Section 2.4.3 in the context of relativistic effects. In fact it exists in two crystallographically distinct modifications: triclinic and tetragonal. The cation $\left[\mathrm{AuXe}_{4}\right]^{2+}$ is square planar with $\mathrm{Au}-\mathrm{Xe}$ bond lengths ranging from 267.0 to 277.8 pm (Fig. 17.5.7(a)). Around the gold atom, there are three weak $\mathrm{Au} \cdots \mathrm{F}$ contacts of 267.1 to 315.3 pm for the triclinic modification, and two contacts of Au* $\cdot \mathrm{F} 292.8 \mathrm{pm}$ for the tetragonal modification.

Figures 17.5.7(b) and (c) compare the structure of trans-[ $\left.\mathrm{AuXe}_{2}\right]\left[\mathrm{SbF}_{6}\right]_{2}$ with that of the trans-[ $\left.\mathrm{AuXe}_{2} \mathrm{~F}\right]\left[\mathrm{SbF}_{6}\right]$ moiety in crystalline $\left[\mathrm{AuXe}{ }_{2} \mathrm{~F}\right]\left[\mathrm{SbF}_{6}\right]$ [ $\left.\mathrm{Sb}_{2} \mathrm{~F}_{11}\right]$. Each Au atom resides in a square-planar environment, with two Xe atoms and two F atoms bonded to it. The $\mathrm{Au}-\mathrm{Xe}$ bond length is 270.9 pm for the former and 259.3 to 261.9 pm for the latter.

Figure $17.5 .7(\mathrm{~d})$ shows the structure of $\left[\mathrm{AuXe}_{2}\right]\left[\mathrm{Sb}_{2} \mathrm{~F}_{11}\right]_{2}$. The $\mathrm{Au}-\mathrm{Xe}$ distances of 265.8 and 267.1 pm are slightly shorter than those in the $\left[\mathrm{AuXe}_{4}\right]^{2+}$ ion.

Fig. 17.5.7.
Structures of some gold-xenon complexes: (a) $\left[\mathrm{AuXe}_{4}\right]^{2+}$,
(b) $\mathrm{AuXe}_{2}\left(\mathrm{SbF}_{6}\right)_{2}$, (c) $\left(\mathrm{AuXe}_{2} \mathrm{~F}\right)\left(\mathrm{SbF}_{6}\right)$, (d) $\left(\mathrm{AuXe}_{2}\right)\left(\mathrm{Sb}_{2} \mathrm{~F}_{11}\right)_{2}$, and (e) $\left(\mathrm{Au}_{2} \mathrm{Xe}_{2} \mathrm{~F}\right)^{3+}$ and its immediate anion environment in $\left[\mathrm{Au}_{2} \mathrm{Xe}_{2} \mathrm{~F}\right]\left[\mathrm{SbF}_{6}\right]_{3}$.

Figure 17.5.7(e) shows the structure of the Z-shaped binuclear [Xe-Au-F-$\mathrm{Au}-\mathrm{Xe}]^{3+}$ ion and its immediate anion environment in $\left[\mathrm{Au}_{2} \mathrm{Xe}_{2} \mathrm{~F}\right]\left[\mathrm{SbF}_{6}\right]_{3}$. The Au atom is coordinated by one Xe atom and three F atoms in a square-planar configuration, with $\mathrm{Au}-\mathrm{Xe}$ bond length 264.7 pm .

### 17.5.7 Krypton compounds

The known compounds of krypton are limited to the +2 oxidation state, and the list includes the following:
(a) $\mathrm{KrF}_{2}$
(b) Salts of $\mathrm{KrF}^{+}$and $\mathrm{Kr}_{2} \mathrm{~F}_{3}^{+}$:
$[\mathrm{KrF}]\left[\mathrm{MF}_{6}\right](\mathrm{M}=\mathrm{P}, \mathrm{As}, \mathrm{Sb}, \mathrm{Bi}, \mathrm{Au}, \mathrm{Pt}, \mathrm{Ta}, \mathrm{Ru})$
$[\mathrm{KrF}]\left[\mathrm{M}_{2} \mathrm{~F}_{11}\right](\mathrm{M}=\mathrm{Sb}, \mathrm{Ta}, \mathrm{Nb})$
$\left[\mathrm{Kr}_{2} \mathrm{~F}_{3}\right]\left[\mathrm{MF}_{6}\right](\mathrm{M}=\mathrm{As}, \mathrm{Sb}, \mathrm{Ta})$
$[\mathrm{KrF}]\left[\mathrm{AsF}_{6}\right] \cdot\left[\mathrm{Kr}_{2} \mathrm{~F}_{3}\right]\left[\mathrm{AsF}_{6}\right]$
(c) Molecular adducts:
$\mathrm{KrF}_{2} \cdot \mathrm{MOF}_{4}(\mathrm{M}=\mathrm{Cr}, \mathrm{Mo}, \mathrm{W})$
$\mathrm{KrF}_{2} \cdot n \mathrm{MoOF}(n=2,3)$
$\mathrm{KrF}_{2} \cdot \mathrm{VF}_{5}$
$\mathrm{KrF}_{2} \cdot \mathrm{MnF}_{4}$
$\mathrm{KrF}_{2} \cdot\left[\mathrm{Kr}_{2} \mathrm{~F}_{3}\right]\left[\mathrm{SbF}_{5}\right]_{2}$
$\mathrm{KrF}_{2} \cdot\left[\mathrm{Kr}_{2} \mathrm{~F}_{3}\right]\left[\mathrm{SbF}_{6}\right]$
(d) Other types
salts of $[\mathrm{RCN}-\mathrm{KrF}]^{+}\left(\mathrm{R}=\mathrm{H}, \mathrm{CF}_{3}, \mathrm{C}_{2} \mathrm{~F}_{5}, n \mathrm{C}_{3} \mathrm{~F}_{7}\right)$
$\mathrm{Kr}\left(\mathrm{OTeF}_{5}\right)_{2}$

## (1) Structure of $\mathbf{K r F}_{\mathbf{2}}$

Krypton difluoride $\mathrm{KrF}_{2}$ exists in two forms in the solid state: $\alpha-\mathrm{KrF}_{2}$ and $\beta$ $\mathrm{KrF}_{2}$, whose crystal structures are shown in Fig. 17.5.8. Specifically, $\alpha-\mathrm{KrF}_{2}$
(a)

(b)

Fig. 17.5.8.
Crystal structure of (a) $\alpha-\mathrm{KrF}_{2}$ and (b) $\beta-\mathrm{KrF}_{2}$.

Fig. 17.5.9.
Structure of $[\mathrm{KrF}]\left[\mathrm{MF}_{6}\right](\mathrm{M}=\mathrm{AS}$, $\mathrm{Sb}, \mathrm{Bi})$.

## (2) Structures of $\left[\mathrm{KrF}^{2}\right]\left[\mathrm{MF}_{6}\right](\mathbf{M}=\mathbf{A s}, \mathbf{S b}, \mathbf{B i})$

These three compounds form an isomorphous series, in which the $[\mathrm{KrF}]^{+}$ cation strongly interacts with the anion by forming a fluorine bridge with the pseudo-octahedral anion bent about $\mathrm{F}_{b}$, as shown in Fig. 17.5.9. The terminal $\mathrm{Kr}-\mathrm{F}_{t}$ bond lengths in these salts ( 176.5 pm for $[\mathrm{KrF}]\left[\mathrm{AsF}_{6}\right]$ and $[\mathrm{KrF}]\left[\mathrm{SbF}_{6}\right]$, 177.4 pm for $\left.[\mathrm{KrF}]\left[\mathrm{BiF}_{6}\right]\right)$ are shorter, and the $\mathrm{Kr}-\mathrm{F}_{b}$ bridge bond lengths (213.1 pm for $[\mathrm{KrF}]\left[\mathrm{AsF}_{6}\right], 214.0 \mathrm{pm}$ for $[\mathrm{KrF}]\left[\mathrm{SbF}_{6}\right]$, and 209.0 pm for [ KrF$\left.]\left[\mathrm{BiF}_{6}\right]\right)$ are longer, than the $\mathrm{Kr}-\mathrm{F}$ bonds of $\alpha-\mathrm{KrF}_{2}(189.4 \mathrm{pm})$.

The $\mathrm{Kr}^{-} \mathrm{F}_{b}-\mathrm{M}$ bridge bond angles ( $133.7^{\circ}$ for $[\mathrm{KrF}]\left[\mathrm{AsF}_{6}\right]$, $139.2^{\circ}$ for $[\mathrm{KrF}]\left[\mathrm{SbF}_{6}\right]$, and $138.3^{\circ}$ for $[\mathrm{KrF}]\left[\mathrm{BiF}_{6}\right]$ ) are consistent with the bent geometry predicted by the VSEPR arrangements at their respective $\mathrm{F}_{b}$ atoms, but are more open than the ideal tetrahedral angle.

## Structural Chemistry of Rare-Earth Elements

### 18.1 Chemistry of rare-earth metals

The lanthanides (Ln) include lanthanum (La) and the following fourteen elements-Ce, Pr, Nd, Pm, Sm, Eu, Gd, Tb, Dy, Ho, Er, Tm, Yb and Luin which the 4 f orbitals are progressively filled. These fifteen elements together with scandium $(\mathrm{Sc})$ and yttrium $(\mathrm{Y})$ are termed the rare-earth metals. The designation of rare earths arises from the fact that these elements were first found in rare minerals and were isolated as oxides (called earths in the early literature). In fact, their occurrence in nature is quite abundant, especially in China, as reserves have been estimated to exceed $84 \times 10^{6}$ tons. In a broader sense, even the actinides (the 5 f elements) are sometimes included in the rare-earth family.

The rare-earth metals are of rapidly growing importance, and their availability at quite inexpensive prices facilitates their use in chemistry and other applications. Much recent progress has been achieved in the coordination chemistry of rare-earth metals, in the use of lanthanide-based reagents or catalysts, and in the preparation and study of new materials. Some of the important properties of rare-earth metals are summarized in Table 18.1.1. In this table, $r_{\mathrm{M}}$ is the atomic radius in the metallic state and $r_{\mathrm{M}^{3+}}$ is the radius of the lanthanide(III) ion in an eight-coordinate environment.

### 18.1.1 Trends in metallic and ionic radii: lanthanide contraction

The term lanthanide contraction refers to the phenomenon of a steady decrease in the radii of the $\mathrm{Ln}^{3+}$ ions with increasing atomic number, from $\mathrm{La}^{3+}$ to $\mathrm{Lu}^{3+}$, amounting overall to 18 pm (Table 18.1.1). A similar contraction occurs for the metallic radii and is reflected in many smooth and systematic changes, but there are marked breaks at Eu and Yb . Lanthanide contraction arises because the 4 f orbitals lying inside the $4 \mathrm{~d}, 5 \mathrm{~s}$, and 5 p orbitals provide only incomplete shielding of the outer electrons from the steadily increasing nuclear charge. Therefore the outer electron cloud as a whole steadily shrinks as the 4 f subshell is filled. In recent years, theoretical work suggests that relativistic effects also plays a significant role. Further details are given in Section 2.4.3.

The spectacular irregularity in the metallic radii of Eu and Yb occurs because they have only two valence electrons in the conduction band, whereas the other lanthanide metals have three valence electrons in the $5 \mathrm{~d} / 6 \mathrm{~s}$ conduction band. Therefore, lanthanide contraction is not manifested by Eu and Yb in the metallic

state or in some compounds such as the hexaborides, where the lower valence of these two elements is evident from the large radii compared with those of neighboring elements.

Lanthanide contraction has important consequences for the chemistry of the third-row transition metals. The reduction in radius caused by the poor shielding ability of the 4 f electrons means that the third-row transition metals are approximately the same size as their second-row congeners, and consequently exhibit similar chemical behavior. For instance, it has been shown that the covalent radius of gold ( 125 pm ) is less than that of silver ( 133 pm ).

### 18.1.2 Crystal structures of the rare-earth metals

The 17 rare-earth metals are known to adopt five crystalline forms. At room temperature, nine exist in the hexagonal closest packed structure, four in the double $c$-axis hcp (dhcp) structure, two in the cubic closest packed structure and one in each of the body-centered cubic packed and rhombic (Sm-type) structures, as listed in Table 18.1.1. This distribution changes with temperature and pressure as many of the elements go through a number of structural phase transitions. All of the crystal structures, with the exception of bcp, are closest packed, which can be defined by the stacking sequence of the layers of closepacked atoms, and are labeled in Fig. 18.1.1.

| hcp: | AB $\cdots$ | dhcp: | ABAC $\cdots$ |
| :--- | :--- | :--- | :--- |
| ccp: | ABC $\cdots$ | Sm-type: | ABABCBCAC $\cdots$ |

Fig. 18.1.1.
Structure types of rare-earth metals.

Structural Chemistry of Selected Elements

If $\mathrm{Ce}, \mathrm{Eu}$, and Yb are excluded, then the remaining 14 rare-earth metals can be divided into two major subgroups:
(a) The heavy rare-earth metals Gd to Lu , with the exception of Yb and the addition of Sc and Y-these metals adopt the hcp structure.
(b) The light rare-earth metals La to Sm , with the exception of Ce and Eu these metals adopt the dhcp structure. (The Sm-type structure can be viewed as a mixture of one part of ccp and two parts of hcp.)

Within each group, the chemical properties of the elements are very similar, so that they invariably occur together in mineral deposits.

### 18.1.3 Oxidation states

Because of stability of the half-filled and filled 4 f subshell, the electronic configuration of the Ln atom is either $[\mathrm{Xe}] 4 \mathrm{f}^{n} 5 \mathrm{~d}^{0} 6 \mathrm{~s}^{2}$ or $[\mathrm{Xe}] 4 \mathrm{f}^{n} 5 \mathrm{~d}^{1} 6 \mathrm{~s}^{2}$.
The most stable and common oxidation state of $\operatorname{Ln}$ is +3 . The principal reason is that the fourth ionization energy $I_{4}$ of a rare-earth atom is greater than the sum of the first three ionization energies $\left(I_{1}+I_{2}+I_{3}\right)$, as listed in Table 18.1.2. The energy required to remove the fourth electron is so great that in most cases it cannot be compensated by chemical bond formation, and thus the +4 oxidation state rarely occurs.

Although the +3 oxidation state dominates lanthanide chemistry, other oxidation states are accessible, especially if a $4 f^{0}, 4 f^{7}$ or $4 f^{14}$ configuration is generated. The most common $2+$ ions are $\mathrm{Eu}^{2+}\left(4 \mathrm{f}^{7}\right)$ and $\mathrm{Yb}^{2+}\left(4 \mathrm{f}^{14}\right)$, and the most common $4+$ ions are $\mathrm{Ce}^{4+}\left(4 \mathrm{f}^{0}\right)$ and $\mathrm{Tb}^{4+}\left(4 \mathrm{f}^{7}\right)$. Of the five lanthanides that exhibit tetravalent chemistry, $\mathrm{Nd}^{4+}$ and $\mathrm{Dy}^{4+}$ are confined to solid-state

Table 18.1.2. Ionization energies of rare-earth elements ( $\mathrm{kJ} \mathrm{mol}^{-1}$ )

| Element | $I_{1}$ | $I_{2}$ | $I_{3}$ | $\left(I_{1}+I_{2}+I_{3}\right)$ | $I_{4}$ |
| :--- | :--- | :--- | :--- | :---: | :--- |

| La | 538 | 1067 | 1850 | 3455 | 4819 |
| Ce | 527 | 1047 | 1949 | 3523 | 3547 |
| Pr | 523 | 1018 | 2086 | 3627 | 3761 |
| Nd | 530 | 1035 | 2130 | 3695 | 3899 |
| Pm | 536 | 1052 | 2150 | 3738 | 3970 |
| Sm | 543 | 1068 | 2260 | 3871 | 3990 |
| Eu | 547 | 1085 | 2404 | 4036 | 4110 |
| Gd | 593 | 1167 | 1990 | 3750 | 4250 |
| Tb | 565 | 1112 | 2114 | 3791 | 3839 |
| Dy | 572 | 1126 | 2200 | 3898 | 4001 |
| Ho | 581 | 1139 | 2204 | 3924 | 4100 |
| Er | 589 | 1151 | 2194 | 3934 | 4115 |
| Tm | 597 | 1163 | 2285 | 4045 | 4119 |
| Yb | 603 | 1176 | 2415 | 4194 | 4220 |
| Lu | 524 | 1340 | 2022 | 3886 | 4360 |

fluoride complexes, while $\operatorname{Pr}^{4+}\left(4 \mathrm{f}^{1}\right)$ and $\mathrm{Tb}^{4+}$ also form the tetrafluoride and dioxide. The most extensive lanthanide(IV) chemistry is that of $\mathrm{Ce}^{4+}$, for which a variety of tetravalent compounds and salts are known (e.g., $\mathrm{CeO}_{2}, \mathrm{CeF}_{4} \cdot \mathrm{H}_{2} \mathrm{O}$ ). The common occurrence of $\mathrm{Ce}^{4+}$ is attributable to the high energy of the 4 f orbitals at the start of the lanthanide series, such that $\mathrm{Ce}^{3+}$ is not sufficiently stable to prevent the loss of an electron.

The crystallographic ionic radii of the rare-earth elements in oxidation states $+2(\mathrm{CN}=6),+3(\mathrm{CN}=6)$, and $+4(\mathrm{CN}=6)$ are presented in Table 18.1.3. The data provide a set of conventional size parameters for the calculation of hydration energies. It should be noted that in most lanthanide(III) complexes the $\mathrm{Ln}^{3+}$ center is surrounded by eight or more ligands, and that in aqueous solution the primary coordination sphere has eight and nine aqua ligands for light and heavy $\mathrm{Ln}^{3+}$ ions, respectively. The crystal radii of $\mathrm{Ln}^{3+}$ ions with $\mathrm{CN}=8$ are listed in Table 18.1.1.

### 18.1.4 Term symbols and electronic spectroscopy

Atomic and ionic energy levels are characterized by a term symbol of the general form ${ }^{2 S+1} L_{J}$. The values of $S, L$, and $J$ of lanthanide ions $\mathrm{Ln}^{3+}$ in the ground state can be deduced from the arrangement of the electrons in the $4 f$ subshell, which are determined by Hund's rules and listed in Table 18.1.4.
Three types of electronic transition can occur for lanthanide compounds. These are $\mathrm{f} \rightarrow \mathrm{f}$ transition, $n \mathrm{f} \rightarrow(n+1) \mathrm{d}$ transition and ligand $\rightarrow$ metal f charge-transfer transition.

In $\mathrm{Ln}^{3+}$ ions, the 4 f orbitals are radially much more contracted than the d orbitals of transition metals, to the extent that the filled 5 s and 5 p orbitals largely shield the 4 f electrons from the ligands. The result is that vibronic coupling is much weaker in $\mathrm{Ln}^{3+}$ compounds than in transition-metal compounds, and hence the intensities of electronic transitions are much lower. As many of

these electronic transitions lie in the visible region of the electromagnetic spectrum, the colors of $\mathrm{Ln}^{3+}$ compounds are typically less intense than those of the transition metals. The colors of the $\mathrm{Ln}^{3+}$ ions in hydrated salts are given in Table 18.1.4. The lack of $4 f$ orbital and ligand interaction means that the $f \rightarrow f$

Table 18.1.4. Electronic configuration, ground state term symbol, and magnetic properties of $\mathrm{Ln}^{3+}$ ions

| $\mathrm{Ln}^{3+}$ | 4f electronic <br> configuration | Ground state <br> term symbol | Color of $\mathrm{Ln}^{3+}$ | Magnetic moment, <br> $\mu(298 \mathrm{~K}) / \mu_{\mathrm{B}}$ |
| :--- | :--- | :--- | :--- | :--- |

Calculated Observed

transition energies for a given $\mathrm{Ln}^{3+}$ change little between compounds, and hence the colors of $\mathrm{Ln}^{3+}$ are often characteristic. In view of the small interaction
of the $\mathrm{Ln}^{3+} 4 \mathrm{f}$ orbitals with the surrounding ligands, the $\mathrm{f} \rightarrow \mathrm{f}$ transition energies in $\mathrm{Ln}^{3+}$ compounds are well defined, and thus the bands in their electronic absorption spectra are much sharper.

Since $\mathrm{f} \rightarrow \mathrm{d}$ transitions are Laporte allowed, they have much higher intensity than $\mathrm{f} \rightarrow \mathrm{f}$ transitions. Ligand-to-metal charge-transfer transitions are also Laporte allowed and also have high intensity. These two types of transitions generally fall in the ultraviolet region, so they do not affect the colors of $\mathrm{Ln}^{3+}$ compounds. For easily reduced $\mathrm{Ln}^{3+}(\mathrm{Eu}$ and Yb$)$, they are at lower energy than the $\mathrm{f} \rightarrow \mathrm{d}$ transitions, and for easily oxidized ligands they may tail into the visible region of the spectrum, giving rise to much more intensely colored complexes.

The $\mathrm{Ln}^{2+}$ ions are often highly colored. This arises because the 4 f orbitals in $\mathrm{Ln}^{2+}$ are destabilized with respect to those in $\mathrm{Ln}^{3+}$, and hence lie closer in energy to the 5 d orbitals. This change in orbital energy separation causes the $\mathrm{f} \rightarrow \mathrm{d}$ transitions to shift from the ultraviolet into the visible region of the spectrum.

The fluorescence which arises from $\mathrm{f} \rightarrow \mathrm{f}$ transitions within the $\mathrm{Ln}^{3+}$ ion is employed in color television sets, the screens of which contain three phosphor emitters. The red emitter is $\mathrm{Eu}^{3+}$ in $\mathrm{Y}_{2} \mathrm{O}_{2} \mathrm{~S}$ or $\mathrm{Eu}^{3+}: \mathrm{Y}_{2} \mathrm{O}_{3}$. The main emissions for $\mathrm{Eu}^{3+}$ are between the ${ }^{5} D_{o} \rightarrow{ }^{7} F_{n}(n=4$ to 0$)$ levels. The green emitter is $\mathrm{Tb}^{3+}$ in $\mathrm{Tb}^{3+}: \mathrm{La}_{2} \mathrm{O}_{2} \mathrm{~S}$. The main emissions for $\mathrm{Tb}^{3+}$ are between the ${ }^{5} D_{4}$ and ${ }^{7} F_{n}(n=6$ to 0$)$ levels. The best blue emitter is $\mathrm{Ag}, \mathrm{Al}: \mathrm{ZnS}$, which has no $\mathrm{Ln}^{3+}$ component.

### 18.1.5 Magnetic properties

The paramagnetism of $\mathrm{Ln}^{3+}$ ions arises from their unpaired 4f electrons which interact little with the surrounding ligands in $\mathrm{Ln}^{3+}$ compounds. The magnetic properties of these compounds are similar to those of the free $\mathrm{Ln}^{3+}$ ions. For most $\mathrm{Ln}^{3+}$ the magnitude of the spin-orbital interaction in f orbital is sufficiently large, so that the excited levels are thermally inaccessible, and hence the magnetic behavior is determined entirely by the ground level. The effective magnetic moment $\mu_{\text {eff }}$ of this level is given by the equation

$$
\mu_{\mathrm{eff}}=g_{J} \sqrt{J(J+1)},
$$

where

$$
g_{J}=\frac{3}{2}+\frac{S(S+1)-L(L+1)}{2 J(J+1)} .
$$

The calculated $\mu_{\text {eff }}$ and observed values from experiments are listed in Table 18.1.4 and shown in Fig. 18.1.2. There is good agreement in all cases except for $\mathrm{Sm}^{3+}$ and $\mathrm{Eu}^{3+}$, both of which have low-lying excited states $\left({ }^{6} H_{31 / 2}\right.$ for $\mathrm{Sm}^{3+}$, and ${ }^{7} F_{1}$ and ${ }^{7} F_{2}$ for $\mathrm{Eu}^{3+}$ ) which are appreciably populated at room temperature.

Structural Chemistry of Selected Elements

### 18.2 Structure of oxides and halides of rare-earth elements

The bonding in the oxides and halides of rare-earth elements is essentially ionic. Their structures are determined almost entirely by steric factors and gradual variation across the series, and can be correlated with changes in ionic radii.
(a)

(b)

### 18.2.1 Oxides

The sesquioxides $\mathrm{M}_{2} \mathrm{O}_{3}$ are the stable oxides for all rare-earth elements except $\mathrm{Ce}, \mathrm{Pr}$, and Tb , and are the final product of calcination of many salts such as oxalates, carbonates, and nitrates. The sesquioxides $\mathrm{M}_{2} \mathrm{O}_{3}$ adopt three structural types:

The type-A (hexagonal) structure consists of $\mathrm{MO}_{7}$ units which approximate to capped octahedral geometry, and is favored by the lightest lanthanides (La, $\mathrm{Ce}, \mathrm{Pr}$, and Nd ). Figure 18.2.1(a) shows the structure of $\mathrm{La}_{2} \mathrm{O}_{3}$.

The type-B (monoclinic) structure is related to type-A, but is more complex as it contains three kinds of non-equivalent M atoms, some with octahedral and the remainder with monocapped trigonal prismatic coordination. In the latter type of coordination geometry, the capping O atom is appreciably more distant than those at the vertices of the prism. For example, in $\mathrm{Sm}_{2} \mathrm{O}_{3}$, the seventh atom is at 273 pm (mean) and the others are at 239 pm (mean). This type is favored by the middle lanthanides ( $\mathrm{Sm}, \mathrm{Eu}, \mathrm{Gd}, \mathrm{Tb}$, and Dy ).

The type-C (cubic) structure is related to the fluorite structure (Fig. 10.1.6), but with one-quarter of the anions removed in such a way as to reduce the
metal coordination number from 8 to 6 , resulting in two different coordination geometries, as shown in Fig. 18.2.1(b). This type is favored by $\mathrm{Sc}, \mathrm{Y}$, and heavy lanthanides from Nd to Lu .

The dioxides $\mathrm{CeO}_{2}$ and $\mathrm{PrO}_{2}$ adopt the fluorite structure with cubic unit-cell parameters $a=541.1$ and 539.2 pm , respectively, and $\mathrm{Tb}_{4} \mathrm{O}_{7}$ is closely related to fluorite.

### 18.2.2 Halides

## (1) Fluorides

Trifluorides are known for all the rare-earth elements. The structure of $\mathrm{ScF}_{3}$ is close to the cubic $\mathrm{ReO}_{3}$ structure [Fig. 10.4.4(a)], in which $\mathrm{Sc}^{3+}$ has octahedral coordination. The $\mathrm{YF}_{3}$ structure has a nine-coordinate $\mathrm{Y}^{3+}$ in a distorted tricapped trigonal prism, eight $\mathrm{F}^{-}$at approximately 230 pm , and the ninth at 260 pm . The $\mathrm{YF}_{3}$ structure type is adopted by the 4 f trifluorides from $\mathrm{SmF}_{3}$ to $\mathrm{LuF}_{3}$.

The early light trifluorides from $\mathrm{LaF}_{3}$ to $\mathrm{HoF}_{3}$ adopt the $\mathrm{LaF}_{3}$ structure, in which the $\mathrm{La}^{3+}$ is 11-coordinate with a fully capped, distorted trigonal prismatic coordination geometry. The neighbors of $\mathrm{La}^{3+}$ are seven $\mathrm{F}^{-}$at $242-8 \mathrm{pm}$, two $\mathrm{F}^{-}$at 264 pm , and a further two $\mathrm{F}^{-}$at 300 pm .

Tetrafluorides $\mathrm{LnF}_{4}$ are known for $\mathrm{Ce}, \mathrm{Pr}$, and Tb . In the structure for $\mathrm{LnF}_{4}$, the $\mathrm{Ln}^{4+}$ ion is surrounded by eight $\mathrm{F}^{-}$forming a slightly distorted square antiprism, which shares its vertices with eight others.

## (2) Chlorides

Chlorides $\mathrm{ScCl}_{3}, \mathrm{YCl}_{3}$, and later $\mathrm{LnCl}_{3}$ (from $\mathrm{DyCl}_{3}$ to $\mathrm{LuCl}_{3}$ ) adopt the $\mathrm{YCl}_{3}$ layer structure, in which the small $\mathrm{M}^{3+}$ ion is surrounded by an octahedron of $\mathrm{Cl}^{-}$neighbors. The early trichlorides (from $\mathrm{LaCl}_{3}$ to $\mathrm{GdCl}_{3}$ ) adopt the $\mathrm{LaCl}_{3}$ structure, in which the large $\mathrm{La}^{3+}$ ion is surrounded by nine approximately equidistant $\mathrm{Cl}^{-}$neighbors in a tricapped trigonal prismatic arrangement. Figure 18.2.2 shows the structure of $\mathrm{LaCl}_{3}$.

Chlorides are also known in oxidation state +2 for $\mathrm{Nd}, \mathrm{Sm}, \mathrm{Eu}, \mathrm{Dy}$, and Tm . The structure of the sesquichloride $\mathrm{Gd}_{2} \mathrm{Cl}_{3}$ is best formulated as
(a)

(b)

$\left[\mathrm{Gd}_{4}\right]^{6+}\left[\mathrm{Cl}^{-}\right]_{6}$ and is made up of infinitive chains of $\mathrm{Gd}_{6}$ octahedra sharing opposite edges, with chlorine atoms capping the triangular faces, as shown in Fig. 18.2.3.

## (3) Bromides and iodides

The trihalides $\mathrm{MBr}_{3}$ and $\mathrm{MI}_{3}$ are known for all the lanthanide elements. The early lanthanide tribromide ( La to $\mathrm{Pr} \mathrm{)} \mathrm{adopt} \mathrm{the} \mathrm{LaCl}_{3}$ structure, while the later tribromides (from Nd to Lu ) and the early triiodides (from La to $\mathrm{Nd)} \mathrm{form} \mathrm{a}$ layer structure with eight-coordinate lanthanide ions.

Ionic dibromides and diiodides are known for $\mathrm{Nd}, \mathrm{Sm}, \mathrm{Eu}, \mathrm{Dy}, \mathrm{Tm}$, and $\mathrm{Yb} . \mathrm{SmI}_{2}, \mathrm{EuI}_{2}$, and $\mathrm{YbI}_{2}$ are useful starting materials for organometallic compounds of these elements in their +2 oxidation states. Iodide $\mathrm{SmI}_{2}$ is a popular one-electron reducing agent for organic synthesis. The diiodides of $\mathrm{La}, \mathrm{Ce}, \mathrm{Pr}$, and Gd exhibit metallic properties and are best formulated as $\mathrm{Ln}^{3+}\left(\mathrm{I}^{-}\right)_{2} e^{-}$with delocalized electrons. The reduction chemistry of lanthanide(II) compounds will be discussed in Section 18.5.

## (4) Oxohalides

Many oxohalides of rare-earth elements have been characterized. The crystal of $\gamma$-LaOF has a tetragonal unit cell with $a=409.1 \mathrm{pm}$ and $c=583.6 \mathrm{pm}$, space group $P 4 / n m m$. In this structure, each $\mathrm{La}^{3+}$ is coordinated by four $\mathrm{O}^{2-}$ and four $\mathrm{F}^{-}$anions, forming a distorted cube, as shown in Fig. 18.2.4. The distance of $\mathrm{La}-\mathrm{O}$ is 261.3 pm and $\mathrm{La}-\mathrm{F} 242.3 \mathrm{pm}$.

### 18.3 Coordination geometry of rare-earth cations

In lanthanide complexes, the Ln ions are hard Lewis acids, which prefer to coordinate hard bases, such as F, O, N ligands. The f-orbitals are not involved to a significant extent in M-L bonds, so their interaction with ligands is almost electrostatic in nature. Table 18.3.1 lists some examples of the various coordination

[^9]numbers and geometries of rare-earth cations, which are determined by three factors:
(1) Steric bulk. The ligands are packed around the metal ion in such a way as to minimize interligand repulsion, and the coordination number is determined
(a)

(e)

(b)

(d)

(f)

Fig. 18.3.1.
Structures of some lanthanide complexes: (a) $\mathrm{La}\left[\mathrm{N}\left(\mathrm{SiMe}_{3}\right)_{2}\right]_{3}, \mathrm{CN}=3$;
(b) $\mathrm{Nd}\left(\mathrm{CH}_{3} \mathrm{CN}\right)\left(\mathrm{CF}_{3} \mathrm{SO}_{3} \cdot\right)_{3}\left[\mathrm{CH}_{3}-\mathrm{N}-\left(\mathrm{CH}_{2}-\mathrm{CH}_{2}-\mathrm{NH}\right)_{3}-\mathrm{CH}_{2}-\mathrm{CH}_{2}\right], \mathrm{CN}=8$;
(c) $\mathrm{LaCl}_{3}(18 \mathrm{C} 6), \mathrm{CN}=9$; (d) $\left[\mathrm{Lu}\left(\mathrm{NO}_{3}\right)_{5}\right]^{2-}, \mathrm{CN}=10$; (e) $\mathrm{La}(15 \mathrm{C} 5)\left(\mathrm{NO}_{3}\right)_{3}, \mathrm{CN}=11$;
(f) $\left[\mathrm{La}\left(\mathrm{NO}_{3}\right)_{6}\right]^{3-}, \mathrm{CN}=12$.
by the steric bulk of the ligands. The coordination number varies over a wide range from 3 to 12 , and lower coordination numbers can be achieved with very bulky ligand such as hexamethyldisilylamide. In $\mathrm{La}\left[\mathrm{N}\left(\mathrm{SiMe}_{3}\right)_{2}\right]_{3}$, the coordination number is only three, as shown in Fig. 18.3.1(a).
(2) Ionic size. The large sizes of lanthanide ions lead to high coordination numbers; eight or nine is very common, and several complexes are known with coordination number 12. For example the $\mathrm{NO}_{3}^{-}$ligand, which has a small bite angle, forms a 12-coordinate $\mathrm{La}^{3+}$ complex. Figures 18.3.1(b) to 18.3.1(f) show
the structures of $\mathrm{Ln}^{3+}$ complexes with coordination numbers ranging from 8 to 12 , respectively. The coordination geometries of high coordination complexes are often irregular.
(3) Chelate effect. Higher coordination numbers are usually achieved with chelating ligands, such as crown ethers, EDTA and $\mathrm{NO}_{3}^{-}$or $\mathrm{CO}_{3}^{2-}$. Cations $\mathrm{Ln}^{3+}$ form a range of complexes with crown ethers. In the crystal structure of $\mathrm{La}(18 \mathrm{C} 6)\left(\mathrm{NO}_{3}\right)_{3}$, the $\mathrm{La}^{3+}$ ion is coplanar with the six O-donors of the crown ether. The flexibility of 18C6 allows it to pucker and bind effectively to the smaller later lanthanides. Dibenzo-18C6 is much less flexible than 18C6, and can only form complexes with large early $\mathrm{Ln}^{3+}$ ions ( La to Nd ) in the presence of the strongly coordinating bidentate $\mathrm{NO}_{3}^{-}$counterion. Complexes of $\mathrm{Ln}^{3+}$ with 15 C 5 or 12 C 4 are known for $\mathrm{La}-\mathrm{Lu}$ with $\mathrm{NO}_{3}^{-}$counterions. The larger $\mathrm{Ln}^{3+}$ ion cannot fit within the cavity of these ligands, so that it sits above the plane of the macrocycle.

In the coordination chemistry of rare-earth metals, compounds containing $\mathrm{M}-\mathrm{M}$ bonds are very rare, but the complexes often exist as dimers or oligomers linked by bridging ligands. Figure 18.3.2 shows the structures of some dimeric and oligomeric coordination compounds: (a) in $\mathrm{Rb}_{5} \mathrm{Nd}_{2}\left(\mathrm{NO}_{3}\right)_{11} \cdot \mathrm{H}_{2} \mathrm{O}$, one $\mathrm{NO}_{3}^{-}$ligand bridges two Nd atoms to form the dimeric anion $\mathrm{Nd}_{2}\left(\mathrm{NO}_{3}\right)_{11}^{5-}$; (b) in the complex $\left[\mathrm{Y}\left(\eta^{5}: \eta^{1}-\mathrm{C}_{5} \mathrm{Me}_{4} \mathrm{SiMe}_{2} \mathrm{~N}^{t} \mathrm{Bu}\right)\left(\mu-\mathrm{C}_{4} \mathrm{H}_{3} \mathrm{~S}\right)\right]_{2}$, a pair of $\mu-\mathrm{C}_{4} \mathrm{H}_{3} \mathrm{~S}$ ligands bridge two Y atoms; (c) in $\mathrm{Yb}_{2}\left(\mathrm{OC}_{6} \mathrm{H}_{3} \mathrm{Ph}_{2}-\right.$ $2,6)_{4}(\mathrm{PhMe})_{1.5}$, two $\mathrm{OC}_{6} \mathrm{H}_{3} \mathrm{Ph}_{2}-2,6$ ligands bridge two Yb atoms; and (d) in $\mathrm{K}^{+}(\mathrm{THF})_{6}\left\{\left[\mathrm{MePhC}\left(\mathrm{C}_{4} \mathrm{H}_{3} \mathrm{~N}\right)_{2}\right] \mathrm{Sm}\right\}_{5}\left(\mu_{5}-\mathrm{I}^{-}\right)$, the pentameric anion is formed
(a)

(c)

(b)

by five bridging [ $\mathrm{MePhC}\left(\mathrm{C}_{4} \mathrm{H}_{3} \mathrm{~N}\right)_{2}$ ] ligands and consolidated by a central $\mu_{5}-\mathrm{I}^{-}$anion.

The lanthanide complexes exhibit a number of characteristic features in their structures and properties:
(a) There is a wide range of coordination numbers, generally 6 to 12 , but 3 to 5 are known, as listed in Table 18.3.1.
(b) Coordination geometries are determined by ligand steric factors rather than crystal field effects. For example, the donor oxygen atoms in different ligands coordinate to the $\mathrm{La}^{3+}$ ions in different geometries: monocapped octahedral $(\mathrm{CN}=7)$, irregular $(\mathrm{CN}=11)$, and icosahedral $(\mathrm{CN}=12)$.
(c) The lanthanides prefer anionic ligands with hard donor atoms of rather high electronegativity (e.g., oxygen and fluorine) and generally form labile "ionic" complexes that undergo facile ligand exchange.
(d) The lanthanides do not form $\mathrm{Ln}=\mathrm{O}$ or $\mathrm{Ln} \equiv \mathrm{N}$ multiple bonds of the type known for many transition metals and certain actinides.
(e) The 4 forbitals in the $\mathrm{Ln}^{3+}$ ions do not participate directly in bonding. Their spectroscopic and magnetic properties are thus largely unaffected by the ligands.

### 18.4 Organometallic compounds of rare-earth elements

In contrast to the extensive carbonyl chemistry of the d-transition metals, lanthanide metals do not form complexes with CO under normal conditions. All organolanthanide compounds are highly sensitive to oxygen and moisture, and in some cases they are also thermally unstable.

Organolanthanide chemistry has mainly been developed using the cyclopentadienyl $\mathrm{C}_{5} \mathrm{H}_{5}(\mathrm{Cp})$ group and its substituted derivatives, such as $\mathrm{C}_{5} \mathrm{Me}_{5}\left(\mathrm{Cp}^{*}\right)$, largely because their size allows some steric protection of the large metal center.

### 18.4.1 Cyclopentadienyl rare-earth complexes

The properties of cyclopentadienyl lanthanide compounds are influenced markedly by the relationship between the size of the lanthanide atoms and the steric demand of the Cp group. The former varies from La to Lu according to lanthanide contraction, while the latter varies from the least bulky Cp to highly substituted $\mathrm{Cp}^{*}$, which is appreciably larger. The Sc and Y complexes are very similar to those of lanthanides with proper allowance for the relative atomic sizes.

## (1) Triscyclopentadienyl complexes

In $\mathrm{LaCp}_{3}$, the coordination requirements of the large $\mathrm{La}^{3+}$ ion are satisfied by formation of a polymer, where each La atom is coordinated to three $\eta^{5}-\mathrm{C}_{5} \mathrm{H}_{5}$ ligands with an additional $\eta^{2}-\mathrm{C}_{5} \mathrm{H}_{5}$ interaction, as shown in Fig. 18.4.1(a). The intermediate-size Sm atom forms a simple $\mathrm{Sm}\left(\eta^{5}-\mathrm{C}_{5} \mathrm{H}_{5}\right)_{3}$ monomeric species, as shown in Fig. 18.4.1(b). The smallest lanthanide, Lu , is unable to accommodate three $\eta^{5}-\mathrm{C}_{5} \mathrm{H}_{5}$ ligands, so that $\mathrm{LuCp}_{3}$ adopts a polymeric structure with
(a)

Structure of (a) $\mathrm{Cp}_{3} \operatorname{Pr}\left(\mathrm{CNC}_{6} \mathrm{H}_{11}\right)$ and (b) $\left[\mathrm{Cp}_{3} \mathrm{SmClSmCp}_{3}\right]^{-}$.
Many adducts of $\mathrm{LnCp}_{3}$ with neutral Lewis bases (such as THF, esters, phosphines, pyridines, and isocyanides) have been prepared and characterized. These complexes usually exhibit pseudo-tetrahedral geometry. Figure 18.4.2(a) shows the structure of $\mathrm{Cp}_{3} \operatorname{Pr}\left(\mathrm{CNC}_{6} \mathrm{H}_{11}\right)$ and Fig. 18.4.2(b) shows the structure of the anion of $\left[\mathrm{Li}(\mathrm{DME})_{3}\right]^{+}\left[\mathrm{Cp}_{3} \mathrm{SmClSmCp}\right]^{-}$, in which two $\mathrm{Cp}_{3} \mathrm{Ln}$ fragments are bridged by one anionic ligand.

### 18.4.2 Biscyclopentadienyl complexes

Many crystal structures of the biscyclopentadienyl rare-earth compounds have been determined; four examples are shown in Fig. 18.4.3.
(a) $\left(\mathrm{Cp}_{2} \mathrm{LnCl}\right)_{2}$

The configuration of dimers of this type is dependent on the relative importance of the steric interaction of the Cp rings with the halide bridge versus the interaction between the Cp rings on both metal centers. $\mathrm{In}\left(\mathrm{Cp}_{2} \mathrm{ScCl}\right)_{2}$, the Cp ring is relatively small in comparison with the halide ligand; accordingly all Cp centroids lie in one plane, and the $\mathrm{Sc}_{2} \mathrm{Cl}_{2}$ plane is perpendicular to it, as shown in Fig. 18.4.3(a).
(b) $\mathrm{Cp}_{2}^{*} \mathrm{Yb}\left(\mathrm{MeBeCp}{ }^{*}\right)$

The $\mathrm{Cp}_{2}^{*} \mathrm{Yb}$ unit can be coordinated by saturated hydrocarbons, as in MeBeCp . The positions of the hydrogens on the bridging methyl group show that this is not a methyl bridge having a $3 c-2 e$ bond between $\mathrm{Yb}-\mathrm{C}-\mathrm{Be}$, as shown in Fig. 18.4.3(b).
(c) $\mathrm{Cp}_{2} \mathrm{LuCl}$ (THF)

This adduct is monomeric with one coordinated THF, forming a pseudotetrahedral arrangement (each $\mathrm{Cp}^{-}$ligand is considered to be tridentate), as shown in Fig. 18.4.3(c).
(d) $\left(\mathrm{Cp}_{2}^{*} \mathrm{Yb}\right)_{2} \mathrm{Te}_{2}$

In the chalcogenide complex $\mathrm{Cp}_{2}^{*} \mathrm{Yb}\left(\mathrm{Te}_{2}\right) \mathrm{YbCp}_{2}^{*}$, the $\mathrm{Te}_{2}$ unit serves as a bridging ligand, as shown in Fig. 18.4.3(d).

## (3) Monocyclopentadienyl complexes

Since monocyclopentadienyl rare-earth complexes require four to six $\sigma$-donor ligands to reach the stable coordination numbers 7 to 9 , monomeric complexes must bind several neutral donor molecules. Generally, some of these donor molecules are easily lost, and dinuclear and polynuclear complexes are formed. This accounts for the fact that monocyclopentadienyl rare-earth complexes exhibit rich structural complexity. Figure 18.4.4 shows the structure of $\mathrm{CpErCl}_{2}(\mathrm{THF})_{3}$.

### 18.4.3 Benzene and cyclooctatetraenyl rare-earth complexes

All the lanthanides and Y are able to bind two substituted benzene rings, such as $\mathrm{Gd}\left(\eta^{6}-\mathrm{C}_{6} \mathrm{H}_{3}{ }^{t} \mathrm{Bu}_{3}\right)_{2}$ and $\mathrm{Y}\left(\eta^{6}-\mathrm{C}_{6} \mathrm{H}_{6}\right)_{2}$. Figure 18.4.5(a) shows the sandwich structure of $\mathrm{Gd}\left(\eta^{6}-\mathrm{C}_{6} \mathrm{H}_{3}{ }^{t} \mathrm{Bu}_{3}\right)_{2}$. In this complex, the Gd center is zero-valent.
The large lanthanide ions are able to bind a planar cyclooctatetraene dianion ligand, as shown in Fig. 18.4.5(b) to Fig. 18.4.5(d). In $\left[\left(\mathrm{C}_{8} \mathrm{H}_{8}\right)_{2} \mathrm{Ce}\right] \mathrm{K}\left[\mathrm{CH}_{3} \mathrm{O}\left(\mathrm{CH}_{2} \mathrm{CH}_{2} \mathrm{O}\right)_{2} \mathrm{CH}_{3}\right]$, $\mathrm{Ce}(\mathrm{III})$ is sandwiched by two $\left(\eta^{8}-\mathrm{C}_{8} \mathrm{H}_{8}\right)$ dianions, as shown in Fig. 18.4.5(b). The structure of $\left(\mathrm{C}_{8} \mathrm{H}_{8}\right)_{3} \mathrm{Nd}_{2}(\mathrm{THF})_{2}$ shows a $\left[\left(\mathrm{C}_{8} \mathrm{H}_{8}\right)_{2} \mathrm{Nd}\right]^{-}$anion coordinating to the $\left[\left(\mathrm{C}_{8} \mathrm{H}_{8}\right) \mathrm{Nd}(\mathrm{THF})_{2}\right]^{+}$cation via two carbon atoms of the $\mathrm{C}_{8} \mathrm{H}_{8}^{2-}$ ligand, as shown in Fig. 18.4.5(c).

In the sandwich complex $\left(\mathrm{C}_{8} \mathrm{H}_{8}\right) \mathrm{Lu}\left(\mathrm{Cp}^{*}\right)$, as shown in Fig. 18.4.5(d), the molecular structure is slightly bent with a ring centroid-Lu-ring centroid angle of $173^{\circ}$. The methyl groups of Cp * are bent away from the Lu center by $0.7^{\circ}-2.3^{\circ}$ from the idealized planar configuration. The averaged $\mathrm{Lu}-\mathrm{C}$ bond distances for the $\mathrm{C}_{8} \mathrm{H}_{8}^{2-}$ and $\mathrm{Cp}^{*-}$ ligands are 243.3 and 253.6 pm , respectively.

### 18.4.4 Rare-earth complexes with other organic ligands

A variety of "open" $\pi$ complexes, such as allyl complexes, are known. Generally, the allyl group is $\eta^{3}$-bound to the rare-earth center. Figure 18.4.6(a) shows the structure of the anion in $\left[\mathrm{Li}_{2}\left(\mu-\mathrm{C}_{3} \mathrm{H}_{5}\right)(\mathrm{THF})_{3}\right]^{+}\left[\mathrm{Ce}\left(\eta^{3}-\mathrm{C}_{3} \mathrm{H}_{5}\right)_{4}\right]^{-}$.

Using bulky ligands or chelating ligands to saturate the complexes coordinatively or sterically, the rare-earth complexes without $\pi$ ligands have been obtained and characterized. The La and Sm complexes with bulky alkyl ligands

Fig. 18.4.5.
Structures of (a) $\mathrm{Gd}\left(\eta^{6}-\mathrm{C}_{6} \mathrm{H}_{3}{ }^{t} \mathrm{Bu}_{3}\right)_{2}$, (b) $\left.\left[\left(\mathrm{C}_{8} \mathrm{H}_{8}\right)_{2} \mathrm{Ce}\right] \mathrm{K}^{2} \mathrm{CH}_{3} \mathrm{O}\left(\mathrm{CH}_{2} \mathrm{CH}_{2} \mathrm{O}\right)_{2} \mathrm{CH}_{3}\right]$, (c) $\left(\mathrm{C}_{8} \mathrm{H}_{8}\right)_{3} \mathrm{Nd}_{2}(\mathrm{THF})_{2}$, and (d) $\left(\mathrm{C}_{8} \mathrm{H}_{8}\right) \mathrm{Lu}\left(\mathrm{Cp}^{*}\right)$.

Fig. 18.4.6.
Structures of some rare-earth complexes: (a) $\left[\mathrm{Ce}\left(\eta^{3}-\mathrm{C}_{3} \mathrm{H}_{5}\right)_{4}\right]^{-}$, (b) $\mathrm{Sm}\left[\mathrm{CH}(\mathrm{SiMe} 3)_{2}\right]_{3}$, and $(\mathrm{c})\left[\mathrm{Lu}\left({ }^{t} \mathrm{Bu}\right)_{4}\right]^{-}$.
$\left[\mathrm{CH}\left(\mathrm{SiMe}_{3}\right)_{2}\right]$ are pyramidal, being stabilized by agostic interactions of methyl groups with the highly Lewis acidic metal center, as shown in Fig. 18.4.6(b).

The second half of the lanthanide series react with the more bulky ${ }^{t} \mathrm{BuLi}$ reagent to form tetrahedrally coordinated complexes, such as $\left[\mathrm{Li}(\text { TMEDA })_{2}\right]^{+}\left[\mathrm{Lu}\left({ }^{t} \mathrm{Bu}\right)_{4}\right]^{-}$. Figure 18.4.6(c) shows the structure of the anion $\left[\mathrm{Lu}\left({ }^{(t} \mathrm{Bu}\right)_{4}\right]^{-}$.

### 18.5 Reduction chemistry in oxidation state +2

Only the elements samarium, europium, and ytterbium have significant "normal" chemistry based on true $\mathrm{Ln}^{2+}$ ions, although $\mathrm{SmCl}_{2}$ and $\mathrm{EuCl}_{2}$ are well-characterized and have been known for over a century. The compounds of $\mathrm{Pr}, \mathrm{Nd}, \mathrm{Dy}, \mathrm{Ho}$, and Tm in oxidation state +2 are unstable in aqueous solution. Lanthanide(II) compounds are of current interest as reductants and coupling agents in organic and main-group chemistry.

### 18.5.1 Samarium(II) iodide

$\mathrm{SmI}_{2}$, which can be prepared conveniently from samarium powder and 1,2diiodoethane in THF, finds application as a versatile one-electron reducing agent in organic synthesis. Two typical synthetic procedures mediated by $\mathrm{SmI}_{2}$ are the pinacol coupling of aldehydes and the Barbier reaction, as shown in the following schemes:

Barbier reaction
$\mathrm{SmI}_{2}$ reacts with a variety of donor solvents to form crystalline solvates. $\mathrm{SmI}_{2}\left(\mathrm{Me}_{3} \mathrm{CCN}\right)_{2}$ is an iodo-bridged polymeric solid containing six-coordinate $\mathrm{Sm}^{2+}$ centers. In contrast, $\mathrm{SmI}_{2}(\mathrm{HMPA})_{4}$, where HMPA is $\left(\mathrm{Me}_{3} \mathrm{~N}\right)_{3} \mathrm{P}=\mathrm{O}$, is a discrete six-coordinate molecule with a linear I-Sm-I unit. The diglyme solvate $\mathrm{SmI}_{2}\left[\mathrm{O}\left(\mathrm{CH}_{2} \mathrm{CH}_{2} \mathrm{OMe}\right)_{2}\right]_{2}$ exhibits eight-coordination.

### 18.5.2 Decamethylsamarocene

The organosamarium(II) complex $\operatorname{Sm}\left(\eta^{5}-\mathrm{C}_{5} \mathrm{Me}_{5}\right)_{2}$ has the bent-metallocene structure, which can be attributed to polarization effects; its THF solvate $\operatorname{Sm}\left(\eta^{5}-\mathrm{C}_{5} \mathrm{Me}_{5}\right)_{2}(\mathrm{THF})_{2}$ exhibits the expected pseudo-tetrahedral coordination geometry. $\left[\mathrm{Sm}\left(\eta^{5}-\mathrm{C}_{5} \mathrm{Me}_{5}\right)_{2}\right]$ is a very powerful reductant, and its notable reactions include the reduction of aromatic hydrocarbons such as anthracene and of dinitrogen, as illustrated in the following scheme:

The $\mathrm{N}-\mathrm{N}$ distance in the dinuclear $\mathrm{N}_{2}$ complex is 129.9 pm , as compared with the bond length of 109.7 pm in dinitrogen, and is indicative of a considerable decrease in bond order. An analogous planar system comprising a side-on bonded $\mu$-(bis- $\left.\eta^{2}\right)-\mathrm{N}_{2}$ ligand between two metal centers, with a much longer $\mathrm{N}-\mathrm{N}$ bond length of 147 pm , occurs in $\left[\mathrm{Cp}_{2}^{\prime \prime} \mathrm{Zr}\right]_{2}\left(\mathrm{~N}_{2}\right)$, as described in Section 15.1.3.

## (1) Diiodides of thulium, dysprosium, and neodymium

The molecular structures of $\mathrm{LnI}_{2}(\mathrm{DME})_{3}(\mathrm{Ln}=\mathrm{Tm}, \mathrm{Dy} ; \mathrm{DME}=$ dimethoxyethane) are shown in Fig. 18.5.1(a) and (b). The larger ionic size of $\mathrm{Dy}^{2+}$ compared with $\mathrm{Tm}^{2+}$ accounts for the fact that the thulium(II) complex is seven-coordinate, whereas the dysprosium(II) complex is eight-coordinate. The complex $\mathrm{NdI}_{2}(\mathrm{THF})_{5}$ has pentagonal bipyramidal geometry with the iodo ligands occupying the axial positions.

Thulium(II) complexes are stabilized by phospholyl or arsolyl ligands that can be regarded as derived from the cyclopentadienyl group by replacing one CH group by a P or As atom. Their decreased $\pi$-donor capacity relative to the parent cyclopentadienyl system enhances the stability of the Tm(II) center, and stable complexes of the bent-sandwiched type have been isolated.

Fig. 18.5.1.
Comparison of the molecular structures of (a) hepta-coordinate $\mathrm{TmI}_{2}(\mathrm{DME})_{3}$ and (b) octa-coordinate $\mathrm{DyI}_{2}(\mathrm{DME})_{3}$.
(b)

The $\mathrm{LnI}_{2}(\mathrm{Ln}=\mathrm{Tm}, \mathrm{Dy}, \mathrm{Nd})$ species have been used in a wide range of reactions in organic and organometallic syntheses, including the reduction of aromatic hydrocarbons and the remarkable reductive coupling of MeCN to form a tripodal $\mathrm{N}_{3}$-ligand, as shown in the following schemes:

## Metal-Metal Bonds and Transition-Metal Clusters

### 19.1 Bond valence and bond number of transition-metal clusters

A dinuclear transition-metal complex contains two transition-metal atoms each surrounded by a number of ligands. A transition-metal cluster has a core of three or more metal atoms directly bonded with each other to form a discrete molecule containing metal-metal ( $\mathrm{M}-\mathrm{M}$ ) bonds. The first organometallic complex reported to possess a $\mathrm{M}-\mathrm{M}$ bond was $\mathrm{Fe}_{2}(\mathrm{CO})_{9}$. Since this $\mathrm{Fe}-\mathrm{Fe}$ bond is supported by three bridging CO ligands, as shown in Fig. 19.1.1(a), it cannot be taken as definitive proof of direct metal-metal interaction. In contrast, the complexes $\mathrm{Re}_{2}(\mathrm{CO})_{10}, \mathrm{Mn}_{2}(\mathrm{CO})_{10}$, and $\left[\mathrm{MoCp}(\mathrm{CO})_{3}\right]_{2}$, with no bridging ligands, provide unequivocal examples of unsupported $\mathrm{M}-\mathrm{M}$ bonding. In these species the metal atoms are considered to be bonded through a single bond of the $2 c$ - $2 e$ type. Figure 19.1.1(b) shows the molecular structure of $\mathrm{Mn}_{2}(\mathrm{CO})_{10}$.

Since polynuclear complexes and cluster compounds are in general rather complicated species, the application of quantitative methods for describing bonding is not only difficult but also impractical. Qualitative approaches and empirical rules often play an important role in treating such cases. We have used the octet rule and bond valence to describe the structure and bonding of boranes and their derivatives (Sections 13.3 and 13.4). Now we use the 18 -electron rule and bond valence to discuss the bonding and structure of polynuclear transition-metal complexes and clusters.

The metal atoms in most transition-metal complexes and clusters obey the 18 -electron rule. The bond valence, $b$, of the skeleton of complex $\left[\mathrm{M}_{n} \mathrm{~L}_{p}\right]^{q-}$ can be calculated from the formula

$$
b=1 / 2(18 n-g),
$$

where $g$ is the total number of valence electrons in the skeleton of the complex, which is the sum of the following three parts:
(a) $n$ times the number of valence electrons of metal atom M ;
(b) $p$ times the number of valence electrons donated to the metal atoms by ligand L; and
(c) $q$ electrons from the net charge of the complex.
(a)

(b)

Fig. 19.1.1.
Structure of dinuclear transition metal complexes: (a) $\mathrm{Fe}_{2}(\mathrm{CO})_{9}$ and (b) $\mathrm{Mn}_{2}(\mathrm{CO})_{10}$.

The bond valence $b$ of the skeleton of a complex or cluster corresponds to the sum of the bond numbers of the metal-metal bonds. For a M-M single bond, the bond number is equal to 1 ; similarly, the bond number is 2 for a $\mathrm{M}=\mathrm{M}$ double bond, 3 for a $\mathrm{M} \equiv \mathrm{M}$ triple bond, 4 for a $\mathrm{M} \equiv \mathrm{M}$ quadruple bond, and 2 for a $3 c-2 e$ MMM bond.

The majority of cluster compounds have carbonyl ligands coordinated to the metal atoms. Some clusters bear NO, CNR, $\mathrm{PR}_{3}$, and H ligands, while others contain interstitial C, N, and H atoms. The compounds can be either neutral or anionic, and the common structural metal building blocks are triangles, tetrahedra, octahedra, and condensed clusters derived from them. The carbonyl ligand has two special features. First, the carbonyl ligand functions as a two-electron donor in the terminal-, edge-, or face-bridging mode, and neither changes the valence of the metal skeleton nor requires the involvement of additional ligand electrons. In contrast, the Cl ligand may change from a one- (terminal) to a three- (edge-bridging) or five- (face-bridging) electron donor. Second, the synergic bonding effects which operate in the alternative bridging modes of the carbonyl ligand lead to comparable stabilization energies and therefore readily favor the formation of transition-metal cluster compounds.

As mentioned in Sections 13.3 and 13.4, the structures of most known boranes and carboranes are based on the regular deltahedron and divided into three types: closo, nido, and arachno. In a closo-structure the skeletal B and C atoms occupy all the vertices of the polyhedron. In the cases of nido- and arachno-structures, one and two of the vertices of the appropriate polyhedron remain unoccupied, respectively. On each skeletal B and C atom, there is always a H atom (or some other simple terminal ligand such as halide) that points away from the center of the polyhedron and is also linked to the skeleton by a radial $2 c-2 e$ single bond. In a polyhedron of $n$ vertices, there are $4 n$ atomic orbitals. Among them, $n$ orbitals are used up for $n$ terminal B-H bonds, the remaining $3 n$ atomic orbitals being available for skeletal bonding. In the skeleton of closo-borane $\mathrm{B}_{n} \mathrm{H}_{n}^{2-}$, there are $4 n+2$ valence electrons ( $n \mathrm{~B}$ atoms contribute $3 n$ electrons, $n \mathrm{H}$ atoms donate $n$ electrons, and the charge accounts for 2 electrons), and hence $2 n+2$ electrons or $n+1$ electron pairs are available for skeletal bonding. These numbers are definite. For the transition-metal cluster compounds, however, the
electron counts vary with different bonding types. For example, octahedral $\mathrm{M}_{6}$ clusters of different compounds form various structures and bond types. Some examples are discussed below and shown in Fig 19.1.2.

Figure 19.1.2(a) shows the structure of $\left[\mathrm{Mo}_{6}\left(\mu_{3}-\mathrm{Cl}_{8} \mathrm{Cl}_{6}\right]^{2-}\right.$. In this structure, eight $\mu_{3}-\mathrm{Cl}$ and six terminal Cl atoms are coordinated to the $\mathrm{Mo}_{6}$ cluster. Each $\mu_{3}-\mathrm{Cl}$ donates five electrons and each terminal Cl donates one electron. Thus the $g$ value is

$$
g=6 \times 6+(8 \times 5+6 \times 1)+2=84
$$

The bond valence of the $\mathrm{Mo}_{6}$ cluster is

$$
b=1 / 2(6 \times 18-84)=12
$$

The bond valence $b$ precisely matches $122 c-2 e$ Mo-Mo bonds, as shown in the front and back views of the $\mathrm{Mo}_{6}$ cluster on the right side of Fig. 19.1.2(a).

Figure 19.1.2(b) shows the structure of $\left[\mathrm{Nb}_{6}\left(\mu_{2}-\mathrm{Cl}_{12}{ }_{12} \mathrm{Cl}_{6}\right]^{4-}\right.$. In this structure, there are $12 \mu_{2}-\mathrm{Cl}$ atoms each donating 3 electrons, plus six terminal $\mu_{1}-\mathrm{Cl}$ atoms, each donating one electron, to the Nb cluster. The $g$ value is

$$
g=6 \times 5+(12 \times 3+6 \times 1)+4=76
$$

The bond valence of the $\mathrm{Nb}_{6}$ cluster is

$$
b=1 / 2(6 \times 18-76)=16
$$

In this $\mathrm{Nb}_{6}$ cluster, each edge is involved in bonding with a $\mu_{2}-\mathrm{Cl}$ ligand, so the edges do not correspond to $2 c-2 e \mathrm{Nb}-\mathrm{Nb}$ bonds. Each face of the $\mathrm{Nb}_{6}$ cluster forms a $3 c-2 e \mathrm{NbNbNb}$ bond, and has bond number 2 . The sum of bond number, 16 , is just equal to the bond valence of 16 , as shown in the front and back views of the Nb cluster in Fig. 19.1.2(b).

Figure 19.1.2(c) shows the structure of $\mathrm{Rh}_{6}\left(\mu_{3}-\mathrm{CO}\right)_{4}(\mathrm{CO})_{12}$. The CO group as a ligand always donates two electrons to the $\mathrm{M}_{n}$ cluster. The $g$ value and bond valence of the $\mathrm{Rh}_{6}$ cluster are

$$
b=1 / 2(6 \times 18-86)=11
$$

The $b$ value of $\mathrm{Rh}_{6}$ is 11 , which just matches the $b$ value of $\mathrm{B}_{6} \mathrm{H}_{6}^{2-}$. The $\mathrm{Rh}_{6}$ cluster is stabilized by four $3 c-2 e \mathrm{RhRhRh}$ bonds and three $2 c-2 e \mathrm{Rh}$-Rh bonds. Various bond formulas can be written for the $\mathrm{Rh}_{6}$ cluster, one of which is shown on the right side of Fig. 19.1.2(c). These formulas are equivalent by resonance and the octahedron has overall $O_{\mathrm{h}}$ symmetry.

### 19.2 Dinuclear complexes containing metal-metal bonds

Studies on dinuclear transition-metal compounds containing metal-metal bonds have deeply enriched our understanding of chemical bonding. The nature and

Fig. 19.1.2.
Structure and bonding of three octahedral clusters: (a) $\left[\mathrm{Mo}_{6}\left(\mu_{3}-\mathrm{Cl}_{8} \mathrm{Cl}_{6}\right]^{2-}\right.$; (b) $\left[\mathrm{Nb}_{6}\left(\mu_{2}-\mathrm{Cl}_{12}\right)_{12} \mathrm{Cl}_{6}\right]^{4-}$; and (c) $\mathrm{Rh}_{6}\left(\mu_{3}-\mathrm{CO}\right)_{4}(\mathrm{CO})_{12}$.
implication of $\mathrm{M}-\mathrm{M}$ bonds are richer and more varied than the covalent bonds of the second-period representative elements. The following points may be noted.
(a) The d atomic orbitals of transition metals are available for bonding, in addition to the s and p atomic orbitals.
(b) The number of valence orbitals increases from 4 for the second-period elements to 9 for the transition-metal atoms. Thus the octet rule suits the former and eighteen-electron rule applies to the latter.
(c) The use of d-orbitals for bonding leads to the possible formation of a quadruple bond (and even a quintuple bond) between two metal atoms, in addition to the familiar single, double, and triple bonds.
(d) The transition-metal atoms interact with a large number of ligands in coordination compounds. The various geometries and electronic factors have significant effects on the properties of metal-metal bonds. The 18 -electron rule is not strictly valid, thus leading to varied $\mathrm{M}-\mathrm{M}$ bond types.

### 19.2.1 Dinuclear transition-metal complexes conforming to the 18 -electron rule

When the structure of a dinuclear complex has been determined, the structural data may be used to enumerate the number of valence electrons available in the complex, to determine its bond valence, and to understand the properties of the metal-metal bond. For a dinuclear complex, the bond valence $b=1 / 2(18 \times 2-$ $g$ ). Table 19.2.1 lists the data for some dinuclear complexes.

In the complex $\mathrm{Ni}_{2}(\mathrm{Cp})_{2}\left(\mu_{2}-\mathrm{PPh}_{2}\right)_{2}$, with two bridging ligands $\left(\mu_{2}-\mathrm{PPh}_{2}\right)$ linking the Ni atoms, the bond valence equals zero, indicating that there is no bonding interaction between them.
$\mathrm{Mn}_{2}(\mathrm{CO})_{10}$ is one of the simplest dimeric compounds containing a metalmetal single bond unsupported by bridging ligands, and its diamagnetic behavior is accounted for in compliance with the 18 -electron rule. The structures of $\mathrm{Tc}_{2}(\mathrm{CO})_{10}, \mathrm{Re}_{2}(\mathrm{CO})_{10}$, and $\mathrm{MnRe}(\mathrm{CO})_{10}$, which are isomorphous with $\mathrm{Mn}_{2}(\mathrm{CO})_{10}$, have also been determined. The measured $\mathrm{M}-\mathrm{M}$ bond lengths ( pm ) are $\mathrm{Tc}-\mathrm{Tc} 303.6$, $\mathrm{Re}-\mathrm{Re} 304.1$, and $\mathrm{Mn}-\mathrm{Re}$ 290.9. The structure of $\mathrm{Fe}_{2}(\mathrm{CO})_{9}$, shown in Fig. 19.1.1(a), has an $\mathrm{Fe}-\mathrm{Fe}$ single bond of 252.3 pm , which is further stabilized by the bridging carbonyl ligands.

Many dinuclear complexes have a $M=M$ double bond. Some examples are

$$
\begin{aligned}
& \mathrm{Co}_{2}(\mathrm{CO})_{2} \mathrm{Cp}_{2}^{*}, \mathrm{Co}=\mathrm{Co} 233.8 \mathrm{pm} ; \\
& \mathrm{Fe}_{2}(\mathrm{NO})_{2} \mathrm{Cp}_{2}, \mathrm{Fe}=\mathrm{Fe} 232.6 \mathrm{pm} ; \\
& \mathrm{Re}_{2}(\mu-\mathrm{Cl})_{2} \mathrm{Cl}_{4}(\mathrm{dppm})_{2}, \mathrm{Re}=\mathrm{Re} 261.6 \mathrm{pm} ; \\
& \mathrm{Mo}_{2}(\mathrm{OR})_{8}\left(\mathrm{R}={ }^{i} \mathrm{Pr},{ }^{t} \mathrm{Bu}\right), \mathrm{Mo}=\mathrm{Mo} 252.3 \mathrm{pm} .
\end{aligned}
$$

Most compounds with triple and quadruple bonds are formed by $\mathrm{Re}, \mathrm{Cr}, \mathrm{Mo}$, and W. The ligands in such compounds are in general relatively hard Lewis bases such as halides, carboxylic acids, and amines. Nevertheless, in some cases $\pi$-acceptor ligands such as carbonyl, phosphines and nitrile are also present.

Table 19.2.1. Dinuclear complexes

| Complex | $g$ | $b$ | M-M(pm) | Bond properties |
| :--- | :--- | :--- | :--- | :--- |
| $\mathrm{Ni}_{2}(\mathrm{Cp})_{2}\left(\mu_{2}-\mathrm{PPh}_{2}\right)_{2}$ | 36 | 0 | 336 | $\mathrm{Ni} \cdots \mathrm{Ni}$, no bonding |
| $\left.(\mathrm{CO})_{5} \mathrm{Mn}_{2} \mathrm{CO}\right)_{5}$ | 34 | 1 | 289.5 | $\mathrm{Mn}-\mathrm{Mn}$, single bond |
| $\mathrm{Co}_{2}\left(\mu_{2}-\mathrm{CH}_{2}\right)\left(\mu_{2}-\mathrm{CO}\right)\left(\mathrm{Cp}^{*}\right)_{2}$ | 32 | 2 | 232.0 | $\mathrm{Co}=\mathrm{Co}$, double bond |
| $\mathrm{Cr}_{2}(\mathrm{CO})_{4}(\mathrm{Cp})_{2}$ | 30 | 3 | 222 | $\mathrm{Cr} \equiv \mathrm{Cr}$, triple bond |
| $\left[\mathrm{Mo}_{2}\left(\mu_{2}-\mathrm{O}_{2} \mathrm{CMe}\right)_{2}(\mathrm{MeCN})_{6}\right]^{2+}$ | 28 | 4 | 213.6 | $\mathrm{Mo} \equiv \mathrm{Mo}$, quadruple bond |

## Structural Chemistry of Selected Elements

### 19.2.2 Quadruple bonds

The recognition and understanding of the quadruple bond is one of the most important highlights in modern inorganic chemistry. The overlap of d atomic orbitals can generate three types of molecular orbitals: $\sigma, \pi$, and $\delta$. These molecular orbitals can be used to form a quadruple bond between two transition-metal atoms under appropriate conditions. In a given compound, however, not all of these orbitals are always available for multiple metal-metal bonding. Thus the 18 -electron rule does not always hold for the dinuclear complexes and needs to be modified according to their structures.
The most interesting aspect of the crystal structure of $\mathrm{K}_{2}\left[\mathrm{Re}_{2} \mathrm{Cl}_{8}\right] \cdot 2 \mathrm{H}_{2} \mathrm{O}$ is the presence of the dianion $\mathrm{Re}_{2} \mathrm{Cl}_{8}^{2-}$ (Fig. 19.2.1), which possesses an extremely short Re-Re bond distance of 224.1 pm , as compared with an average $\mathrm{Re}-\mathrm{Re}$ distance of 275 pm in rhenium metal. Another unusual feature is the eclipsed configuration of the Cl atoms with a $\mathrm{Cl} \cdots \mathrm{Cl}$ separation of 332 pm . As the sum of van der Waals radii of two Cl atoms is 360 pm , the staggered configuration would normally be expected for $\mathrm{Re}_{2} \mathrm{Cl}_{8}^{2-}$. These two features are both attributable to the formation of a $\mathrm{Re} \equiv \operatorname{Re}$ quadruple bond.

The bonding in the skeleton of the $\left[\mathrm{Re}_{2} \mathrm{Cl}_{8}\right]^{2-}$ ion can be formulated as follows: each Re atom uses its square-planar set of $\operatorname{dsp}^{2}\left(\mathrm{~d}_{x^{2}-y^{2}}, \mathrm{~s}, \mathrm{p}_{x}, \mathrm{p}_{y}\right)$ hybrid orbitals to overlap with ligand Cl p orbitals to form $\mathrm{Re}-\mathrm{Cl}$ bonds. The $\mathrm{p}_{z}$ atomic orbital of Re is not available for bonding. The remaining $\mathrm{d}_{z^{2}}, \mathrm{~d}_{x z}$, $\mathrm{d}_{y z}$, and $\mathrm{d}_{x y}$ atomic orbitals on each Re atom overlap with the corresponding orbitals on the other Re atom to generate the following MOs:

$$
\begin{aligned}
\mathrm{d}_{z^{2}} \pm \mathrm{d}_{z^{2}} & \rightarrow \sigma \text { and } \sigma^{*} \mathrm{MO} \\
\mathrm{~d}_{x z} \pm \mathrm{d}_{x z} & \rightarrow \pi \text { and } \pi^{*} \mathrm{MO} \\
\mathrm{~d}_{y z} \pm \mathrm{d}_{y z} & \rightarrow \pi \text { and } \pi^{*} \mathrm{MO} \\
\mathrm{~d}_{x y} \pm \mathrm{d}_{x y} & \rightarrow \delta \text { and } \delta^{*} \mathrm{MO}
\end{aligned}
$$

Figure 19.2.2 shows the pairing up of d AO's of two Re atoms to form MO's and the ordering of the energy levels. In the $\left[\mathrm{Re}_{2} \mathrm{Cl}_{8}\right]^{2-}$ ion, the two Re atoms have 16 valence electrons including two from the negative charge. Eight valence electrons are utilized to form eight $\mathrm{Re}-\mathrm{Cl}$ bonds, and the remaining eight occupy four metal-metal bonding orbitals to form a quadruple bond: one $\sigma$ bond, two $\pi$ bonds, and one $\delta$ bond, leading to the $\sigma^{2} \pi^{4} \delta^{2}$ configuration.

Fig. 19.2.1.

The structures of two transition-metal complexes that contain a $\mathrm{Mo} \equiv \mathrm{Mo}$ quadruple bond are shown in Fig. 19.2.3. In the compound $\left[\mathrm{Mo}_{2}\left(\mathrm{O}_{2} \mathrm{CMe}\right)_{2}(\mathrm{NCMe})_{6}\right]\left(\mathrm{BF}_{4}\right)_{2}$, each Mo atom is six-coordinate, and all nine valence AO's are used for bonding according to the 18 -electron rule. In the cation $\left[\mathrm{Mo}_{2}\left(\mathrm{O}_{2} \mathrm{CMe}\right)_{2}(\mathrm{NCMe})_{6}\right]^{2+}$,

$$
g=2 \times 6+2 \times 3+6 \times 2-2=28,
$$

and

$$
b=1 / 2(2 \times 18-28)=4 .
$$

The Mo-Mo bond distance of 213.6 pm is in accord with the quadruple $\mathrm{Mo} \equiv \mathrm{Mo}$ bond. In the molecule $\mathrm{Mo}_{2}\left(\mathrm{O}_{2} \mathrm{CMe}\right)_{4}$, each Mo atom is five-coordinate and has one empty $\mathrm{AO}\left(\mathrm{p}_{z}\right)$ which is not used for bonding. It obeys the 16 -electron rule with $g=2 \times 6+4 \times 3=24$ and $b=1 / 2(2 \times 16-24)=4$. The observed Mo-Mo distance of 209.3 pm is consistent with that expected of a quadruple bond.

A large number of dinuclear complexes containing a $\mathrm{M} \equiv \mathrm{M}$ quadruple bond formed by the Group 16 and 17 metals $\mathrm{Cr}, \mathrm{Mo}, \mathrm{W}, \mathrm{Re}$, and Tc have been reported in the literature. Selected examples are listed in Table 19.2.2.

Fig. 19.2.2.
Overlap of d orbitals leading to the formation of a quadruple bond between two metal atoms. Note that the $z$ axis of each metal atom is taken to point toward the other, such that if a right-handed coordinate system is used for the atom on the left, a left-handed coordinate system must be used for the atom on the right.

Table 19.2.2. Compounds containing a $\mathrm{M} \equiv \mathrm{M}$ quadruple bond

| Compound | $\mathrm{M} \equiv \mathrm{M}$ | Distance $(\mathrm{pm})$ | Rule | $g$ |
| :--- | :--- | :--- | :--- | :--- |

* hpp is the anion of 1,3,4,6,7,8-hexahydro- $2 H$-pyrimido-[1,2-a]-pyrimidine (Hhpp); pyz is pyrazine.

The quadruple bond can undergo a variety of interesting reactions, as outlined in Fig. 19.2.4.
(1) There is a rich chemistry in which ligands are exchangable, and virtually every type of ligand can be used except the strong $\pi$ acceptors.
(2) Addition of a mononuclear species to an $\mathrm{M} \equiv \mathrm{M}$ bond can yield a trinuclear cluster.
(3) Two quadruple bonds can combine to form a metallacyclobutadiyne ring.
(4) Oxidative addition of acids to generate a $\mathrm{M} \equiv \mathrm{M}$ bond (particularly $\mathrm{W} \equiv \mathrm{W}$ ) is a key part of molybdenum and tungsten chemistry.
(5) Phosphines can act as reducing agents as well as ligands to give products with triple bonds of the $\sigma^{2} \pi^{4} \delta^{2} \delta^{* 2}$ type, as in $\mathrm{Re}_{2} \mathrm{Cl}_{4}\left(\mathrm{PEt}_{3}\right)_{4}$.
(6) Photo excitation by the $\delta \rightarrow \delta^{*}$ transition can lead to reactive species which are potentially useful in photosensitizing various reactions, including the splitting of water.

(b)

Fig. 19.2.3.
Structure of (a) $\left[\mathrm{Mo}_{2}\left(\mathrm{O}_{2} \mathrm{CMe}\right)_{2}(\mathrm{NCMe})_{6}\right]^{2+}$ and (b) $\mathrm{Mo}_{2}\left(\mathrm{O}_{2} \mathrm{CMe}\right)_{4}$.

(7) Electrochemical oxidation or reduction reduces the bond order and generates reactive intermediates.
(8) With $\pi$-acceptor ligands, the $\mathrm{M} \equiv \mathrm{M}$ bonds are usually cleaved to give mononuclear products, which are sometimes inaccessible by any other synthetic route.

### 19.2.3 Bond valence of metal-metal bond

In dinuclear complexes, the bond valence of the metal-metal (M-M) bond can be calculated from its number of bonding electrons, $g_{\mathrm{M}}$. A simple procedure for counting the metal-metal bond valence is as follows:
(a) Calculate the $g$ value in the usual manner.
(b) Calculate the number of valence electron used for M-L bonds, $g_{\mathrm{L}}$.
(c) Calculate the number of valence electron used for M-M bonds, $g_{\mathrm{M}}=$ $g-g_{\mathrm{L}}$.
(d) Assign the $g_{\mathrm{M}}$ electrons to the following orbitals according to the energy sequence: $\sigma,\left(\pi_{x}, \pi_{y}\right), \delta, \delta^{*},\left(\pi_{x}^{*}, \pi_{y}^{*}\right)$, and $\sigma^{*}$, as shown in Fig. 19.2.2.
Some examples are presented below:
(1) $\mathrm{Mo}_{2}\left(\mathrm{O}_{2} \mathrm{CMe}\right)_{4}$

$$
g=2 \times 6+4 \times 3=24, \quad g_{\mathrm{L}}=8 \times 2=16, \quad g_{\mathrm{M}}=g-g_{\mathrm{L}}=24-16=8 .
$$

The electronic configuration is $\sigma^{2} \pi^{4} \delta^{2}$, and the bond order is 4 ; i.e., the bond valence is 4 . For this $\mathrm{Mo} \equiv$ Mo bond, the bond length is 209.3 pm .
(2) $\left.\mathrm{Mo}_{2}\left(\mathrm{O}_{2} \mathrm{CMe}\right)_{2}(\mathrm{MeCN})_{6}\right]^{2+}$

$$
\begin{aligned}
& g=2 \times 6+2 \times 3+6 \times 2-2=28, \quad g_{\mathrm{L}}=2 \times 5 \times 2=20, \\
& g_{\mathrm{M}}=28-20=8
\end{aligned}
$$

The electronic configuration is $\sigma^{2} \pi^{4} \delta^{2}$, and the bond valence is 4 . So again this is a $\mathrm{Mo} \equiv \mathrm{Mo}$ bond, and the bond length is 213.6 pm .

Some reaction types of dimetal compounds containing a $\mathrm{M} \equiv \mathrm{M}$ quadruple bond.

Fig. 19.2.5.
Structure of (a) $\mathrm{Re}_{2} \mathrm{Cl}_{4}\left(\mathrm{PEt}_{3}\right)_{4}$ and (b)
$\mathrm{Mo}_{2}\left(\mathrm{CH}_{2} \mathrm{SiMe}_{3}\right)_{6}$

(b)

(3) $\mathrm{Re}_{2} \mathrm{Cl}_{4}\left(\mathrm{PEt}_{3}\right)_{4}$

$$
g=2 \times 7+4 \times 1+4 \times 2=26, \quad g_{\mathrm{L}}=8 \times 2=16, \quad g_{\mathrm{M}}=26-16=10 .
$$

The structure of the molecule is shown in Fig. 19.2.5(a). The electronic configuration is $\sigma^{2} \pi^{4} \delta^{2} \delta^{* 2}$. The bond valence is 3 , indicating a $\operatorname{Re} \equiv \operatorname{Re}$ triple bond, and the bond length is 223.2 pm .
(4) $\mathrm{Mo}_{2}\left(\mathrm{CH}_{2} \mathrm{SiMe}_{3}\right)_{6}$

The molecule has $D_{3 \mathrm{~d}}$ symmetry, as shown in Fig. 19.2.5(b).

$$
g=2 \times 6+6 \times 1=18, \quad g_{\mathrm{L}}=6 \times 2=12, \quad g_{\mathrm{M}}=18-12=6
$$

The electronic configuration is $\sigma^{2} \pi^{4}$. The length of the $\mathrm{Mo} \equiv$ Mo triple bond is 216.7 pm .
(5) $\mathrm{Mo}_{2}(\mathrm{OR})_{8},\left(\mathrm{R}={ }^{i} \mathrm{Pr},{ }^{t} \mathrm{Bu}\right)$

$$
g=2 \times 6+8 \times 1=20, \quad g_{\mathrm{L}}=8 \times 2=16, \quad g_{\mathrm{M}}=20-16=4 .
$$

The electronic configuration is $\sigma^{2} \pi_{x}^{1} \pi_{y}^{1}$, indicating a $\mathrm{Mo}=\mathrm{Mo}$ double bond. The experimental bond distance is 252.3 pm , and the molecule is a paramagnetic species.

### 19.2.4 Quintuple bonding in a dimetal complex

Recently, structural evidence for the first quintuple bond between two metal atoms was found in the dichromium(I) complex $\mathrm{Ar}^{\prime} \mathrm{CrCrAr}^{\prime}$ (where $\mathrm{Ar}^{\prime}$ is the sterically encumbering monovalent 2,6-bis[(2,6-diisopropyl)phenyl]phenyl ligand). This complex exists as air- and moisture-sensitive dark-red crystals that remain stable up to $200^{\circ} \mathrm{C}$. X-ray diffraction revealed a centrosymmetric molecule with a planar trans-bent $\mathrm{C}-\mathrm{Cr}-\mathrm{Cr}-\mathrm{C}$ backbone with measured structural parameters $\mathrm{Cr}-\mathrm{Cr} 183.51(4) \mathrm{pm}, \mathrm{Cr}-\mathrm{C} 213.1(1) \mathrm{pm}$, and $\mathrm{C}-\mathrm{Cr}-\mathrm{Cr}$ $102.78(3)^{\circ}$. Characterization of the compound is further substantiated by magnetic and spectroscopic data, as well as theoretical computations. Figure 19.2.6 shows the molecular geometry and structural formula of $\mathrm{Ar}^{\prime} \mathrm{CrCrAr}^{\prime}$.

In principle, a homodinuclear transition-metal species can form up to six bonds using the $n$ s and five ( $n-1$ )d valence orbitals. In a simplified bonding description of $\mathrm{Ar}^{\prime} \mathrm{CrCrAr}^{\prime}$, the planar $\mathrm{C}-\mathrm{Cr}-\mathrm{Cr}-\mathrm{C}$ skeleton has idealized molecular symmetry $C_{2 \mathrm{~h}}$ with reference to a conventional $z$ axis lying perpendicular to it. For each chromium atom, a local $z$ axis is chosen to be directed toward

the other chromium atom, and the local $x$ axis to lie in the skeletal plane. Each chromium atom (electronic configuration $3 \mathrm{~d}^{5} 4 \mathrm{~s}^{1}$ ) uses it 4 s orbital to overlap with a $\mathrm{sp}^{2}$ hybrid orbital on the ipso carbon atom of the terphenyl ligand to form a $\mathrm{Cr}-\mathrm{C} \sigma$ bond. That leaves five d orbitals at each $\mathrm{Cr}(\mathrm{I})$ center for the formation of a fivefold (i.e., quintuple) metal-metal bond, which has one $\sigma$ $\left(\mathrm{d}_{z^{2}}+\mathrm{d}_{z^{2}}\right.$; symmetry species $\left.A_{\mathrm{g}}\right)$, two $\pi\left(\mathrm{d}_{y z}+\mathrm{d}_{y z}, \mathrm{~d}_{x z}+\mathrm{d}_{x z} ; A_{\mathrm{u}}, B_{\mathrm{u}}\right)$ and two $\delta$ $\left(\mathrm{d}_{x^{2}-y^{2}}+\mathrm{d}_{x^{2}-y^{2}}, \mathrm{~d}_{x y}+\mathrm{d}_{x y} ; A_{\mathrm{g}}, B_{\mathrm{g}}\right)$ components. The situation is actually more complex as mixing of the chromium $4 \mathrm{~s}, 3 \mathrm{~d}_{z^{2}}$ and $3 \mathrm{~d}_{x^{2}-y^{2}}$ orbitals (all belonging to $A_{\mathrm{g}}$ ) can occur. In an alternative bonding scheme, each chromium atom may be considered to be $\mathrm{d}_{z^{2}} \mathrm{~s}$ hybridized. The outward-extended $\left(\mathrm{s}-\mathrm{d}_{z^{2}}\right)$ hybrid orbital is used to form a $\mathrm{Cr}-\mathrm{C} \sigma$ bond. Note that this type of overlap results in a $\mathrm{C}-\mathrm{Cr}-\mathrm{Cr}$ angle of $90^{\circ}$ and allows free rotation of the $\mathrm{C}-\mathrm{Cr}$ bond about the $\mathrm{Cr}-\mathrm{Cr}$ axis, and it is the steric repulsion between the pair of bulky $\mathrm{Ar}^{\prime}$ ligands that accounts for the obtuse $\mathrm{C}-\mathrm{Cr}-\mathrm{Cr}$ bond angle and the trans-bent geometry of the central $\mathrm{C}-\mathrm{Cr}-\mathrm{Cr}-\mathrm{C}$ core. The pair of chromium $\left(\mathrm{s}+\mathrm{d}_{z^{2}}\right)$ hybrid orbitals aligned along the common local $z$ axis overlap to form the metal-metal $\sigma$ bond, while the $\pi$ and $\delta$ bonds are formed in the manner described above. In either bonding description, there is a formal bond order of 5 between the chromium(I) centers.

### 19.3 Clusters with three or four transition-metal atoms

### 19.3.1 Trinuclear clusters

Table 19.3.1 lists the structural data and bond valences of some trinuclear clusters. In $\mathrm{Os}_{3}(\mathrm{CO})_{9}\left(\mu_{3}-\mathrm{S}\right)_{2}$, the $\mathrm{Os}_{3}$ unit is in a bent configuration with two $\mathrm{Os}-\mathrm{Os}$ bonds of average length 281.3 pm , and the other Os. . Os distance ( 366.2 pm ) is significantly longer. The cluster $(\mathrm{CO})_{5} \mathrm{Mn}-\mathrm{Fe}(\mathrm{CO})_{4}-\mathrm{Mn}(\mathrm{CO})_{5}$ adopts a linear configuration. The other clusters are all triangular. The $\mathrm{Fe}_{3}$ skeleton of $\mathrm{Fe}_{3}(\mathrm{CO})_{12}$ has 48 valence electrons, and the $\mathrm{Fe}_{3}$ unit contains three $\mathrm{Fe}-\mathrm{Fe}$ single bonds. The $\mathrm{Os}_{3}$ skeleton of $\mathrm{Os}_{3} \mathrm{H}_{2}(\mathrm{CO})_{10}$, a 46-electron triangular cluster, has one $\mathrm{Os}=\mathrm{Os}$ double bond and two Os-Os single bonds. The length of the Os=Os double bond is 268.0 pm , and the Os-Os single bonds are 281.8 and 281.2 pm .

The remaining three clusters $\left[\mathrm{Mo}_{3}\left(\mu_{3}-\mathrm{S}\right)_{2}\left(\mu_{2}-\mathrm{Cl}_{3}\right)_{3} \mathrm{Cl}_{6}\right]^{3-},\left[\mathrm{Mo}_{3}\left(\mu_{3}-\mathrm{O}\right)\right.$ $\left.\left(\mu_{2}-\mathrm{O}\right)_{3} \mathrm{~F}_{9}\right]^{5-}$, and $\mathrm{Re}_{3}\left(\mu_{2}-\mathrm{Cl}_{3}\left(\mathrm{CH}_{2} \mathrm{SiMe}_{3}\right)_{6}\right.$ all have nearly equilateral $\mathrm{M}_{3}$ skeletons. According to the calculated bond valences of 5, 6, and 9 for the

Fig. 19.2.6.

$\mathrm{Ar}^{\prime} \mathrm{CrCrAr}^{\prime}\left(\mathrm{Ar}^{\prime}=\right.$
$\mathrm{C}_{6} \mathrm{H}_{3}-2,6\left(\mathrm{C}_{6} \mathrm{H}_{3}-2,6-{ }^{\mathrm{i}} \mathrm{Pr}_{2}\right)_{2}$.

Table 19.3.1. Some trinuclear clusters

* Bond order of $1 \frac{2}{3}$.

Table 19.3.2. Some tetranuclear clusters

* Bond order of $1 \frac{1}{3}$.
metal-metal bonds in these compounds, the bond types are Mo---Mo (bond order $1 \frac{2}{3}$ ), $\mathrm{Mo}=\mathrm{Mo}$, and $\mathrm{Re} \equiv \operatorname{Re}$, respectively.

### 19.3.2 Tetranuclear clusters

Table 19.3.2 lists the bond valence and structural data of some tetranuclear clusters.

The bond valence of $\mathrm{Re}_{4}\left(\mu_{3}-\mathrm{H}\right)_{4}(\mathrm{CO})_{12}$ is 8 , and the tetrahedral $\mathrm{Re}_{4}$ skeleton can be described in two ways: (I) resonance between valence-bond structures, leading to a formal bond order of $1 \frac{1}{3}$, and (II) four $3 c-2 e$ ReReRe bonds. Since there are already four $\mu_{3}-\mathrm{H}$ capping the faces, description (II) is not as good as (I).
(I)

(II)

In other examples listed in Table 19.3.2, the calculated bond valence $b$ is just equal to the number of edges of the corresponding metal skeleton, signifying $2 c-2 e \mathrm{M}-\mathrm{M}$ single bonds.

### 19.4 Clusters with more than four transition-metal atoms

### 19.4.1 Pentanuclear clusters

Selected examples of pentanuclear metal clusters are listed in Table 19.4.1. In these examples, the calculated bond valence $b$ is exactly the same as the number of edges of the metal skeleton, indicating $2 c-2 e \mathrm{M}-\mathrm{M}$ bonds. In general, electron-rich species have lower bond valence and more open structures than the electron-deficient ones.

The structures and skeletal bond valences of $\mathrm{Os}_{5}(\mathrm{CO})_{16}$ and $\mathrm{B}_{5} \mathrm{H}_{5}{ }^{2-}$ are similar as a pair, as are also $\mathrm{Fe}_{5} \mathrm{C}(\mathrm{CO})_{15}$ and $\mathrm{B}_{5} \mathrm{H}_{9}$. But the bonding types in the boranes and the metal clusters are not the same. Since every B atom in a polyhedral borane has three AO's for bonding of the $\mathrm{B}_{n}$ skeleton, any vertex more than three-connected must involve multicenter bonds. In the transition-metal skeleton, the $\mathrm{M}_{n}$ atoms form either $2 c-2 e$ single bonds or $3 c-2 e$ multicenter bonds.

Some clusters have 76 valence electrons based on a trigonal bipyramidal skeleton, such as $\left[\mathrm{Ni}_{5}(\mathrm{CO})_{12}\right]^{2-},\left[\mathrm{Ni}_{3} \mathrm{Mo}_{2}(\mathrm{CO})_{16}\right]^{2-}, \mathrm{Co}_{5}(\mathrm{CO})_{11}\left(\mathrm{PMe}_{2}\right)_{3}$, and $\left[\mathrm{FeRh}_{4}(\mathrm{CO})_{15}\right]^{2-}$, which are not shown in Table 19.4.1. The additional four valence electrons compared to $\mathrm{Os}_{5}(\mathrm{CO})_{16}$ have a significant effect on its geometry, and the bond lengths to the apical metal atoms are increased, and the bond valence $b$ is decreased.

The cluster $\left[\mathrm{Os} 5 \mathrm{C}(\mathrm{CO})_{14}\left(\mathrm{O}_{2} \mathrm{CMe}\right) \mathrm{I}\right]$ has 78 valence electrons, which is not shown in Table 19.4.1, and its bond valence is equal to $6:\left[b=\frac{1}{2}(5 \times 18-78)=\right.$ 6 ]. This cluster has a deformed trigonal bipyramidal geometry with no bonding in the equatorial plane of the bipyramid.

### 19.4.2 Hexanuclear clusters

Table 19.4.2 lists the bond valence and structural data of some selected examples of hexanuclear clusters. The first three clusters have different $b$ values, yet they

## Structural Chemistry of Selected Elements

Table 19.4.1. Some pentanuclear clusters

| Cluster | $g$ | $b$ | No. of edges | Figure |
| :--- | :---: | :---: | :---: | :---: |
| $\mathrm{Os}_{5}(\mathrm{CO})_{16}$ | 72 | 9 | 9 | (a) |
| $\mathrm{Fe}_{5} \mathrm{C}(\mathrm{CO})_{15}$ | 74 | 8 | 8 | (b) |
| $\mathrm{Os}_{5} \mathrm{H}_{2}(\mathrm{CO})_{16}$ | 74 | 8 | 8 | (c) |
| $\mathrm{Ru}_{5} \mathrm{C}(\mathrm{CO})_{15} \mathrm{H}_{2}$ | 76 | 7 | 7 | (d) |
| $\mathrm{Os}_{5}(\mathrm{CO})_{18}$ | 76 | 7 | 7 | (e) |
| $\mathrm{Os}_{5}(\mathrm{CO})_{19}$ | 78 | 6 | 6 | (f) |
| $\mathrm{Re}_{2} \mathrm{Os}_{3} \mathrm{H}_{2}(\mathrm{CO})_{20}$ | 80 | 5 | 5 | (g) |

are all octahedral with 12 edges. There are three stable types of bonding schemes for an octahedron, as shown in Fig. 19.1.2:
(a) $\mathrm{Mo}_{6} \mathrm{Cl}_{14}{ }^{2-}, g=84, b=12$; in this cluster there are $122 c-2 e$ bonds at the 12 edges.
(b) $\mathrm{Nb}_{6} \mathrm{Cl}_{18}{ }^{4-}, g=76, b=16$; in this cluster there are eight $3 c-2 e$ bonds on the eight faces of an octahedron.
(c) $\mathrm{Rh}_{6}(\mathrm{CO})_{16}, g=86, b=11$; in this cluster there are four $3 c-2 e$ bonds on four faces and three $2 c-2 e$ bonds at three edges, as in the case of $\mathrm{B}_{6} \mathrm{H}_{6}^{2-}$.

Table 19.4.2. Some hexanuclear clusters

Other clusters listed in Table 19.4.2 have the property that their $b$ value equals the number of edges of their $\mathrm{M}_{n}$ skeletons.

### 19.4.3 Clusters with seven or more transition-metal atoms

Table 19.4.3 listed the bond valence and structural data of some selected examples of high-nuclearity clusters, each consisting of seven or more transition-metal atoms. The skeletal structures of these clusters are shown in Fig. 19.4.1.

Table 19.4.3. Clusters with more than six transition metal atoms

| Cluster | $g$ | $b$ | Structure <br> (Fig. 19.4.1) | Remark |
| :--- | ---: | ---: | :---: | :--- |

When the number of metal atoms in a cluster increases, the geometries of the clusters become more complex, and some are often structurally better described in terms of capped or decapped polyhedra and condensed polyhedra. For example, the first and second clusters listed in Table 19.4.3 are a capped octahedron and a bicapped octahedron, respectively. Consequently, capping or decapping with a transition-metal fragment to a deltapolyhedral cluster leads to an increase or decrease in the cluster valence electron count of 12 . When a transition-metal atom caps a triangular face of the cluster, it forms three $\mathrm{M}-\mathrm{M}$ bonds with the vertex atoms, so according to the 18 -electron rule, the cluster needs an additional $18-6=12$ electrons. The parent octahedron of $\left[\mathrm{Os}_{6}(\mathrm{CO})_{18}\right]^{2-}$ has $g=86$, the monocapped octahedron $\mathrm{Os}_{7}(\mathrm{CO})_{21}$ has $g=98$, and the bicapped octahedron $\left[\mathrm{Os}_{8}(\mathrm{CO})_{22}\right]^{2-}$ has $g=110$.

(b)

(e)

(c)

(f)

Fig. 19.4.1.
Structures of some transition-metal clusters: (a) $\mathrm{Os}_{7}(\mathrm{CO})_{21}$,
(b) $\left[\mathrm{Os}_{8}(\mathrm{CO})_{22}\right]^{2-}$, (c)
$\left[\mathrm{Rh}_{9} \mathrm{P}(\mathrm{CO})_{21}\right]^{2-}$, (d) $\left[\mathrm{Rh}_{10} \mathrm{P}(\mathrm{CO})_{22}\right]^{-}$,
(e) $\left[\mathrm{Rh}_{11}(\mathrm{CO})_{23}\right]^{3-}$, and
(f) $\left[\mathrm{Rh}_{12} \mathrm{Sb}(\mathrm{CO})_{27}\right]^{3-}$.

The metal cluster of $\left[\mathrm{Rh}_{10} \mathrm{P}(\mathrm{CO})_{22}\right]^{-}$forms a deltapolyhedron, which has $g=142$, as shown in Fig. 19.4.1(d). The skeleton of $\left[\mathrm{Rh}_{9} \mathrm{P}(\mathrm{CO})_{21}\right]^{2-}$ is obtained by removal of a vertex transition-metal fragment. The skeletal valence electron count of $\left[\mathrm{Rh}_{9} \mathrm{P}(\mathrm{CO})_{21}\right]^{2-}$ gives $g=142-12=130$.

The metal cluster of $\left[\mathrm{Rh}_{11}(\mathrm{CO})_{23}\right]^{3-}$ is composed of three face-sharing octahedra, as shown in Fig. 19.4.1(e). The metal cluster of $\left[\mathrm{Rh}_{12} \mathrm{Sb}(\mathrm{CO})_{27}\right]^{3-}$ consists of an icosahedron with an encapsulated Sb atom at its center.

Generally, capped or decapped deltapolyhedral clusters are characterized by the number of skeletal valence electrons $g$

$$
g=(14 n+2) \pm 12 m
$$

where $n$ is the number of M atoms in the parent deltapolyhedron and $m$ is the number of capped $(+)$ or decapped $(-)$ metal fragments.
A classical example of correlation of structure with valence electron count of transition-metal clusters is shown in Fig. 19.4.2. There the structures of a series of osmium clusters are systematized by applying the capping and decapping procedures.

### 19.4.4 Anionic carbonyl clusters with interstitial main-group atoms

There is much interest in transition-metal carbonyl clusters containing interstitial (or semi-interstitial) atoms in view of the fact that insertion of the encapsulated atom inside the metallic cage increases the number of valence electrons but leaves the molecular geometry essentially unperturbed. The clusters are generally anionic, and the most common interstitial heteroatoms are carbon, nitrogen, and phosphorus. Some representative examples are displayed in Fig. 19.4.3.

The core of the anionic carbonyl cluster $\left[\mathrm{Co}_{6} \mathrm{Ni}_{2}(\mathrm{C})_{2}(\mathrm{CO})_{16}\right]^{2-}$ consists of two trigonal prisms sharing a rectangular face [Fig. 19.4.3(a)]. All four vertical edges and two horizontal edges, one on the top face and the other on the bottom face, are each bridged by a carbonyl group. Each of the two $\mathrm{Co}^{*}$ atoms has two terminal carbonyl groups, and each of the Ni and Co atoms has one.

The $\left[\mathrm{Os}_{18} \mathrm{Hg}_{3}(\mathrm{C})_{2}(\mathrm{CO})_{42}\right]^{2-}$ cluster is composed of two tricapped octahedral $\mathrm{Os}_{9}(\mathrm{C})(\mathrm{CO})_{21}$ units sandwiching a $\mathrm{Hg}_{3}$ triangle (Fig. 19.4.3(b)). Each corner Os atom in the top and bottom faces has three terminal carbonyl groups, and the remaining Os atoms each have two.

The core of the $\left[\mathrm{Fe}_{6} \mathrm{Ni}_{6}(\mathrm{~N})_{2}(\mathrm{CO})_{24}\right]^{2-}$ cluster comprises a central $\mathrm{Ni}_{6}$ octahedron that shares a pair of opposite faces with two $\mathrm{Ni}_{3} \mathrm{Fe}_{3}$ octahedra, as shown in Fig. 19.4.3(c). The interstitial N atoms occupy the centers of the $\mathrm{Ni}_{3} \mathrm{Fe}_{3}$ octahedra. Each Fe atom has two terminal carbonyl groups, and each Ni atom has one.

The metallic core of the $\left[\mathrm{Rh}_{28}(\mathrm{~N})_{4}(\mathrm{CO})_{41} \mathrm{H}_{x}\right]^{4-}$ cluster is composed of three layers of Rh atoms in a close-packed ABC sequence, as shown in Fig. 19.4.3(d). Four N and an unknown number of H atoms occupy the octahedral holes.

The metal atoms in $\left[\mathrm{Ru}_{8}(\mathrm{P})(\mathrm{CO})_{22}\right]^{-}$constitute a square antiprismatic assembly [Fig. 19.4.3(e)]. Two opposite slant edges are each bridged by a carbonyl group. Each Ru bridged atoms has two terminal carbonyl groups, and each

of the remaining four has three. Comparison of this cluster core with those of $\left[\mathrm{Rh}_{9}(\mathrm{P})(\mathrm{CO})_{21}\right]^{2-}[$ Fig. 19.4.3(f) $]$ and $\left[\mathrm{Rh}_{10}(\mathrm{~S})(\mathrm{CO})_{22}\right]^{2-}[$ Fig. 19.4.3 (g) $]$ shows that the latter two are derived from successive capping of the rectangular faces of the square antiprism.

### 19.5 Iso-bond valence and iso-structural series

For a cluster consisting of $n_{1}$ transition-metal atoms and $n_{2}$ main-group atoms, the bond valence $b$ is evaluated as

$$
b=\frac{1}{2}\left(18 n_{1}+8 n_{2}-g\right),
$$

Fig. 19.4.2.
The structures of osmium carbonyl compounds vary with an increase or decrease of the valence electrons.

Fig. 19.4.3.
Molecular structure of some carbonyl cluster anions containing encapsulated heteroatoms; all terminal CO groups are omitted for clarity;
(a) $\left[\mathrm{Co}_{6} \mathrm{Ni}_{2}(\mathrm{C})_{2}(\mathrm{CO})_{16}\right]^{2-}$; only the bridging CO groups are shown; (b) $\left[\mathrm{Os}_{18} \mathrm{Hg}_{3}(\mathrm{C})_{2}(\mathrm{CO})_{42}\right]^{2-}$; (c) $\left[\mathrm{Fe}_{6} \mathrm{Ni}_{6}(\mathrm{~N})_{2}(\mathrm{CO})_{24}\right]^{2-}$;
(d) $\left[\mathrm{Rh}_{28}(\mathrm{~N})_{4}(\mathrm{CO})_{41} \mathrm{H}_{x}\right]^{4-}$; to avoid clutter, not all Rh-Rh bonds are included; (e) $\left[\mathrm{Ru}_{8}(\mathrm{P})(\mathrm{CO})_{22}\right]^{-}$; (f) $\left[\mathrm{Rh}_{9}(\mathrm{P})(\mathrm{CO})_{21}\right]^{2-}$;
(g) $\left[\mathrm{Rh}_{10}(\mathrm{~S})(\mathrm{CO})_{22}\right]^{2-}$.
where $g$ is the number of valence electrons of the skeleton formed by the $n_{1}$ transition-metals and $n_{2}$ main-group atoms.

When a BH group of the octahedral cluster $(\mathrm{BH})_{6}^{2-}$ is replaced by a $\mathrm{CH}^{+}$ group, both $g$ and $b$ retain their values and the structure of the cluster anion $(\mathrm{BH})_{5} \mathrm{CH}^{-}$remains octahedral. On the other hand, when a BH group of $(\mathrm{BH})_{6}^{2-}$ is replaced by a $\mathrm{Ru}(\mathrm{CO})_{3}$ group, the $b$ value still remains the same. But $g$

$\left[\mathrm{Ru}(\mathrm{CO})_{3}\right]_{4}(\mathrm{CH})_{2}$
$g=66, b=11$
$g=66, b=11$

$$
\begin{gathered}
{\left[\mathrm{Ru}(\mathrm{CO})_{3}\right]_{6}^{2-}} \\
g=86, b=11
\end{gathered}
$$

Fig. 19.5.1.
Iso-bond valence and iso-structural series of $\mathrm{B}_{6} \mathrm{H}_{6}^{2-}$.
increases its value by 10 , as a BH group contributes 4 electrons to the skeleton, while a $\mathrm{Ru}(\mathrm{CO})_{3}$ group contributes 14 ( 8 from Ru and 2 from each CO ). Therefore, replacement of one or more BH groups in $(\mathrm{BH})_{6}^{2-}$ by either $\mathrm{CH}^{+}$ or $\mathrm{Ru}(\mathrm{CO})_{3}$ groups results in a series of iso-bond valence and iso-structural clusters. The structures of some members of this series, $(\mathrm{BH})_{6}^{2-},(\mathrm{BH})_{4}(\mathrm{CH})_{2}$, $\left[\mathrm{Ru}(\mathrm{CO})_{3}\right]_{4}(\mathrm{CH})_{2}$, and $\left[\mathrm{Ru}(\mathrm{CO})_{3}\right]_{6}^{2-}$, are shown in Fig. 19.5.1. Similar substitutions by either transition-metal or representative-element groups give rise to a variety of cluster compounds, and five iso-structural series of clusters containing both transition-metal and main-group element components are displayed in Fig. 19.5.2.

Clearly the structure of a given cluster depends on electronic, geometric, and other factors. Hence the structure of a compound cannot be predicted until it has been determined experimentally. Still, based on the bond valence and structural principle illustrated above, an educated guess on the structure of a cluster becomes feasible. In addition, the bond valence concept provides a useful link between apparently dissimilar clusters such as $(\mathrm{BH})_{6}^{2-}$ and $\left[\mathrm{Ru}(\mathrm{CO})_{3}\right]_{4}(\mathrm{CH})_{2}$.

### 19.6 Selected topics in metal-metal interactions

Since the 1980s, studies on metal clusters and metal string complexes have revealed unusual interactions between metal atoms, some of which are discussed in this section.

### 19.6.1 Aurophilicity

The term aurophilicity (or aurophilic attraction) refers to the formally nonbonding but attractive interaction between gold(I) atoms in gold cluster compounds. The $\mathrm{Au}(\mathrm{I})$ atom has a closed-shell electronic configuration: [Xe] $4 f^{14} 5 d^{10} 6 s^{0}$. Normally, repulsion exists between the nonbonding homoatoms. However, there is extensive crystallographic evidence of attractive interaction between gold(I) cations. Figure 19.6.1 shows the structures of three $\mathrm{Au}(\mathrm{I})$ compounds.
(1) $\mathrm{O}\left[\mathrm{AuP}(o-\text { tol })_{3}\right]_{3}^{+}\left(o\right.$-tol $\left.=\mathrm{C}_{6} \mathrm{H}_{4} \mathrm{Me}-2\right)$ : In $\mathrm{O}\left[\mathrm{AuP}(o \text {-tol })_{3}\right]_{3}\left(\mathrm{BF}_{4}\right)$, the O atom forms covalent bonds with three Au atoms in a $\mathrm{OAu}_{3}$ pyramidal configuration, as shown in Fig. 19.6.1(a). The Au atoms are linearly

coordinated by O and P atoms. In this structure, the mean $\mathrm{Au} \cdots \mathrm{Au}$ distance is 308.6 pm , which is shorter than the sum of van der Waals radii, $2 \times 166=332 \mathrm{pm}$.
(2) $\mathrm{S}\left[\mathrm{AuP}(o-\mathrm{tol})_{3}\right]_{4}^{2+}: \operatorname{In~} \mathrm{S}\left[\mathrm{AuP}(o-\text { tol })_{3}\right]_{4}\left(\mathrm{ClO}_{4}\right)_{2}$, the $\mathrm{SAu}_{4}$ unit takes a squarepyramidal configuration, as shown in Fig. 19.6.1(b). The Au atoms are near linearly coordinated by S and P atoms. The $\mathrm{Au} \cdots \mathrm{Au}$ distances lie in the range of 288.3 to 293.8 pm , and the mean distance is 293.0 pm . The distance of the S atom to the center of the $\mathrm{Au}_{4}$ basal plane is 130 pm .
(3) $\mathrm{Au}_{11} \mathrm{I}_{3}\left[\mathrm{P}\left(p-\mathrm{C}_{6} \mathrm{FH}_{4}\right)_{3}\right]_{7}$ : The structure of the molecule is shown in Fig. 19.6.1(c). In the $\mathrm{Au}_{11}$ cluster, the central Au atom is surrounded by ten Au atoms, which form an incomplete icosahedron (lacking two vertices) with each vertex carrying one terminal iodo ligand or $\mathrm{P}\left(p-\mathrm{C}_{6} \mathrm{FH}_{4}\right)_{3}$ group.

The mean $\mathrm{Au} \cdots \mathrm{Au}$ distance from the central atom to the surrounding atoms is 268 pm , and the mean distance between the ten Au vertices is 298 pm .

In other gold(I) cluster compounds, such as tetrahedral [(AuL) $)_{4}\left(\mu_{4}-\mathrm{N}\right)$ ] and $\left[(\mathrm{AuL})_{4}\left(\mu_{4}-\mathrm{O}\right)\right]^{2+}$, trigonal-bipyramidal $\left[(\mathrm{AuL})_{5}\left(\mu_{5}-\mathrm{C}\right)\right]^{+},\left[(\mathrm{AuL})_{5}\left(\mu_{5}-\right.\right.$ $\mathrm{N})]^{2+}$ and $\left[(\mathrm{AuL})_{5}\left(\mu_{5}-\mathrm{P}\right)\right]^{2+}$, and octahedral $\left[(\mathrm{AuL})_{6}\left(\mu_{6}-\mathrm{C}\right)\right]^{2+}$ and $\left[(\mathrm{AuL})_{6}\right.$ $\left.\left(\mu_{6}-\mathrm{N}\right)\right]^{3+}\left(\mathrm{L}=\mathrm{PPh}_{3}\right.$ or $\left.\mathrm{PR}_{3}\right)$, the $\mathrm{Au} \cdots \mathrm{Au}$ distances lie in the range 270 to 330 pm . These data substantiate that aurophilicity is a common phenomenon among gold cluster complexes.

Fig. 19.6.1.
Molecular structure of gold cluster compounds: (a) $\mathrm{O}[\mathrm{AuP}(o-t o l) 3]_{3}^{+}$, (b) $\mathrm{S}\left[\mathrm{AuP}(o-\text { tol })_{3}\right]_{4}^{2+}$, (c) $\mathrm{Au}_{11} \mathrm{I}_{3}\left[\mathrm{P}\left(p-\mathrm{C}_{6} \mathrm{FH}_{4}\right)_{3}\right]_{7}$.

Fig. 19.6.2.
Structure of some gold oligomeric aggregate molecules: (a) $\mathrm{Au}_{5}(\mathrm{mes})_{5}$ (mes $=\mathrm{C}_{6} \mathrm{H}_{3} \mathrm{Me}_{3}-2,4,6$ ); (b) $[\mathrm{LAuCl}]_{4}$, $\mathrm{L}=\mathrm{HN}\left(\mathrm{CH}_{2}\right)_{4} \mathrm{CH}_{2}$; and
(c) $\left[\mathrm{O}\left(\mathrm{AuPPh}_{3}\right)_{3}\right]_{2}$.

Aurophilicity presumably arises from relativistic modification of the gold valence AOs energies, which brings the 5d and 6 s orbitals into close proximity in the energy level diagram. In more recent theoretical studies, the effect is primarily attributed to electron correlation, which takes precedence over $6 \mathrm{~s} / 5 \mathrm{~d}$ hybridization. To date, the origin of the aurophilicity has not yet been unambiguously established.

Making use of the concept of aurophilicity, simple gold compounds can be combined to yield complicated oligomeric aggregates in designed synthesis. Figure 19.6.2 shows the structures of three oligomeric molecules.
(a)

(b)

(c)

### 19.6.2 Argentophilicity and mixed metal complexes

By analogy to aurophilicity, argentophilicity has been demonstrated to exist in silver cluster complexes. In the crystal structures of a variety of silver(I) double and multiple salts containing a fully encapsulated acetylide dianion $\mathrm{C}_{2}^{2-}$ (IUPAC name acetylenediide) in different polyhedral silver cages (see Fig. 14.3.11), there exist many $\mathrm{Ag} \cdots \mathrm{Ag}$ contacts shorter than twice the van der Waals radius of silver $(2 \times 170=340 \mathrm{pm})$. Further details are given in Chapter 20.

Taking advantage of both aurophilicity and argentophilicity, tetranuclear mixed-metal complexes which contain pairs of Au and Ag atoms have been prepared, as shown in Fig. 19.6.3. In the preparation of mixed gold/silver polynuclear complexes, aurophilicity and argentophilicity have been utilized to promote cluster formation. Figure 19.6 .4 shows the cores of several mixed gold-silver clusters.

The $\left[\mathrm{Au}_{13} \mathrm{Ag}_{12}\right]$ molecular skeletons (a) and (b) of $\left[\left(\mathrm{Ph}_{3} \mathrm{P}\right)_{10} \mathrm{Au}_{13} \mathrm{Ag}_{12} \mathrm{Br}_{8}\right]$ $\mathrm{SbF}_{6}$ and $\left[\left(p-\text { tol }_{3} \mathrm{P}\right)_{10} \mathrm{Au}_{13} \mathrm{Ag}_{12} \mathrm{Br}_{8}\right] \mathrm{Br}$, respectively, can each be considered as two centered icosahedra sharing a common vertex. In an alternative description, the 25 metal atoms constitute three fused icosahedra, with a common pentagon shared between an adjacent pair of fused icosahedra. Structure (a) adopts the ses (staggered-eclipsed-staggered) configuration, and the sequence of relative positioning of atoms is ABBA. Structure (b) adopts the sss (staggered-staggered-staggered) configuration, and the sequence is ABAB . The structure of (c) consists of the three centered icosahedra, each of which uses one edge to form a central triangle, with an additional Ag atom lying above and below it. The structure of (d) consists of six Au atoms that form a planar six-membered ring, with one Ag atom located at the center; each edge of the $\mathrm{Au}_{6}$ hexagon is bridged by a bridging C atom, with three C atoms lying above the plane and three below it.

### 19.6.3 Metal string molecules

A metal string molecule contains a linear metal-atom chain in its structure. In a molecule of this type, all or a part of the neighboring metal atoms are involved in metal-metal bonding interactions. A general strategy of synthesizing metal string molecules is to design bridging ligands possessing multiple donor sites arranged in a linear sequence such that they can coordinate simultaneously to metal centers.

(c)

(d)

Fig. 19.6.4.
Skeletal structure of some mixed $\mathrm{Au} / \mathrm{Ag}$ clusters (filled circle, Au ; open circle, Ag ): (a) $\left[\mathrm{Au}_{13} \mathrm{Ag}_{12}\right]$ in
$\left[\left(\mathrm{Ph}_{3} \mathrm{P}\right)_{10} \mathrm{Au}_{13} \mathrm{Ag}_{12} \mathrm{Br}_{8}\right] \mathrm{SbF}_{6}$,
(b) $\left[\mathrm{Au}_{13} \mathrm{Ag}_{12}\right]$ in
$\left[\left(p-\text { tol }_{3} \mathrm{P}\right)_{10} \mathrm{Au}_{13} \mathrm{Ag}_{12} \mathrm{Br}_{8}\right] \mathrm{Br}$,
(c) $\left[\mathrm{Au}_{18} \mathrm{Ag}_{20}\right]$ in
$\left[\left(p-\text { tol }{ }_{3} \mathrm{P}\right)_{12} \mathrm{Au}_{18} \mathrm{Ag}_{20} \mathrm{Cl}_{14}\right]$, and
(d) $\left[\mathrm{AgAu}_{6} \mathrm{C}_{6}\right]$ in
$\left[\mathrm{Ag}\left(\mathrm{AuC}_{6} \mathrm{H}_{2}\left(\mathrm{CHMe}_{2}\right)_{3}\right)_{6} \mathrm{CF}_{3} \mathrm{SO}_{3}\right.$.
(1) Metal string molecules constructed with oligo( $\alpha$-pyridyl)amido ligand
The common formula of a series of polypyridylamines is shown below:

$n=0$, Hdpa
$n=1, \mathrm{H}_{2}$ tpda
$n=2, \mathrm{H}_{3}$ teptra
$n=3, \mathrm{H}_{4}$ peptea
Four fully deprotonated polypyridylamines, or oligo( $\alpha$-pyridyl)amido ligands, can coordinate simultaneously to metal atoms from the upper, lower, front, and back directions to form a metal string molecule:

| $n$ | M (II) |
| :--- | :--- |
| 0 | $\mathrm{Cr}, \mathrm{Ru}, \mathrm{Co}, \mathrm{Rh}, \mathrm{Ni}, \mathrm{Cu}$ |
| 1 | $\mathrm{Cr}, \mathrm{Co}, \mathrm{Ni}$ |
| 2 | $\mathrm{Cr}, \mathrm{Ni}$ |
| 3 | $\mathrm{Cr}, \mathrm{Ni}$ |

As an oligo( $\alpha$-pyridyl)amido ligand has an odd number of donor sites, the corresponding metal string molecule has the same number of metal atoms.

From the reactions of $\mathrm{Ni}(\mathrm{II})$ salts with polypyridylamines, a series of metal string molecules, in which the number of nickel atom varies from 3 (i.e., $n=$

## Structural Chemistry of Selected Elements

0 ) to 9 (i.e., $n=3$ ), have been prepared. The structures of these molecules are very similar. Figure 19.6 .5 shows the structure of $\left[\mathrm{Ni}_{9}\left(\mu_{9} \text {-peptea }\right)_{4} \mathrm{Cl}_{2}\right]$, $\left(\mathrm{H}_{4}\right.$ peptea $=$ pentapyridyltetramine $)$. The nine Ni atoms are in a straight line, and the distances between atoms are approximately equal. Every N atom in the four ( $\alpha$-pyridyl)amido ligands coordinates to one Ni atom. Each Ni atom is coordinated by four N atoms to form a square oriented perpendicular to the metal string. Because of steric repulsion between H atoms of the neighboring pyridine rings, the ( $\alpha$-pyridyl)amido ligands are helically distributed around the string axis, as shown in Fig. 19.6.5.

Fig. 19.6.5.
Structure of $\left[\mathrm{Ni}_{9}\left(\mu_{9} \text {-peptea }\right)_{4} \mathrm{Cl}_{2}\right]$ (filled circle, Ni ; large open circle, Cl ; small open circle, N ; and small filled circle, C ).
The $\mathrm{Ni}-\mathrm{Ni}$ and $\mathrm{Ni}-\mathrm{N}$ distances in a family of related metal string molecules, in which the numbers of Ni atoms are 3, 5, 7, and 9, are shown in Fig. 19.6.6. The $\mathrm{Ni}-\mathrm{Ni}$ distances increase from the center toward each terminal, and the $\mathrm{Ni}-\mathrm{N}$ distances are nearly equal except for the outermost ones. These effects
(a)

(c)

(d)

Fig. 19.6.6.
Bond lengths in metal string molecules (in pm): (a) $\mathrm{Ni}_{3}\left(\mu_{3}-\mathrm{dpa}_{4}\right)_{4} \mathrm{Cl}_{2}$, (b) $\mathrm{Ni}_{5}(\mu 5 \text {-tpda) })_{4} \mathrm{Cl}_{2}$, (c) $\mathrm{Ni}_{7}\left(\mu_{7}-\text { teptra }\right)_{4} \mathrm{Cl}_{2}$, and (d) $\mathrm{Nig}_{9}\left(\mu_{9} \text {-peptea) }\right)_{4} \mathrm{Cl}_{2}$.
are attributable to the fact that, unlike the inner metal atoms, each terminal metal atom has square-pyramidal coordination.

The metal string molecule $\left[\mathrm{Cr}_{5}(\mathrm{tpda})_{4} \mathrm{Cl}_{2}\right] \cdot 2 \mathrm{Et}_{2} \mathrm{O} \cdot 4 \mathrm{CHCl}_{3}$ contains alternately long and short metal-metal distances, as shown in Fig. 19.6.7. The short $\mathrm{Cr}-\mathrm{Cr}$ distances are 187.2 and 196.3 pm , which correspond to the quadruple bond $\mathrm{Cr} \equiv \mathrm{Cr}$. The long $\mathrm{Cr} \cdots \mathrm{Cr}$ distances are 259.8 and 260.9 pm , which are indicative of nonbonding interaction.

## (2) Hexanuclear metal string cationic complexes

Modification of the $\mathrm{H}_{2}$ tpda ligand by substitution of the central pyridyl group with a naphthyridyl group gives rise to the new ligand 2,7-bis ( $\alpha$-pyridylamino)-1,8-naphthyridine ( $\mathrm{H}_{2}$ bpyany), which has been used to generate a series of hexanuclear metal string complexes of the general formula $\left[\mathrm{M}_{6}\left(\mu_{6} \text {-bpyany }\right)_{4} \mathrm{X}_{2}\right] \mathrm{Y}_{n}\left(\mathrm{M}=\mathrm{Co}, \mathrm{Ni} ; \mathrm{X}^{-}=\right.$terminal monoanionic ligand; $\mathrm{Y}^{-}=$counter monoanion; $n=1,2$ ). All compounds contain a linear hexanuclear cation helically supported by four bpyany ${ }^{2-}$ ligands and conforms approximately to idealized $D_{4}$ molecular symmetry if the axial terminal ligands are ignored. The structure of a representative example is shown in Fig. 19.6.8.

The averaged metal-metal bond lengths in the series of linear $\mathrm{M}_{6}^{12+}$ $(\mathrm{M}=\mathrm{Co}, \mathrm{Ni})$ complexes and their $\mathrm{M}_{6}^{11+}$ one-electron reduction products are

## Structural Chemistry of Selected Elements

tabulated in Table 19.6.1. In all complexes the outermost $\mathrm{M}-\mathrm{M}$ distance is in general slightly longer than the inner bond distances, but neither the nature of the axial ligands nor the addition of one electron to the $\mathrm{Co}_{6}^{12+}$ system results in significant structural changes. In contrast, the innermost $\mathrm{Ni}-\mathrm{Ni}$ bond shows a substantial decrease of $9.4(3) \mathrm{pm}$ upon one-electron reduction of the $\mathrm{Ni}_{6}^{12+}$ system. The crystallographic data are consistent with the proposed model of a delocalized electronic structure for the $\mathrm{Co}_{6}^{n+}(n=11,12)$ complexes, whereas the extra electron in the $\mathrm{Ni}_{6}^{12+}$ system partakes in a $\delta$ bond constructed from $\mathrm{d}_{x^{2}-y^{2}}$ orbitals of the naphthyridyl-coordinated nickel atoms.

## (3) Mixed-valence metal string complexes of gold

The structures of two gold metal string molecules are shown in Fig. 19.6.9. The formula of molecule (a) in this figure is:

From the $\mathrm{Au}-\mathrm{Au}$ bond lengths shown and related theoretical calculations, the valence states of the Au atoms are in the sequence of $\mathrm{Au}(\mathrm{III})-\mathrm{Au}(\mathrm{I})-\mathrm{Au}(\mathrm{I})-\mathrm{Au}(\mathrm{I})-\mathrm{Au}(\mathrm{III})$. The molecular cation is composed of the central unit $\left[\mathrm{Au}\left(\mathrm{C}_{6} \mathrm{~F}_{5}\right)_{2}\right]^{-}$and two outer dinuclear gold cations $\left[\mathrm{Au}_{2}\left\{\left(\mathrm{CH}_{2}\right)_{2}\left(\mathrm{PPh}_{2}\right)\right\}_{2} \mathrm{C}_{6} \mathrm{~F}_{5}\right]^{+}$, with the central unit donating electrons to the outer units.

The formula of molecule (b) in Fig. 19.6.9 is

(a)

(b)

From the Au -Au bond lengths shown and theoretical calculations, the valence states of the Au atoms are identified as $\mathrm{Au}(\mathrm{III})-\mathrm{Au}(\mathrm{I})-\mathrm{Au}(\mathrm{I})-\mathrm{Au}(\mathrm{I})-\mathrm{Au}(\mathrm{I})-$ $\mathrm{Au}(\mathrm{III})$.

### 19.6.4 Metal-based infinite chains and networks

Infinite metal-based chains are expected to be much more promising as conducting inorganic "molecular wires" than short-chain oligomers. The infinite rhodium chain, $\left[\mathrm{Rh}\left(\mathrm{CH}_{3} \mathrm{CN}\right)_{4}^{1.5+}\right]_{\infty}$, consists of alternating $\mathrm{Rh}-\mathrm{Rh}$ distances of 284.42 and 292.77 pm, and is a semiconductor. Figure 19.6.10 shows a section of the infinite cationic chain in the polymer $\left[\left\{\mathrm{Rh}\left(\mathrm{CH}_{3} \mathrm{CN}\right)_{4}\right\}\left(\mathrm{BF}_{4}\right)_{1.5}\right]_{\infty}$.

A series of polymeric complexes featuring the metallophilic interaction between gold(I) and thallium(I) has been synthesized employing acid-base strategy. For example, the treatment of $\mathrm{Bu}_{4} \mathrm{~N}\left[\mathrm{Au}\left(\mathrm{C}_{6} \mathrm{Cl}_{5}\right)_{2}\right]$ with $\mathrm{TlPF}_{6}$ in THF gave $\left[\mathrm{AuTl}\left(\mathrm{C}_{6} \mathrm{Cl}_{5}\right)_{2}\right]_{n}$, which consists of an infinite linear $(\mathrm{Tl} \cdots \mathrm{Au} \cdots)_{\infty}$ chain consolidated by unsupported $\mathrm{Au}^{\mathrm{I}} \ldots \mathrm{Tl}{ }^{\mathrm{I}}$ interactions, as shown in Fig. 19.6.11(a).

In the presence of triphenylphosphine oxide, and also depending on the nature of the pentahalophenyl group employed, similar synthetic reactions afforded $\left[\mathrm{AuTl}\left(\mathrm{C}_{6} \mathrm{~F}_{5}\right)_{2}\left(\mathrm{Ph}_{3} \mathrm{P}=\mathrm{O}\right)_{2}\right]_{n}$ and $\left[\mathrm{AuTl}\left(\mathrm{C}_{6} \mathrm{Cl}_{5}\right)_{2}\left(\mathrm{Ph}_{3} \mathrm{P}=\mathrm{O}\right)_{2}(\mathrm{THF})\right]_{n}$ with the

Fig. 19.6.10.

Fig. 19.6.11.
Structure of (a) $\left[\mathrm{AuTl}\left(\mathrm{C}_{6} \mathrm{Cl}_{5}\right)_{2}\right]_{n}$ and (b) $\left[\mathrm{AuTl}\left(\mathrm{C}_{6} \mathrm{~F}_{5}\right)_{2}\left(\mathrm{Ph}_{3} \mathrm{P}=\mathrm{O}\right)_{2}\right]_{n}$.

Fig. 19.6.12.
Structure of $\left[\mathrm{AuTl}\left(\mathrm{C}_{6} \mathrm{Cl}_{5}\right)_{2}\left(\mathrm{Ph}_{3} \mathrm{P}=\mathrm{O}\right)_{2}(\mathrm{THF})\right]_{n}$.
phosphine oxide incorporated into their polymeric structures. In the pentafluorophenyl complex, thallium(I) adopts a distorted trigonal-bipyramidal geometry with one equatorial coordination site filled by a stereochemically active lone pair, forming a linear $(\mathrm{Tl} \cdots \mathrm{Au} \cdots)_{\infty}$ chain, as shown in Fig. 19.6.11(b). In contrast, the pentachlorophenyl complex comprises an infinite zigzag ( $\left.\mathrm{Tl} \cdots \mathrm{Au} \cdots \mathrm{Tl}^{\prime} \cdots \mathrm{Au} \cdots\right)_{\infty}$ chain constructed from two kinds of thallium(I) centers with distorted trigonal-pyramidal and pseudo-tetrahedral geometries for Tl and $\mathrm{Tl}^{\prime}$ (each possessing a stereochemically active lone pair), respectively, as shown in Fig. 19.6.12.

Fig. 19.6.13.
Layer structure of $\left[\mathrm{AuTl}\left(\mathrm{C}_{6} \mathrm{~F}_{5}\right)_{2} \text { (bipy) }\right]_{n}$. The bridging 4, $4^{\prime}$-bypyridine ligand is represented by a thick rod joining its two terminal N atoms.

Fig. 19.6.14.
Layer structure of $\left.\left[\mathrm{Au}_{2} \mathrm{Tl}_{2}\left(\mathrm{C}_{6} \mathrm{Cl}_{5}\right)_{4} \text { (bipy }\right)_{1.5}(\mathrm{THF})\right]_{n}$. Atom Tl is shown in boldface type to distinguish it from atom $\mathrm{Tl}^{\prime}$. Each bridging 4,4 '-bypyridine ligand is represented by a thick rod joining the terminal N atoms.

Similar acid-base reactions with the introduction of the exo-bidentate bridging ligand $4,4^{\prime}$-bipyridine led to the formation of $\left[\mathrm{AuTl}\left(\mathrm{C}_{6} \mathrm{~F}_{5}\right)_{2} \text { (bipy) }\right]_{n}$ and $\left[\mathrm{Au}_{2} \mathrm{Tl}_{2}\left(\mathrm{C}_{6} \mathrm{Cl}_{5}\right)_{4}(\mathrm{bipy})_{1.5}(\mathrm{THF})\right]_{n}$, which exhibit higher-dimensional polymeric structures. In the pentafluorophenyl complex, linear tetranuclear $\mathrm{Tl} \cdots \mathrm{Au} \cdots \mathrm{Au} \cdots \mathrm{Tl}$ units are linked through bipyridine bridges to form a honeycomb-like network, as shown in Fig. 19.6.13.

The pentachlorophenyl complex contains two kinds of thallium(I) centers: atom Tl is coordinated by two bipyridyl N atoms, whereas atom $\mathrm{Tl}^{\prime}$ is bound to a THF ligand and a bipyridyl N atom, as shown in Fig. 19.6.14. The asymmetric unit contains two non-equivalent bridging $4,4^{\prime}$-bipyridine ligands, one of which occupies a $\overline{1}$ site in the unit cell and necessarily exists in the planar configuration. Hetero-metallophilic interaction generates infinite ( $\left.\mathrm{Tl} \cdots \mathrm{Au} \cdots \mathrm{Tl}^{\prime} \cdots \mathrm{Au} \cdots\right)_{\infty}$ zigzag chains linked by the first kind of bridging bipyridine ligand (located in a general position and nonplanar) across Tl and $\mathrm{Tl}^{\prime}$ to form a brick-like layer. The centrosymmetric bipyridine, which is bound to Tl and represented by a dangling rod in the figure, connects the Tl atoms in adjacent layers to form a double layer.

## Supramolecular Structural Chemistry

### 20.1 Introduction

Supramolecular chemistry is a highly interdisciplinary field of science covering the chemical, physical, and biological features of molecular assemblies that are organized and held together by intermolecular interactions. The basic concepts and terminology were introduced by J.-M. Lehn, who together with D. J. Cram and C. J. Pedersen were awarded the 1987 Nobel Prize in Chemistry. In the words of Lehn, supramolecular chemistry may be defined as chemistry beyond the molecule, i.e., the study of organized entities of higher complexity (supermolecule) resulting from the association of two or more chemical species consolidated by intermolecular forces. The relationship of supermolecules to molecules and intermolecular binding is analogous to that of molecules to atoms and covalent bonds (Fig. 20.1.1).

A clarification about vocabulary in the chemical literature: the prefix in the word supermolecule (a noun) is derived from the Latin super, meaning "more than" or "above"; it should not be used interchangeably with the prefix supra in the word supramolecular (an adjective), which means "beyond" or "at a higher level than."

### 20.1.1 Intermolecular interactions

Intermolecular interactions constitute the core of supramolecular chemistry. The design of supermolecules requires a clear understanding of the nature, strength, and spatial attributes of intermolecular bonding, which is a generic term that includes ion pairing (Coulombic), hydrophobic and hydrophilic interactions, hydrogen bonding, host-guest complementarity, $\pi-\pi$ stacking, and van der Waals interactions. For inorganic systems, coordination bonding is included in this list if the metal acts as an attachment template. Intermolecular interactions in organic compounds can be classified as (a) isotropic, medium-range forces that define molecular shape, size, and close packing and (b) anisotropic, longrange forces, which are electrostatic and involve heteroatom interactions. In general, isotropic forces (van der Waals interactions) usually mean dispersive and repulsive forces, including $\mathrm{C} \cdots \mathrm{C}, \mathrm{C} \cdots \mathrm{H}$, and $\mathrm{H} \cdots \mathrm{H}$ interactions, while most interactions involving heteroatoms ( $\mathrm{N}, \mathrm{O}, \mathrm{Cl}, \mathrm{Br}, \mathrm{I}, \mathrm{P}, \mathrm{S}, \mathrm{Se}$, etc.) with one another or with carbon and hydrogen are anisotropic in character, including ionic forces, strongly directional hydrogen bonds ( $\mathrm{O}-\mathrm{H} \cdots \mathrm{O}, \mathrm{N}-\mathrm{H} \cdots \mathrm{O}$ ),

weakly directional hydrogen bonds $(\mathrm{C}-\mathrm{H} \cdots \mathrm{O}, \mathrm{C}-\mathrm{H} \cdots \mathrm{N}, \mathrm{C}-\mathrm{H} \cdots \mathrm{X}$, where X is a halogen, and $\mathrm{O}-\mathrm{H} \cdots \pi$ ), and other weak forces such as halogen $\cdots$ halogen, nitrogen $\cdots$ nitrogen, and sulfur $\cdots$ halogen interactions. In a crystal, various strong and weak intermolecular interactions coexist (sometimes in delicate balance, as is demonstrated by the phenomenon of polymorphism) and consolidate the three-dimensional scaffolding of the molecules.
(a)

(b)

### 20.1.2 Molecular recognition

The concept of molecular recognition has its origin in effective and selective biological functions, such as substrate binding to a receptor protein, enzyme reactions, assembly of protein-DNA complexes, immunological antigen-antibody association, reading of the genetic code, signal induction by neurotransmitters, and cellular recognition. Many of these functions can be performed by artificial receptors, whose design requires an optimal match of the steric and electronic features of the non-covalent intermolecular forces between substrate and receptor. Some of the recognition processes that have been well studied by chemists include spherical recognition of metal cations by cryptates, tetrahedral recognition by macrotricyclic cryptands, recognition of specific anions, and the binding and recognition of neutral molecules through Coulombic, donor-acceptor, and in particular hydrogen-bonding interactions (see Fig. 20.1.2).

Fig. 20.1.3.
Aspects of supramolecular hierarchy in increasing superstructural complexity.

Molecular recognition studies are typically carried out in solution, and the effects of intermolecular interactions are often probed by spectroscopic methods.

### 20.1.3 Self-assembly

The term "self-assembly" is used to designate the evolution toward spatial confinement through spontaneous connection of molecular components, resulting in the formation of discrete or extended entities at either the molecular or the supramolecular level. Molecular self-assembly yields covalent structures, while in supramolecular self-assembly several molecules spontaneously associate into a single, highly structured supramolecular aggregate. In practice, self-assembly can be achieved if the molecular components are loaded with recognition features that are mutually complementary; i.e., they contain two or more interaction sites for establishing multiple connections. Thus well-defined molecular and supramolecular architectures can be spontaneously generated from specifically "engineered" building blocks. For example, self-assembly occurs with interlocking of molecular components using $\pi-\pi$ interactions (Fig. 20.1.3) and the formation of capsules with some curved molecules bearing complementary hydrogen bonding sites (Fig. 20.1.4).

The cyclic octapeptide cyclo-[-(D-Ala-L-Glu-D-Ala-L-Gln) $2_{2}$-] has been designed by Ghadiri and co-workers to generate a hydrogen-bonded organic nanotube having an internal diameter of approximately $0.7-0.8 \mathrm{~nm}$ (Fig. 20.1.5).

### 20.1.4 Crystal engineering

Structural chemists and crystallographers rightfully regard an organic crystal as the "supermolecule par excellence," being composed of Avogadro's number of molecules self-assembled by mutual recognition at an amazing level of precision. In contrast to a molecule, which is constructed by connecting atoms with covalent bonds, a molecular crystal (solid-state supermolecule) is built by connecting molecules with intermolecular interactions. The process of

Table 20.1.1. Comparison of crystal engineering and molecular recognition

|  | Crystal engineering | Molecular recognition |
| :---: | :---: | :---: |
| (1) | Concerned with the solid state | Concerned mainly with solution phase |
| (2) | Considers both convergent and divergent binding of molecules | Most cases only focus on convergent binding of molecules |
| (3) | Intermolecular interaction are examined directly in terms of their geometrical features obtained from X-ray crystallography | Intermolecular interactions are studied indirectly in terms of association constants obtained from various spectroscopic (NMR, UV, etc.) methods |
| (4) | Design strategies involve the control of the threedimensional arrangement of molecules in the crystal; such an arrangement ideally results in desired chemical and physical properties | Design strategies are confined to the mutual recognition of generally two species: the substrate and the receptor; such recognition is expected to mimic some biological functionality |
| (5) | Both strong and weak interactions are considered independently or jointly in the design strategy | Only strong interactions such as hydrogen bonding are generally used for the recognition event |
| (6) | The design may involve either single-component species or multicomponent species; a single-component molecular crystal is a prime example of self-recognition | The design usually involves two distinct species: the substrate and the receptor; ideas concerning self-recognition are poorly developed |
| (7) | In host-guest complexes, the host cavity is composed of several molecules whose synthesis may be fairly simple; the geometry and functionality of the guest molecules are often of significance in the complexation | In host-guest complexes, the host cavity is often a single macrocyclic molecule whose synthesis is generally tedious; the host framework rather than the guest molecule plays a critical role in the complexation |
| (8) | Systematic retrosynthetic pathways may be deduced with the Cambridge Structural Database (CSD) to design new recognition patterns using both strong and weak | There is no systematic set of protocols for the identification of new recognition patterns; much depends on individual style and preferences |

crystallization is one of the most precise and spectacular examples of molecular recognition.

The determination of crystal structures by X-ray crystallography provides precise and unambiguous data on intermolecular interactions. Crystal engineering has been defined by Desiraju as "the understanding of intermolecular interactions in the context of crystal packing and in the utilization of such knowledge in the design of new solids with desired physical and chemical properties."

Crystal engineering and molecular recognition are twin tenets of supramolecular chemistry that depend on multiple matching of functionalities among molecular components. Historically, crystal engineering has been developed by structural and physical chemists with a view to design new materials and solid-state reactions, whereas molecular recognition has been developed by physical organic chemists interested in mimicking biological processes. The methodologies and goals of these two related fields are summarized in Table 20.1.1.

### 20.1.5 Supramolecular synthon

In the context of organic synthesis, the term "synthon" was introduced by Corey in 1967 to refer to "structural units within molecules which can be formed and/or assembled by known or conceivable synthetic operations." This general definition was modified by Desiraju for supramolecular chemistry: "Supramolecular synthons are structural units within supermolcules which can be formed and/or

Structural Chemistry of Selected Elements

assembled by known or conceivable synthetic operations involving intermolecular interactions." The goal of crystal engineering is to recognize and design synthons sufficiently robust to be carried over from one network structure to another, which ensures generality and predictability. Some common examples of supramolecular synthons are shown in Fig. 20.1.6.

It should be emphasized that supramolecular synthons are derived from designed combinations of interactions and are not identical to the interactions. A supramolecular synthon incorporates both chemical and geometrical recognition features of two or more molecular fragments, i.e., both explicit and implicit involvement of intermolecular interactions. However, in the simplest cases, a single interaction may be regarded as a synthon, for instance $\mathrm{Cl} \cdots \mathrm{Cl}, \mathrm{I} \cdots \mathrm{I}$ or $\mathrm{N} \cdots \mathrm{Br}$ [Figs. 20.1.6(23-25)]. Besides the strong hydrogen bonds ( $\mathrm{N}-\mathrm{H} \cdots \mathrm{O}$ and $\mathrm{O}-\mathrm{H} \cdots \mathrm{O}$ ), which are expected to be frequently involved in supramolecular synthons [Figs. 20.1.6(1-5)], weak hydrogen bonds of the $\mathrm{C}-\mathrm{H} \cdots \mathrm{X}$ variety and $\pi-\pi$ interactions may also be significant. Although such weaker interactions have low energies in the range of 2 to $20 \mathrm{~kJ} \mathrm{~mol}^{-1}$, their cumulative effects on molecular association and crystal structure and packing are just about as predictable as the effects of conventional hydrogen bonding.

The nature of the $\mathrm{X} \cdots \mathrm{X}$ interaction in trimer synthon 44 is illustrated in Fig. 20.1.7. The $\mathrm{C}-\mathrm{X}$ bond in a halo-substituted phenyl ring is polarized, so that there are regions of positive and negative electrostatic potentials around the X atom. The cyclic interaction of three $\mathrm{C}-\mathrm{X}$ groups optimizes electrostatic potential overlap in the halogen trimer system.

### 20.2 Hydrogen-bond directed assembly

Hydrogen bonding is an indispensable tool for designing molecular aggregates within the fields of supramolecular chemistry, molecular recognition, and crystal engineering. It is well recognized that in organic crystals certain building blocks or supramolecular synthons have a clear pattern preference, and molecules that contain these building blocks tend to crystallize in specific arrangements with efficient close packing. As already mentioned in Section 11.2.1, three important rules are generally applicable to the formation of hydrogen bonds between functional groups in neutral organic molecules:
(a) all strong donor and acceptor sites are fully utilized;
(b) intramolecular hydrogen bonds giving rise to a six-membered ring will form in preference to intermolecular hydrogen bonds; and
(c) the remaining proton donors and acceptors not used in (b) will form intermolecular hydrogen bonds to one another.

For additional rules and a full discussion the reader is referred to the papers of Etter [Acc. Chem. Res. 23, 120-6 (1990); J. Phys. Chem. 95, 4601-10 (1991)]. Figure 20.2 . 1 shows a hydrogen-bonded polar sheet where 3,5 -dinitrobenzoic acid and 4-aminobenzoic acid are co-crystallized.

### 20.2.1 Supramolecular architectures based on the carboxylic acid dimer synthon

Carboxylic acids are commonly used as pattern-controlling functional groups for the purpose of crystal engineering. The most prevalent hydrogen bonding patterns formed by carboxylic acids are the dimer and the catemer. Carboxylic acids containing small substituent groups (formic acid, acetic acid) form the catemer motif, while most others (especially aromatic carboxylic acids) form
(a)

dimers, although not exclusively. In the case of di- and polycarboxylic acids, terephthalic acid, and isophthalic acid form linear and zigzag ribbons (or tapes), respectively, trimesic acid (1,3,5-benzenetricarboxylic acid) with its threefold molecular symmetry forms a hydrogen-bonded sheet, and adamantane-1,3,5, 7-tetracarboxylic acid forms a diamondoid network (Fig. 20.2.2).

If a bulky hydrophobic group is introduced at the 5-position of isophthalic acid, a cyclic hexamer (rosette) is generated. In the crystal structure of trimesic acid, the voids are filled through interpenetration of two honeycomb

Some examples of graph-set descriptors of hydrogen-bonded structural motifs.
of adopting a systematic notation for the topology of hydrogen-bonded motifs and networks, a graph-set approach has been suggested by Etter and Ward. This provides a description of hydrogen-bonding schemes in terms of four pattern designators $(G)$, i.e., infinite chain ( $C$ ), ring $(R)$, discrete complex $(D)$, and intramolecular (self-associating) ring $(S)$, which together with the degree of the pattern ( $n$, the number of atoms comprising the pattern), the number of donors (d), and the number of acceptors (a) are combined to form the quantitative graph-set descriptor $G_{d}^{a}(n)$. Examples of the use of these quantitative descriptors are given in Fig. 20.2.3.

Preferable hydrogen-bonding patterns of a series of related compounds containing a particular type of functional group can be obtained by graph-set analysis. For example, most primary amides prefer forming cyclic dimers and chains with a common hydrogen-bonding pattern $C(4)\left[R_{2}^{1}(6)\right]$. Furthermore, important insights may be gained by graph-set analysis of two seemingly unrelated organic crystals, which may lead to similar hydrogen-bonding patterns involving different functional groups. Some of the most common supramolecular synthons found in the Cambridge Structure Database are illustrated below:

The same set of hydrogen bond donors and acceptors may be connected in alternate ways to generate distinguishable motifs, giving rise to different
(c)

Patterns of hydrogen bonding found in three polymorphic forms of 5,5-diethylbarbituric acid. The graph-set descriptors are (a) $C(6)\left[R_{2}^{2}(8) R_{4}^{2}(12)\right]$,
(b) $C(10)\left[R_{2}^{2}(8)\right]$, and
(c) $C(6)\left[R_{2}^{2}(8) R_{4}^{4}(16)\right]$.
polymorphic forms. A good example is 5,5-diethylbarbituric acid, for which three crystalline polymorphs that exhibit polymeric ribbon structures are shown in Fig. 20.2.4.

### 20.2.3 Supramolecular construction based on complementary hydrogen bonding between heterocycles

The simple heterocyclic compounds melamine and cyanuric acid possess perfectly matched sets of donor/acceptor sites, $6 / 3$ and $3 / 6$ respectively, for complementary hydrogen bonding to form a planar hexagonal network (Fig. 20.2.5). Three distinct structural motifs can be recognized in this extended array: (a) linear tape,, (b) crinkled tape and (c) cyclic hexameric aggregate (rosette). Using barbituric acid derivatives and 2,4,6-triaminopyrimidine derivatives, the group of Whitesides has successfully synthesized all three preconceived systems. The conceptual design involves disruption of $\mathrm{N}-\mathrm{H} \cdots \mathrm{O}$ and $\mathrm{N}-\mathrm{H} \cdots \mathrm{N}$ hydrogen bonding in specific directions by introducing suitable hydrophobic bulky groups (Fig. 20.2.6).

The group of Reinhoudt has reported the construction of a $D_{3}$ hydrogenbonded assembly of three calix[4]arene bismelamine and six barbituric acid derivatives (Fig. 20.2.7).

### 20.2.4 Hydrogen-bonded networks exhibiting the supramolecular rosette pattern

Ward has shown that the self-assembly of cations and anions in a guanidinium sulfonate salt, through precise matching of donor and acceptor sites, gives rise to a layer structure displaying the rosette motif, which is not planar but corrugated since the configuration at the S atom is tetrahedral (Fig. 20.2.8). If the sulfonate R group is small, a bilayer structure with interdigitated substituents is formed [structural motif (a)]. When $R$ is large, a single layer structure with substituents alternating on opposite sides of the hydrogen-bonded layer is obtained [motif (b)]. Alternatively, the use of disulfonates provides covalent linkage between

cyanuric acid

melamine

Fig. 20.2.5.

adjacent layers to generate a pillared three-dimensional network, which may enclose a variety of guest species G [motif (c)].

The design and construction of hydrogen-bonded "supramolecular rosettes" from guanidinium/organic sulfonate, trimesic acid, or cyanuric acid/melamine depend on utilization of their topological equivalence, i.e., equal numbers of donor and acceptor hydrogen bonding sites and $C_{3}$ symmetry of the component moieties. As a modification of this strategy, a new kind of "fused-rosette ribbon" can be constructed with the guanidinium cation $\left(\mathrm{GM}^{+}\right)$and hydrogen carbonate dimer $\left(\mathrm{HC}^{-}\right)_{2}$ in the ratio of 1:1 (Fig. 20.2.9).

Each supramolecular rosette comprises a quasi-hexagonal assembly of two $\mathrm{GM}^{+}$and four $\mathrm{HC}^{-}$units connected by strong $\mathrm{N}_{\mathrm{GM}}-\mathrm{H} \cdots \mathrm{O}_{\mathrm{HC}}$ and $\mathrm{O}_{\mathrm{HC}}-\mathrm{H} \cdots \mathrm{O}_{\mathrm{HC}}$ hydrogen bonds. The $\left(\mathrm{HC}^{-}\right)_{2}$ dimer is shared as a common edge of adjacent rosettes and makes full use of its remaining acceptor sites in linking with $\mathrm{GM}^{+}$. On the other hand, each $\mathrm{GM}^{+}$in the resulting linear ribbon (or tape) still possesses a pair of free donor sites, and it is anticipated that some "molecular linker" with suitable acceptor sites may be used to bridge an array of parallel ribbons to form a sheet-like network. This design objective has been realized in the synthesis and characterization of the inclusion compound $5\left[\mathrm{C}\left(\mathrm{NH}_{2}\right)_{3}^{+}\right] \cdot 4\left(\mathrm{HCO}_{3}^{-}\right) \cdot 3\left[(n-\mathrm{Bu})_{4} \mathrm{~N}^{+}\right] \cdot 2\left[1,4-\mathrm{C}_{6} \mathrm{H}_{4}-\left(\mathrm{COO}^{-}\right)_{2}\right] \cdot 2 \mathrm{H}_{2} \mathrm{O}$ with the terephthalate ( $\mathrm{TPA}^{2-}$ ) anion functioning as a linker.

(a)

Fig. 20.2.6.
(a) Linear tape and (b) rosette 1:1 complexes constructed with barbituric acid derivatives and 2,4,6-triaminopyrimidine derivatives.

As shown in Fig. 20.2.10, each $\mathrm{HC}^{-}$provides one donor and one acceptor site to form a planar dimer motif $\left[\mathbf{A}, R_{2}^{2}(8)\right]$. The remaining eight acceptor sites of each $\left(\mathrm{HC}^{-}\right)_{2}$ dimer are topologically complemented by four $\mathrm{GM}^{+}$ units, such that each $\mathrm{GM}^{+}$connects two $\left(\mathrm{HC}^{-}\right)_{2}$ dimers through two pairs of $\mathrm{N}-\mathrm{H}_{\text {syn }} \cdots \mathrm{O}$ hydrogen bonds $\left[\mathbf{B}, R_{2}^{2}(8)\right]$. Thus two $\mathrm{GM}^{+}$units and two $\left(\mathrm{HC}^{-}\right)_{2}$ dimers constitute a planar, pseudo-centrosymmetric, quasi-hexagonal supramolecular rosette $\left[\mathbf{C}, R_{6}^{4}(12)\right]$ with inner and outer diameters of approximately 0.55 and 0.95 nm , respectively. In the resulting fused-rosette ribbon, the remaining two exo-orientated donor sites of each $\mathrm{GM}^{+}$unit form a pair of $\mathrm{N}-$ $\mathrm{H}_{\mathrm{anti}} \cdots \mathrm{O}$ hydrogen bonds [D, $\left.R_{2}^{2}(8)\right]$ with a TPA ${ }^{2-}$ carboxylate group. Thus two types of ladders are developed: type (I) [TPA ${ }^{2-}$ composed of $\mathrm{C}(10)$ to $\mathrm{C}(17)$ and $\mathrm{O}(13)$ to $\mathrm{O}(16)$ ] is consolidated by two independent water molecules that alternately bridge carboxylate oxygen atoms of neighboring steps by pairs of donor $\mathrm{O}_{\mathrm{w}}-\mathrm{H} \cdots$ O hydrogen bonds, generating a centrosymmetric ring motif $[\mathbf{E}$, $\left.R_{4}^{4}(22)\right]$ and pentagon pattern $\left[\mathbf{F}, R_{6}^{3}(12)\right]$; in the type (II) ladder [TPA ${ }^{2-}$ composed of $\mathrm{C}(18)$ to $\mathrm{C}(25)$ and $\mathrm{O}(17)$ to $\mathrm{O}(20)$ ], carboxylate oxygen atoms $\mathrm{O}(18)^{\prime}$

and $\mathrm{O}(19)$ belonging to adjacent steps are connected by the remaining $\mathrm{GM}^{+}$ ions, which are not involved in rosette formation, via two pairs of donor hydrogen bonds [G, $\left.R_{2}^{1}(6)\right]$ (Fig. 20.2.11(a)). The remaining two donor sites of each free $\mathrm{GM}^{+}$ion are linked to a carboxylate oxygen atom and a water molecule of TPA ${ }^{2-}$ column (I) of an adjacent layer to form a pentagon motif $\left[\mathbf{H}, R_{3}^{2}(8)\right]$, thus yielding a three-dimensional pillared layer structure (Fig. 20.2.11(b)). The large voids in the pillar region generate nanoscale channels extending along the [100] direction. The dimensions of the cross section of each channel are approximately $0.8 \times 2.2 \mathrm{~nm}$, within which three independent $\left[(n-\mathrm{Bu})_{4} \mathrm{~N}\right]^{+}$cations are aligned in separate columns in a well-ordered manner.

(a) Hydrogen-bonding motifs $\mathbf{G}$ and $\mathbf{H}$ involving linkage of the free guanidinium ion to neighboring rosette ribbon-terephthalate layers.
(b) Schematic presentation of the pillared layer structure.

Drawing upon the above successful design of a linear "fused-rosette ribbon" assembled from the $\left(\mathrm{HC}^{-}\right)_{2}$ dimer and $\mathrm{GM}^{+}$in 1:1 molar ratio, it would be challenging to attempt the hydrogen-bond mediated construction of two premeditated anionic rosette-layer architectures using guanidinium and ubiquitous $C_{3}$-symmetric oxo-anions that carry unequal charges, namely guanidiniumcarbonate I and guanidinium-trimesate II, as illustrated in Fig. 20.2.12.

In principle, the negatively charged, presumably planar network I can be combined with one molar equivalent of tetraalkylammonium ion $\mathrm{R}_{4} \mathrm{~N}^{+}$of the right size as interlayer template to yield a crystalline inclusion compound of stoichiometric formula $\left(\mathrm{R}_{4} \mathrm{~N}^{+}\right)\left[\mathrm{C}\left(\mathrm{NH}_{2}\right)_{3}^{+}\right] \mathrm{CO}_{3}^{2-}$ that is reminiscent of the graphite intercalates. Anionic network II, on the other hand, needs twice as many monovalent cations for charge balance, and furthermore possesses honeycomb-like host cavities of diameter $\sim 700 \mathrm{pm}$ that must be filled by

suitable guest species. The expected formula of the corresponding inclusion compound is $\left(\mathrm{R}_{4} \mathrm{~N}^{+}\right)_{2}\left[\mathrm{C}\left(\mathrm{NH}_{2}\right)_{3}^{+}\right]\left[1,3,5-\mathrm{C}_{6} \mathrm{H}_{3}\left(\mathrm{COO}^{-}\right)_{3}\right] \cdot \mathrm{G}$, where G is an entrapped guest moiety with multiple hydrogen-bond donor sites to match the nearly planar set of six carboxylate oxygens that line the inner rim of each cavity.

Crystallization of $\left(\mathrm{R}_{4} \mathrm{~N}^{+}\right)\left[\mathrm{C}\left(\mathrm{NH}_{2}\right)_{3}^{+}\right] \mathrm{CO}_{3}^{2-}$ by variation of R , based on conceptual network $\mathbf{I}$, was not successful. Taking into account the fact that the guanidinium ion can function as a pillar between layers and the carbonate ion is capable of forming up to twelve acceptor hydrogen bonds, as observed in crystalline bis(guanidinium) carbonate and $\left[\left(\mathrm{C}_{2} \mathrm{H}_{5}\right)_{4} \mathrm{~N}^{+}\right]_{2} \cdot \mathrm{CO}_{3}^{2-} \cdot 7\left(\mathrm{NH}_{2}\right)_{2} \mathrm{CS}$ [see Fig. 11.2.2(b)], the synthetic strategy was modified by incorporating a second guanidinium salt $\left[\mathrm{C}\left(\mathrm{NH}_{2}\right)_{3}\right] \mathrm{X}$ as an extra component. After much experimentation with various combinations of R and X , the targeted construction of network $\mathbf{I}$, albeit in undulating form, was realized through the isolation of crystalline $4\left[\left(\mathrm{C}_{2} \mathrm{H}_{5}\right)_{4} \mathrm{~N}^{+}\right] \cdot 8\left[\mathrm{C}\left(\mathrm{NH}_{2}\right)_{3}^{+}\right] \cdot 3\left(\mathrm{CO}_{3}\right)^{2-} \cdot 3\left(\mathrm{C}_{2} \mathrm{O}_{4}\right)^{2-} \cdot 2 \mathrm{H}_{2} \mathrm{O}(\mathbf{1})$.

In the asymmetric unit of ( $\mathbf{1}$ ), there are two independent carbonate anions and five independent guanidinium cations, which are henceforth conveniently referred to by their carbon atom labels in bold type. Carbonate $\mathbf{C}(\mathbf{1})$ and guanidinium $\mathbf{C}(\mathbf{3})$ each has one bond lying in a crystallographic mirror plane; together with carbonate $\mathbf{C}(\mathbf{2})$ and guanidinium $\mathbf{C}(\mathbf{4})$, they form a nonplanar zigzag ribbon running parallel to the $b$ axis, neighboring units being connected by a pair of strong $\mathrm{N}^{+}-\mathrm{H} \cdots \mathrm{O}^{-}$hydrogen bonds (Fig. 20.2.13). Adjacent anti-parallel $\left\{\left[\mathrm{C}\left(\mathrm{NH}_{2}\right)_{3}\right]^{+} \cdot \mathrm{CO}_{3}^{2-}\right\}_{\infty}$ ribbons are further cross-linked by strong $\mathrm{N}^{+}-\mathrm{H} \cdots \mathrm{O}^{-}$hydrogen bonds to generate a highly corrugated rosette layer, which is folded into a plane-wave pattern by guanidinium $\mathbf{C}(\mathbf{5})$ (Fig. 20.2.14). Guanidinium $\mathbf{C}(\mathbf{6})$ and $\mathbf{C}(\mathbf{7})$ protruding away from carbonate $\mathbf{C}(\mathbf{1})$ and $\mathbf{C}(\mathbf{2})$ are hydrogen-bonded to the twofold disordered oxalate ion containing $\mathbf{C}(\mathbf{8})$ and $\mathbf{C}(9)$ (Fig. 20.2.14), forming a pouch that cradles the disordered $\left(\mathrm{C}_{2} \mathrm{H}_{5}\right)_{4} \mathrm{~N}^{+}$ion. The carbonate ions $\mathbf{C}(\mathbf{1})$ and $\mathbf{C}(\mathbf{2})$ each form eleven acceptor hydrogen bonds, only one fewer than the maximum number. The resulting composite hydrogenbonded layers at $x=1 / 4$ and ${ }^{3 / 4}$ are interconnected by $\left[\left(\mathrm{C}_{2} \mathrm{O}_{4}^{2-} \cdot\left(\mathrm{H}_{2} \mathrm{O}\right)_{2}\right]_{\infty}\right.$

Fig. 20.2.13.
Projection diagram showing a portion of the nonplanar anionic rosette network I concentrated at $a=1 / 4$ in the crystal structure of (1). The atom types are differentiated by size and shading, and hydrogen bonds are indicated by dotted lines. Adjacent antiparallel $\left\{\left[\mathrm{C}\left(\mathrm{NH}_{2}\right)_{3}\right]^{+} \cdot \mathrm{CO}_{3}^{2-}\right\}_{\infty}$ ribbons run parallel to the $b$ axis. Symmetry transformations: $\mathrm{A}(1 / 2-x, 1-y$, $1 / 2+z) ;$ B $(1 / 2-x, y-1 / 2, z-1 / 2)$.

chains derived from centrosymmetric oxalate $\mathbf{C}(\mathbf{1 0})$ and water molecules O1w and O 2 w via strong ${ }^{+} \mathrm{N}-\mathrm{H} \cdots \mathrm{O}^{-}$hydrogen bonds to generate a complex three-dimensonal host framework, within which the second kind of disordered $\left(\mathrm{C}_{2} \mathrm{H}_{5}\right)_{4} \mathrm{~N}^{+}$ions are accommodated in a zigzag fashion within channels extending along the [010] direction.

The predicted assembly of guanidinium-trimesate network II was achieved through the crystallization of $\left[\left(\mathrm{C}_{2} \mathrm{H}_{5}\right)_{4} \mathrm{~N}^{+}\right]_{2} \cdot\left[\mathrm{C}\left(\mathrm{NH}_{2}\right)_{3}^{+}\right] \cdot[1,3$, $\left.5-\mathrm{C}_{3} \mathrm{H}_{3}\left(\mathrm{COO}^{-}\right)_{3}\right] \cdot 6 \mathrm{H}_{2} \mathrm{O}(2)$. The guanidinium and trimesate ions are connected together by pairs of strong charge-assisted ${ }^{+} \mathrm{N}-\mathrm{H} \cdots \mathrm{O}^{-}$hydrogen bonds to generate an essentially planar rosette layer with large honeycomb cavities [Fig. 20.2.15 (left)]. Three independent water molecules constitute a cyclic $\left(\mathrm{H}_{2} \mathrm{O}\right)_{6}$ cluster of symmetry 2 , which is tightly fitted into each host cavity by adopting a flattened-chair configuration in an out-of-plane orientaion, with $\mathrm{O} \cdots \mathrm{O}$ distances comparable to 275.9 pm in deuterated ice $\mathrm{I}_{\mathrm{h}}$. Each water molecule has its ordered hydrogen atom pointing outward to form a strong $\mathrm{O}-\mathrm{H} \cdots \mathrm{O}^{-}$hydrogen bond with a carboxylate oxygen on the inner rim of the cavity. The well-ordered $\left(\mathrm{C}_{2} \mathrm{H}_{5}\right)_{4} \mathrm{~N}^{+}$guests, represented by large spheres, are sandwiched between anionic rosette host layers with an interlayer spacing of $\sim 7.5 \AA$ [Fig. 20.2.15 (right)].

Fig. 20.2.14.
Perspective view of the crystal structure of (1) along [001]. The undulating guanidinium-carbonate rosette network $\mathbf{I}$ appears as a sinusoidal cross section. Adjacent composite hydrogen-bonded layers are interconnected by a $\left[\mathrm{C}_{2} \mathrm{O}_{4}^{2-} \cdot\left(\mathrm{H}_{2} \mathrm{O}\right)_{2}\right]_{\infty}$ chain. The disordered oxalate is shown in one possible orientation, and the two different types of disordered $\mathrm{Et}_{4} \mathrm{~N}^{+}$ions (represented by large semi-transparent spheres) are included in the pouches and the zigzag channels running parallel to the [010] direction, respectively.

Fig. 20.2.15.
(Left) Projection diagram showing the hydrogen-bonding scheme in the infinite rosette layer II of (2). Only one of the two cyclic arrangements of disordered H atoms lying on the edges of each $\left(\mathrm{H}_{2} \mathrm{O}\right)_{6}$ ring is displayed. Symmetry transformation: $\mathrm{A}\left(1-x, y,{ }^{1} / 2-z\right)$. (Right) Sandwich-like crystal structure of (2) viewed along the $b$ axis.

The malleability of guanidinium-carbonate network $\mathbf{I}$, rendered possible by the prolific hydrogen-bond accepting capacity of its carbonate building block, opens up opportunities for further exploration of supramolecular assembly. The flattened-chair $\left(\mathrm{H}_{2} \mathrm{O}\right)_{6}$ guest species, filling the cavity within robust guanidinium-trimesate layer II and being comparable to that in the host lattice of bimesityl-3,3'-dicarboxylic acid, may conceivably be replaced by appropriate hydrogen-bond donor molecules. The present anionic rosette networks are unlike previously reported neutral honeycomb lattices of the same $(6,3)$ topology, thus expanding the scope of de novo engineering of charge-assisted hydrogen-bonded networks using ionic modular components, from which discrete molecular aggregates bearing the rosette motif may be derived.

### 20.3 Supramolecular chemistry of the coordination bond

The predictable coordination geometry of transition metals and the directional characteristics of interacting sites in a designed ligand provide the blueprint (or programmed instructions) for the rational synthesis of a wide variety of supramolecular inorganic and organometallic systems. Current research is concentrated in two major areas: (a) the construction of novel supermolecules from the intermolecular association of a few components and (b) the spontaneous organization (or self-assembly) of molecular units into one-, two-, and threedimensional arrays. In the solid state, the supermolecules and supramolecular arrays can further associate with one another to yield gigantic macroscopic conglomerates, i.e., supramolecular structures of higher order.

### 20.3.1 Principal types of supermolecules

The supermolecules that have been synthesized include large metallocyclic rings, helices, host-guest complexes, and interlocked structures such as catenanes, rotaxanes, and knots.

[2]rotaxane

molecular necklace

polyrotaxane

topomers of a trefoil knot

polycatenane

Borromean link

The simplest catenane is [2]catenane which contains two interlocked rings. A polycatenane has three or more rings interlocked in a one-to-one linear fashion. A rotaxane has a ring component (or a bead) threaded by a linear component (or a string) with a stopper at each end. A polyrotaxane has several rings threaded onto the same string. A molecular necklace is a cyclic oligorotaxane with several rings threaded by a closed loop. There are two topological isomers for a trefoil knot. The Borromean link is composed of three interlocked rings such that the scission of any one ring unlocks the other two. These topologies are shown in Fig. 20.3.1.

### 20.3.2 Some examples of inorganic supermolecules

## (1) Ferric wheel

The best known example of a large metallocyclic ring is the "ferric wheel" $\left[\mathrm{Fe}(\mathrm{OMe})_{2}\left(\mathrm{O}_{2} \mathrm{CCH}_{2} \mathrm{Cl}\right)\right]_{10}$ prepared from the reaction of oxo-centered trinuclear $\left[\mathrm{Fe}_{3} \mathrm{O}\left(\mathrm{O}_{2} \mathrm{CCH}_{2} \mathrm{Cl}\right)_{6}\left(\mathrm{H}_{2} \mathrm{O}\right)_{3}\right]\left(\mathrm{NO}_{3}\right)$ and $\mathrm{Fe}\left(\mathrm{NO}_{3}\right)_{3} \cdot 9 \mathrm{H}_{2} \mathrm{O}$ in methanol. An X-ray analysis showed that it is a decameric wheel having a diameter of about 1.2 nm with a small and unoccupied hole in the middle (Fig. 20.3.2). Each pair of iron(III) centers are bridged by two methoxides and one $O, O^{\prime}$-chloroacetate group.

## (2) Hemicarceplex

A carcerand is a closed-surface, globular host molecule with a hollow interior that can enclose guest species such as small organic molecules and inorganic ions to form a carceplex. A hemicarcerand is a carcerand that contains portals large enough for the imprisoned guest molecule to escape at high temperatures, but otherwise remains stable under normal laboratory conditions. The hemicarcerand host molecule designed by Cram shown in Fig. 20.3.3 has idealized $D_{4 \mathrm{~h}}$ symmetry with its fourfold axis roughly coincident with the long axis of the ferrocene guest, which lies at an inversion center and hence adopts a fully staggered $D_{5 d}$ conformation. The 1,3-diiminobenzene groups connecting the northern and southern hemispheres of the hemicarceplex are arranged like paddles in a paddle wheel around the circumference of the central cavity.

Fig. 20.3.1.

Fig. 20.3.2.
Molecular structure of the ferric wheel.

Fig. 20.3.3.
A hemicarceplex consisting of a hemicarcerand host molecule enclosing a ferrocene guest molecule.

## (3) [2]Catenane $\mathbf{P t}(\mathrm{II})$ complex

The coordination bond between a pyridyl N atom and $\mathrm{Pt}(\mathrm{II})$ is normally quite stable, but it becomes labile in a highly polar medium at high concentration. Figure 20.3.4 shows the overall one-way transformation of a binuclear cyclic $\mathrm{Pt}(\mathrm{II})$ complex into a dimeric [2]catenane framework, which can be isolated as its nitrate salt upon cooling.

(4) Helicate

In a helicate the polytopic ligand winds around a linear array of metal ions lying on the helical axis, so that its ligation sites match the coordination requirements

$\left(\mathrm{NO}_{3}\right)_{8}$
of the metal centers. The two enantiomers of a helicate are designated $P$ - for a right-handed helix and $M$ - for a left-handed helix [Fig. 20.3.5(a)]. An example of a $M$-type $\mathrm{Cu}(\mathrm{I})$ double helicate is shown in Fig. 20.3.5(b). Double helicates containing up to five $\mathrm{Cu}(\mathrm{I})$ centers and triple helicates involving the wrapping of oligobidentate ligands around octahedral $\mathrm{Co}(\mathrm{II})$ and $\mathrm{Ni}(\mathrm{II})$ centers have been synthesized.

## (5) Molecular trefoil knot

The first molecular trefoil knot was successfully synthesized by DietrichBuchecker and Sauvage according to the scheme shown in Fig. 20.3.6. A specially designed ligand consisting of two diphenolic 1,10-phenanthroline units tied together by a tetramethylene tether was reacted with $\left[\mathrm{Cu}(\mathrm{MeCN})_{4}\right] \mathrm{BF}_{4}$ to give a dinuclear double helix. This precursor was then treated under high dilution conditions with two equivalents of the diiodo derivative of hexaethylene glycol in the presence of $\mathrm{Cs}_{2} \mathrm{CO}_{3}$ to form the cyclized complex in low yield. Finally, demetallation of this helical dicopper complex yielded the desired free trefoil knot with retention of topological chirality. It should be noted that in the crucial cyclization step, the double helical precursor is in equilibrium with a

non-helical species, which leads to an unknotted dicopper complex consisting of two 43 -membered rings arranged around two $\mathrm{Cu}(\mathrm{I})$ centers in a face-to-face manner (Fig. 20.3.7).

## (6) Molecular Borromean link

The connection between chemistry and topology is exemplified by the elegant construction of a molecular Borromean link that consists of three identical interlocked rings. In the designed synthesis, each component ring comprises two short and two long segments. The programmed, one-step self-assembly process is indicated by the scheme illustrated in Fig. 20.3.8.

Self-assembly of the molecular Borromean link (a dodecacation $\mathbf{B R}^{12+}$ ) is achieved by a template-directed cooperative process that results in over $90 \%$ yield. Each of the three component rings ( L ) in $\mathbf{B} \mathbf{R}^{12+}$ is constructed from [2+2] macrocyclization involving two DFP (2,6-diformylpyridine) and two DAB (diamine containing a $2,2^{\prime}$-bipyridyl group) molecules. Kinetically labile

Fig. 20.3.7.
Template synthesis of a free trefoil knot and an unknotted product.
zinc(II) ions serve efficiently as templates in multiple molecular recognition that results in precise interlocking of three macrocyclic ligands:
$6 \mathrm{DFB}+6\left[\mathrm{DABH}_{4}\right]\left(\mathrm{CF}_{3} \mathrm{CO}_{2}\right)_{4}+9 \mathrm{Zn}\left(\mathrm{CF}_{3} \mathrm{CO}_{2}\right)_{2} \xrightarrow{\mathrm{CH}_{3} \mathrm{OH}}\left[\mathrm{L}_{3}\left(\mathrm{ZnCF}_{3} \mathrm{CO}_{2}\right)_{6}\right] \cdot 3\left[\mathrm{Zn}\left(\mathrm{CF}_{3} \mathrm{CO}_{2}\right)_{4}\right]+12 \mathrm{H}_{2} \mathrm{O}$
III
$\left[\mathbf{B R}\left(\mathrm{CF}_{3} \mathrm{CO}_{2}\right)_{6}\right] \cdot 3\left[\mathrm{Zn}\left(\mathrm{CF}_{3} \mathrm{CO}_{2}\right)_{4}\right]$
An X-ray analysis of $\left[\mathbf{B R}\left(\mathrm{CF}_{3} \mathrm{CO}_{2}\right)_{6}\right] \cdot 3\left[\mathrm{Zn}\left(\mathrm{CF}_{3} \mathrm{CO}_{2}\right)_{4}\right]$ revealed that the hexacation $\left[\mathbf{B R}\left(\mathrm{CF}_{3} \mathrm{CO}_{2}\right)_{6}\right]^{6+}$ has $S_{6}$ symmetry with each macrocyclic ligand L adopting a chair-like conformation (Fig. 20.3.8). The interlocked rings are consolidated by six $\mathrm{Zn}(\mathrm{II})$ ions, each being coordinated in a slightly distorted octahedral geometry by the endo-tridentate diiminopyridyl group of one ring, the exo-bidentate bipyridyl group of another ring, and an oxygen atom of a $\mathrm{CF}_{3} \mathrm{CO}_{2}^{-}$ligand. Each bipyridyl group is sandwiched unsymmetrically between a pair of phenolic rings at $\pi-\pi$ stacking distance of 361 and 366 pm in different directions.

In the crystal packing, the $\left[\mathbf{B R}\left(\mathrm{CF}_{3} \mathrm{CO}_{2}\right)_{6}\right]^{6+}$ ions are arranged in hexagonal arrays with intermolecular $\pi-\pi$ stacking interactions of 331 pm and $\mathrm{C}-\mathrm{H} \cdots \mathrm{O}=\mathrm{C}$ hydrogen bonds ( $\mathrm{H} \cdots \mathrm{O} 252 \mathrm{pm}$ ), generating columns along $c$ that accommodate the $\left[\mathrm{Zn}\left(\mathrm{CF}_{3} \mathrm{CO}_{2}\right)_{4}\right]^{2-}$ counterions.

### 20.3.3 Synthetic strategies for inorganic supermolecules and coordination polymers

Two basic approaches for the synthesis of inorganic supermolecules and one-, two-, and three-dimensional coordination polymers have been developed:

DFP (used in construction of short ring segment)

DAB (used in construction of long ring segment)

Fig. 20.3.8.
Synthetic scheme for one-step supramolecular assembly of the molecular Borromean link $\left[\mathrm{L}_{3} \mathrm{Zn}_{6}\right]^{12+} \equiv \mathbf{B R}^{12+}$; its three component interlocked rings are differentiated by different degrees of shading. Each octahedral zinc(II) ion is coordinated by an endo- $\mathrm{N}_{3}$ ligand set and a chelating bipyridyl group belonging to a different ring, the monodentate acetate ligand being omitted for clarity. From K. S. Chichak, S. J. Cantrill, A. R. Pease, S.-H. Chiu, G. W. V. Cave, J. L. Atwood and J. F. Stoddart, Science (Washington) 304, 1308-12 (2004).
(1) Transition-metal ions are employed as nodes and bifunctional ligands as spacers. Commonly used spacer ligands are pseudohalides such as cyanide, thiocyanate, and azide, and N -donor ligands such as pyrazine, $4,4^{\prime}$ bipyridine, and $2,2^{\prime}$-bipyrimidine. Besides discrete supermolecules, some one-, two-, and three-dimensional architectural motifs generated from this strategy are shown in Fig. 20.3.9.

If all nodes at the boundary of a portion of a motif are bound by terminal ligands, a discrete molecule will be formed. An example is the square grid shown in Fig. 20.3.10. Reaction of the tritopic ligand $6,6^{\prime}$ -bis[2-(6-methylpyridyl)]-3,3'-bipyridazine ( $\mathrm{Me}_{2} \mathrm{bpbpz}$ ) with silver triflate in 2:3 molar ratio in nitromethane results in self-assembly of a complex of the formula $\left[\mathrm{Ag}_{9}\left(\mathrm{Me}_{2} \mathrm{bpbpz}\right)_{6}\right]\left(\mathrm{CF}_{3} \mathrm{SO}_{3}\right)_{9}$. X-ray analysis showed that the $\left[\mathrm{Ag}_{9}\left(\mathrm{Me}_{2} \mathrm{bpbpz}\right)_{6}\right]^{9+}$ cation is in the form of a $3 \times 3$ square grid, with two sets of $\mathrm{Me}_{2} \mathrm{bpbpz}$ ligands positioned above and below the mean plane of the silver centers, as shown in Fig. 20.3.10(a), so that each $\mathrm{Ag}(\mathrm{I})$ atom is in a distorted tetrahedral environment. The grid is actually distorted into a diamond-like shape due to the curved nature of the ligand, and the

(a)

angle between the mean planes of the two sets of ligands is about $72^{\circ}$ (Fig. 20.3.10(b)).
(2) Exodentate multitopic ligands are used to link transition metal ions into building blocks. Some examples of such ligands are 2,4,6-tris(4-pyridyl)-1,3,5-triazine, oligopyridines, and 3- and 4-pyridyl-substituted porphyrins.

In the following sections, selected examples from the recent literature are used to illustrate the creative research activities in transition-metal supramolecular chemistry.

### 20.3.4 Molecular polygons and tubes

## (1) Nickel wheel

The reaction of hydrated nickel acetate with excess 6-chloro-2-pyridone (Hchp) produces in $60 \%$ yield a dodecanuclear nickel complex, which can be recrystallized from tetrahydrofuran as a solvate of stoichiometry $\left[\mathrm{Ni}_{12}\left(\mathrm{O}_{2} \mathrm{CMe}\right)_{12}(\mathrm{chp})_{12}\left(\mathrm{H}_{2} \mathrm{O}\right)_{6}(\mathrm{THF})_{6}\right]$. X-ray structure analysis revealed that this wheel-like molecule (Fig. 20.3.11) lies on a crystallographic threefold axis. There are two kinds of nickel atoms in distorted octahedral coordination: $\mathrm{Ni}(1)$ is bound to three O atoms from acetate groups, two O atoms from chp ligands, and an aqua ligand, whereas $\mathrm{Ni}(2)$ is surrounded by two acetate O atoms, two chp O atoms, an aqua ligand, and the terminal THF ligand. All ligands, other than THF, are involved in bridging pairs of adjacent nickel atoms. The structure of this nickel metallocycle resembles that of the decanuclear "ferric wheel" $\left[\mathrm{Fe}(\mathrm{OMe})_{2}\left(\mathrm{O}_{2} \mathrm{CCH}_{2} \mathrm{Cl}\right)\right]_{10}$ (see Fig. 20.3.2). Both complexes feature a closed chain of intersecting $\mathrm{M}_{2} \mathrm{O}_{2}$ rings, with each ring additionally bridged by an acetate ligand. They differ in that in the ferric wheel the carboxylate ligands are all exterior to the ring, whereas in the nickel wheel half of the acetate ligands lie within the central cavity.

Hchp

## (2) Nano-sized tubular section

The ligand 2,4,6-tris[(4-pyridyl)methylsulfanyl]-1,3,5-triazine (tpst) possesses nine possible binding sites to transition metals for the assembly of supramolecular systems. Its reaction with $\mathrm{AgNO}_{3}$ in a 1:2 molar ratio in $\mathrm{DMF} / \mathrm{MeOH}$ followed by addition of $\mathrm{AgClO}_{4}$ produces $\mathrm{Ag}_{7}(\mathrm{tpst})_{4}\left(\mathrm{ClO}_{4}\right)_{2}\left(\mathrm{NO}_{3}\right)_{5}(\mathrm{DMF})_{2}$. In the crystal structure, two tpst ligands coordinate to three silver(I) ions to form a bicyclic ring. Two such rings are fitted together by $\mathrm{Ag}-\mathrm{N}$ and $\mathrm{Ag}-\mathrm{S}$ bonds involving a pair of bridging silver ions to generate a nano-sized tubular section $\left[\mathrm{Ag}_{7}(\mathrm{tpst})_{4}\right]$ with dimensions of $1.34 \times 0.96 \times 0.89 \mathrm{~nm}$, which encloses two perchlorate ions and two DMF molecules (Fig. 20.3.12). The tubular sections are further linked by additional $\mathrm{Ag}-\mathrm{N}$ and $\mathrm{Ag}-\mathrm{S}$ bonds to form an infinite chain. The nitrate ions are located near the silver ions and imbedded in between the linear polymers.

The two independent tpst ligands are each bound to four silver atoms but in different coordination modes: three pyridyl N plus one thioether S , or three pyridyl N plus one triazine N . The silver atoms exhibit two kinds of coordination modes: normal linear $\mathrm{AgN}_{2}$ and a very unusual $\mathrm{AgN}_{2} \mathrm{~S}_{2}$ mode of distorted square-planar geometry.

## (3) Infinite square tube

The reaction of 2-aminopyrimidine (apym), $\mathrm{Na}\left[\mathrm{N}(\mathrm{CN})_{2}\right]$, and $\mathrm{M}\left(\mathrm{NO}_{3}\right)_{2} \cdot 6 \mathrm{H}_{2} \mathrm{O}$ $(\mathrm{M}=\mathrm{Co}, \mathrm{Ni})$ gives $\mathrm{M}\left[\mathrm{N}(\mathrm{CN})_{2}\right]_{2}($ apym $)$, which consists of a packing of infinite molecular tubes of square cross section. In each tube, the metal atoms constitute the edges and three connecting $\mathrm{N}(\mathrm{CN})_{2}^{-}$(dicyanamide) ligands form the sides (Fig. 20.3.13). The octahedral coordination of the metal atoms is completed by chains of two-connecting ligands (with the amide nitrogen uncoordinated) which occupy the outside of each edge, as well as monodentate apym ligands. The length of a side of the molecular tube is 486.4 pm for $\mathrm{M}=\mathrm{Co}$ and 482.1

### 20.3.5 Molecular polyhedra

## (1) Tetrahedral iron(II) host-guest complex

The structural unit M (tripod) ${ }^{n+}$ (tripod $\left.=\mathrm{CH}_{3} \mathrm{C}\left(\mathrm{CH}_{2} \mathrm{PPh}_{2}\right)_{3}\right)$ has been used as a template for the construction of many supramolecular complexes. For example, the host-guest complex $\left[\mathrm{BF}_{4} \subset\left\{(\text { tripod })_{3} \mathrm{Fe}\right\}_{4}(\right.$ trans $\left.\mathrm{NCCH}=\mathrm{CHCN})_{6}\left(\mathrm{BF}_{4}\right)_{4}\right]\left(\mathrm{BF}_{4}\right)_{3}$ has been synthesized from the reaction of tripod, $\mathrm{Fe}\left(\mathrm{BF}_{4}\right)_{3} \cdot 6 \mathrm{H}_{2} \mathrm{O}$, and fumaronitrile in a 4:4:6 molar ratio in $\mathrm{CH}_{2} \mathrm{Cl}_{2} / \mathrm{EtOH}$ at $20^{\circ} \mathrm{C}$. The tetranuclear Fe (II) complex has idealized symmetry $T$, with a crystallographic twofold axis passing through the midpoints of a pair of edges of the $\mathrm{Fe}_{4}$ tetrahedron (Fig. 20.3.14). The B-F bonds of the encapsulated $\mathrm{BF}_{4}^{-}$ ion point toward the corner iron atoms. Each face of the $\mathrm{Fe}_{4}$ tetrahedron is

capped by a $\mathrm{BF}_{4}^{-}$group, and the remaining three are located in voids between the complex cations.

## (2) Cubic molecular box

The cyanometalate box $\left\{\mathrm{Cs} \subset\left[\mathrm{Cp} * \mathrm{Rh}(\mathrm{CN})_{3}\right]_{4}\left[\mathrm{Mo}(\mathrm{CO})_{3}\right]_{4}\right\}^{3-}$ is formed in low yield from the reaction of $\left[\mathrm{Cp} * \mathrm{Rh}(\mathrm{CN})_{3}\right]^{-}\left(\mathrm{Cp}^{*}=\mathrm{C}_{5} \mathrm{Me}_{5}\right)$ and $\left(\eta^{6}-\mathrm{C}_{6} \mathrm{H}_{3} \mathrm{Me}_{3}\right) \mathrm{Mo}(\mathrm{CO})_{3}$ in the presence of cesium ions, and it can be crystallized as a $\mathrm{Et}_{4} \mathrm{~N}^{+}$salt. The $\mathrm{Cs}^{+}$ion serves as a template in the self-assembly of the anionic molecular box, which has a cubic $\mathrm{Rh}_{4} \mathrm{Mo}_{4}(\mu-\mathrm{CN})_{12}$ core with three exterior carbonyl ligands attached to each Mo and a Cp * group to each Rh . The encapsulated $\mathrm{Cs}^{+}$ion has a formal coordination number of 12 if interaction with the centers of cyano groups is considered (Fig. 20.3.15).

## (3) Lanthanum square antiprism

A tris-bidentate pyrazolone ligand, 4-(1,3,5-benzenetricarbonyl)-tris(3-methyl-1-phenyl-2-pyrazoline-5-one $\left(\mathrm{H}_{3} \mathrm{~L}\right)$, has been designed and synthesized. When this rigid $C_{3}$-symmetric ligand was reacted with $\mathrm{La}(\mathrm{acac})_{3}$ in dimethylsufoxide (DMSO), the complex $\mathrm{La}_{8} \mathrm{~L}_{8}(\mathrm{DMSO})_{24}$ was obtained in $81 \%$ yield. An X-ray analysis revealed a square-antiprismatic structure with idealized $D_{4 \mathrm{~d}}$ symmetry, with each $\mathrm{L}^{3-}$ ligand occupying one of the eight triangular faces (Fig. 20.3.16). In the coordination sphere of the $\mathrm{La}^{3+}$ ion, six sites are filled by O atoms from three $\mathrm{L}^{3-}$ ligands and the remaining three by DMSO molecules which point into the central cavity. It was found that the DMSO ligands could be replaced partially by methanol in recrystallization.

Fig. 20.3.14.
Molecular structure of the tetrahedral Fe (II) host-guest complex cation. The capping $\mathrm{BF}_{4}^{-}$groups and the phenyl rings of the tripod ligands have been omitted for clarity. From S. Mann, G. Huttner, L. Zsolnai and K. Heinze, Angew. Chem. Int. Ed. 35, 2808-9 (1996).

## Structural Chemistry of Selected Elements

Fig. 20.3.15.

## (4) Super-adamantoid cage

A 2:3 molar mixture of $\mathrm{MeC}\left(\mathrm{CH}_{2} \mathrm{PPh}_{2}\right)_{3}$ (triphos) and silver triflate gives $\left[\mathrm{Ag}_{6}(\text { triphos })_{4}\left(\mathrm{CF}_{3} \mathrm{SO}_{3}\right)_{4}\right]\left(\mathrm{CF}_{3} \mathrm{SO}_{3}\right)_{2}$ in high yield. The inorganic "superadamantoid" cage $\left[\mathrm{Ag}_{6}(\text { triphos })_{4}\left(\mathrm{CF}_{3} \mathrm{SO}_{3}\right)_{4}\right]^{2+}$ exhibiting approximate $T$ molecular symmetry is formed with the $\mathrm{CF}_{3} \mathrm{SO}_{3}^{-}$ion as a template. In the cage structure (Fig. 20.3.17), an octahedron of silver(I) ions is bound by two sets of tritopic triphos and triflate ligands, each occupying four alternating faces of the octahedron. Thus six silver ions and four triphos ligands constitute one adamantane core, and likewise the silver ions and triflate ligands form a second adamantane core. A novel feature in this structure is the "endo-methyl" conformation of the triphos ligand, leaving only a small cavity at the center.

## (5) Chemical reaction in a coordination cage

Flat panel-like ligands with multiple interacting sites have been used for metaldirected self-assembly of many fascinating supramolecular 3D structures. A simple triangular "molecular panel" is 2,4,6-tris(4-pyridyl)-1,3,5-triazine (L), which has been employed by Fujita to assemble a discrete $\left[\{\mathrm{Pt}(\text { bipy })\}_{6} \mathrm{~L}_{4}\right]^{12+}$ (bipy $=2,2^{\prime}$-bipyridine) coordination cage in quantitative yield by treating $\operatorname{Pt}($ bipy $)\left(\mathrm{NO}_{3}\right)_{2}$ with L in a 3:2 molar ratio. In this complex cation, the $\mathrm{Pt}(\mathrm{II})$ atoms constitute an octahedron, and the triangular panels (L ligands) are located at four of the eight faces (Fig. 20.3.18). The Pt(bipy) ${ }^{2+}$ fragment thus serves as a cis-protected coordination block, each linking a pair of molecular panels. The nano-sized central cavity with a diameter of $\sim 1 \mathrm{~nm}$ is large enough to accommodate several guest molecules. Different types of guest species such as adamantane, adamantane carboxylate, $o$-carborane, and anisole have been used. In particular, C-shaped molecules such as cis-azobenzene and cis-stilbene derivatives can be encapsulated in the cavity as a dimer stabilized by the "phenyl-embrace" interaction.

Fig. 20.3.17.
The super-adamantoid core of the $\left[\mathrm{Ag}_{6}(\text { triphos })_{4}\left(\mathrm{CF}_{3} \mathrm{SO}_{3}^{-}\right)_{4}\right]^{2+}$ cage. The broken lines indicate one of the two adamantane cores formed by silver ions and triflate ligands, whose F atoms have been omitted for clarity. From S. L. James, D. M. P. Mingos, A. J. P. White and D. Williams, Chem Commun., 2323-4 (2000).

L

Fig. 20.3.18.
Self-assembly of $\left[\{\operatorname{Pt}(\text { bipy })\}_{6} \mathrm{~L}_{4}\right]^{12+}$ cage.

Useful chemical reactions have been carried out in the nano-sized cavity, as illustrated by the in situ isolation of a labile cyclic siloxane trimer (Fig. 20.3.19). In the first step, three to four molecules of phenyltrimethoxysilane enter the cage and are hydrolyzed to siloxane molecules. Next, condensation takes place in the confined environment to generate the cyclic trimer $\{\mathrm{SiPh}(\mathrm{OH}) \mathrm{O}-\}_{3}$, which is trapped and stabilized in a pure form. The overall reaction yields an inclusion complex $\left[\{\mathrm{SiPh}(\mathrm{OH}) \mathrm{O}-\}_{3} \subset\{\mathrm{Pt}(\text { bipy })\}_{6} \mathrm{~L}_{4}\right]\left(\mathrm{NO}_{3}\right)_{12} \cdot 7 \mathrm{H}_{2} \mathrm{O}$, which can be crystallized from aqueous solution in $92 \%$ yield. The all-cis configuration of the cyclic siloxane trimer and the structure of the inclusion complex have been determined by NMR and ESI-MS.

## (6) Nanoscale dodecahedron

The dodecahedron is a Platonic solid that contains 12 fused pentagons formed from 20 vertices and 30 edges. An organic molecule of this exceptionally high icosahedral $\left(I_{\mathrm{h}}\right)$ symmetry is the hydrocarbon dodecahedrane $\mathrm{C}_{20} \mathrm{H}_{20}$, which was first synthesized by Paquette in 1982. Recently an inorganic ana$\log$ has been obtained from edge-directed self-assembly of a metallocyclic structure (Fig. 20.3.20) in a remarkably high $99 \%$ yield. The tridentate ligand at each vertex is tris( $4^{\prime}$-pyridyl)methanol, and the linear bidentate subunit at each edge is bis $\left[4,4^{\prime}\right.$ - trans- $\left.\left.\mathrm{Pt}\left(\mathrm{PEt}_{3}\right)_{2}\left(\mathrm{CF}_{3} \mathrm{SO}_{3}\right)\right)\right]$ benzene. The dodecahedral molecule carries 60 positive charges and encloses $60 \mathrm{CF}_{3} \mathrm{SO}_{3}^{-}$anions, and its estimated diameter $d$ along the threefold axis is about 5.5 nm . Using bis $\left[4,4^{\prime}-\left(\right.\right.$ trans $\left.\left.-\mathrm{Pt}\left(\mathrm{PPh}_{3}\right)_{2}\left(\mathrm{CF}_{3} \mathrm{SO}_{3}\right)\right)\right]$ biphenyl as a longer linear linker, $d$ for the resulting enlarged dodecahedron increases to about 7.5 nm .

Fig. 20.3.19.
Generation and stabilization of cyclic siloxane trimer in a self-assembled coordination cage. From M. Yoshizawa, T. Kusukawa, M. Fujita, and K. Yamaguchi. J. Am. Chem. Soc. 122, 6311-12, (2000).

Fig. 20.3.20.
Self-assembly of a nanoscale dodecahedron. The OH group attached to each quaternary C atom of the tris( $4^{\prime}$-pyridyl)methanol molecule has been omitted for clarity. From B. Olenyuk, M. D. Levin, J. A. Whiteford, J. E. Shield and P. J. Stang, J. Am. Chem. Soc. 121, 10434-5 (2000).

## Fig. 20.3.21.

The $\left[\mathrm{Mn}_{9}(\mu-\mathrm{CN})_{30} \mathrm{Mo}_{6}\right]$ core of the high-spin cluster. From J. Larionova, M. Gross, M. Pilkington, H. Andres, H. Stoeckli-Evans, H. U. Güdel and S. Decurtins, Angew. Chem. Int. Ed. 39, 1605-9 (2000).

## (7) High-spin rhombic dodecahedron

The cluster $\left[\mathrm{Mn}^{\mathrm{II}}\left\{\mathrm{Mn}^{\mathrm{II}}(\mathrm{MeOH})_{3}\right\}_{8}(\mu-\mathrm{CN})_{30}\left\{\mathrm{Mo}(\mathrm{CN})_{3}\right\}_{6}\right] \cdot 5 \mathrm{MeOH} .2 \mathrm{H}_{2} \mathrm{O}$ has a pentadecanuclear core of idealized $O_{\mathrm{h}}$ symmetry, as shown in Fig. 20.3.21. The nine $\mathrm{Mn}(\mathrm{II})$ ions constitute a body-centered cube, the six $\mathrm{Mo}(\mathrm{V})$ ions define an octahedron, and the two polyhedra interpenetrate each other so that the peripheral atoms exhibit the geometry of a rhombic dodecahedron. Each pair of adjacent metal centers is linked by a $\mu$-cyano ligand with Mo bonded to C and Mn bonded to N . Each outer $\mathrm{Mn}(\mathrm{II})$ atom is surrounded by three methanol ligands, leading to octahedral coordination. Similarly, three terminal cyano ligands are bound to each $\operatorname{Mo}(\mathrm{V})$ to establish an eight-coordination environment.

Actually the cluster has a lower symmetry with a crystallographic $C_{2}$ axis passing through the central Mn atom and the midpoints of two opposite Mo $\cdots$ Mo edges. The resulting neutral cluster has a high-spin ground state with $S=25^{1 / 2}$. [Note that $S=2^{1 / 2}$ for $\mathrm{Mn}(\mathrm{II})$ and $\frac{1}{2}$ for $\mathrm{Mo}(\mathrm{V})$; thus the total spin of the system is $9 \times 2^{1 / 2}+6 \times 1 / 2=25^{1 / 2}$.]

### 20.4 Selected examples in crystal engineering

Examples from the recent literature that illustrate various approaches in the rational design of novel crystalline materials are given in this section.

### 20.4.1 Diamondoid networks

The three-dimensional network structure of diamond can be considered as constructed from the linkage of nodes ( C atoms) with rods ( $\mathrm{C}-\mathrm{C}$ bonds) in a tetrahedral pattern. From the viewpoint of crystal engineering, in a diamondoid network the node can be any group with tetrahedral connectivity, and the linking rods (or linker) can be all kinds of bonding interactions (ionic, covalent, coordination, hydrogen bond, and weak interactions) or molecular fragment.

The molecular skeletons of adamantane, $\left(\mathrm{CH}_{2}\right)_{6}(\mathrm{CH})_{4}$, and hexamethylenetetramine, $\left(\mathrm{CH}_{2}\right)_{6} \mathrm{~N}_{4}$ (Fig. 20.4.1) constitute the characteristic structural units of diamondoid networks containing one and two kinds of four-connected nodes, respectively. If the rod is long, the resulting diamondoid network

Fig. 20.4.1.
Molecular structure of (a) adamantane and (b) hexamethylenetetramine.
becomes quite porous, and stability can only be achieved by interpenetration. If two diamondoid networks interpenetrate to form the crystal structure, the degree of interpenetration $\rho$ is equal to 2 . Examples in which $\rho$ ranges from 2 to 9 are known.

Some crystalline compounds that exhibit diamondoid structures are listed in Table 20.4.1. The rod linking a pair of nodes can be either linear or nonlinear.

In the crystal structure of $\mathrm{Cu}_{2} \mathrm{O}$, each O atom is surrounded tetrahedrally by four Cu atoms, and each Cu atom is connected to two O atoms in a linear fashion. Hence the node is the O atom, and the rod is $\mathrm{O}-\mathrm{Cu}-\mathrm{O}$. Figure 20.4.2 shows a single $\mathrm{Cu}_{2} \mathrm{O}$ diamondoid network, and the crystal structure is composed of two interpenetrating networks.

In the crystal structure of ice-VII, which is formed under high pressure, the node is the O atom, and the rod is a hydrogen bond. Since the H atoms are disordered, the hydrogen bond is written as $\mathrm{O} \cdots \mathrm{H} \cdots \mathrm{O}$ in Table 20.4.1, indicating equal population of $\mathrm{O}-\mathrm{H} \cdots \mathrm{O}$ and $\mathrm{O} \cdots \mathrm{H}-\mathrm{O}$. The degree of interpenetration is two, as shown in Fig. 20.4.3.

Figures 20.4.4(a) and 20.4.4(b) illustrate the crystal structure of the $1: 1$ complex of tetraphenylmethane and carbon tetrabromide. The nodes comprise $\mathrm{C}\left(\mathrm{C}_{6} \mathrm{H}_{5}\right)_{4}$ and $\mathrm{CBr}_{4}$ molecules, and the each linking rod is the weak interaction between a Br atom and a phenyl group. The hexamethylenetetramine-like structural unit is outlined by broken lines. Figures 20.4.4(c) and 20.4.4(d) show the crystal structure of tetrakis(4-bromophenyl)methane, which has a distorted diamondoid network based on the hexamethylenetetramine building unit. If the synthon composed of the aggregation of four Br atoms is considered as a node, then two kinds of nodes ( $\mathrm{Br}_{4}$ synthon and quatenary C atom) are connected by rods consisting of $p$-phenylene moeities.

Figure 20.4.5 shows the crystal structure of $\left[\mathrm{Cu}\left\{1,4-\mathrm{C}_{6} \mathrm{H}_{4}(\mathrm{CN})_{2}\right\}_{2}\right] \mathrm{BF}_{4}$. The nodes are the four-connected Cu atoms, each being coordinated tetrahedrally by $\mathrm{N} \equiv \mathrm{C}-\mathrm{C}_{6} \mathrm{H}_{4}-\mathrm{C} \equiv \mathrm{N}$ ligands as rods. The adamantane-like structure unit is shown in Fig. 20.4.5(a), and repetition of such units along a twofold axis leads to fivefold interpenetration. The remaining space is filled by the $\mathrm{BF}_{4}^{-}$ions.

Figure 20.4.6 shows the crystal structure of $\mathrm{C}\left(\mathrm{C}_{6} \mathrm{H}_{4} \mathrm{C}_{2} \mathrm{C}_{5} \mathrm{NH}_{4} \mathrm{O}\right)$. $8 \mathrm{C}_{2} \mathrm{H}_{5} \mathrm{COOH}$. The whole $\mathrm{C}\left(\mathrm{C}_{6} \mathrm{H}_{4} \mathrm{C}_{2} \mathrm{C}_{5} \mathrm{NH}_{4} \mathrm{O}\right)_{4}$ molecule serves as a node, and

Crystal structure of $\mathrm{C}\left(\mathrm{C}_{6} \mathrm{H}_{4} \mathrm{C}_{2} \mathrm{C}_{5} \mathrm{NH}_{4} \mathrm{O}\right)_{4} \cdot 8 \mathrm{CH}_{3} \mathrm{CH}_{2} \mathrm{COOH}$. The structure of the host molecule is shown in the upper right and the pairwise linkage of pyridone groups is shown at the lower right.
such nodes are connected by rods each comprising a pair of $\mathrm{N}-\mathrm{H} \cdots \mathrm{O}$ hydrogen bonds between pyridine groups. As the resulting diamondoid network is quite open, sevenfold interpenetration occurs, and the remaining space is used to accommodate the ethanol guest molecules.

In the crystal structure of $\left[\mathrm{Ag}\left\{\mathrm{C}\left(4-\mathrm{C}_{6} \mathrm{H}_{4} \mathrm{CN}\right)_{4}\right\}\right] \mathrm{BF}_{4} \cdot x \mathrm{PhNO}_{2}$, the structural unit is of the hexamethylenetetramine type (Fig. 20.4.7). The nodes are Ag atoms and $\mathrm{C}\left(4-\mathrm{C}_{6} \mathrm{H}_{4} \mathrm{CN}\right)_{4}$ molecules, and the rods are $\mathrm{CN} \rightarrow \mathrm{Ag}$ coordination bonds. The void space is filled by the nitrobenzene guest molecules and $\mathrm{BF}_{4}^{-}$ions.

### 20.4.2 Interlocked structures constructed from cucurbituril

Cucurbituril is a hexameric macrocyclic compound with the formula $\left(\mathrm{C}_{6} \mathrm{H}_{6} \mathrm{~N}_{4} \mathrm{O}_{2}\right)_{6}$ shaped like a pumpkin which belongs to the botanical family Cucurbitaceae. This macrocyclic cavitand has idealized symmetry $D_{6 \mathrm{~h}}$ with a hydrophobic internal cavity of about 0.55 nm . The two portals, which are each laced by six hydrophilic carbonyl groups, have a diameter of 0.4 nm [Fig. 20.4.8(a)].

Like a molecular bead, cucurbituril can be threaded with a linear diammonium ion to form an inclusion complex [Fig. 20.4.8(b)]. This is stabilized by the fact that each protonated amino N atom forms hydrogen bonds to three of the

six carbonyl groups at its adjacent portal. Since each rotaxane unit has two terminal pyridyl groups, it can serve as an exo-bidentate ligand to link up transition metals to form a polyrotaxane which may take the form of a linear coordination polymer, a zigzag polymer, a molecular necklace, or a puckered layer network [Fig. 20.4.8(c)]. The structures of the linear and zigzag polyrotaxane polymers are shown in Fig. 20.4.9.

The two-dimensional network is constructed from the fusion of chair-like hexagons with $\mathrm{Ag}(\mathrm{I})$ ions at the corners and rotaxane units forming the edges. The nitrate ions lie above and below the puckered layer such that each $\operatorname{Ag}(\mathrm{I})$ ion is coordinated by three rotaxanes and a nitrate ion in a distorted tetrahedral geometry. In the crystal structure, two sets of parallel two-dimensional networks stacked in different directions make a dihedral angle of $69^{\circ}$, and they interpenetrate in such a way that a hexagon belonging to one set interlocks with four hexagons of the other set, and vice versa.

The rotaxane building unit can be modified by replacing the 4-pyridyl group by another functional group such as 3-cyanobenzyl. When a rotaxane unit built in this way is treated with $\mathrm{Tb}\left(\mathrm{NO}_{3}\right)_{3}$ under hydrothermal conditions, the cyano group is converted to the carboxylate group to generate a three-dimensional coordination polymeric network. The basic building block of the framework consists of a binuclear $\mathrm{Tb}^{3+}$ center and two types of rotaxane units: type I having bridging 3-phenylcarboxylate terminals and type II having chelating carboxylate terminals (Fig. 20.4.10).

The binuclear terbium centers and type I rotaxanes form a two-dimensional layer. Stacked layers are further interconnected via type II rotaxanes to form a three-dimensional polyrotaxane network, which has an inclined $\alpha$-polonium topology with the binuclear terbium centers behaving as six-connected nodes (Fig. 20.4.10). The void space in the crystal packing is filled by a free rotaxane unit, $\mathrm{NO}_{3}^{-}$and $\mathrm{OH}^{-}$counter ions, and water molecules.

### 20.4.3 Inorganic crystal engineering using hydrogen bonds

The utilization of hydrogen bonding in inorganic crystal design has gained prominence in recent years. A conceptual framework for understanding supramolecular chemistry involving metals and metal complexes is provided by the domain model according to Dance and Brammer (Fig. 20.4.11).

The central metal domain of a metal complex consists of the metal atom M , a metal hydride group, or a number of metal atoms if a metal cluster complex is considered. The ligand domain is composed of ligand atoms L directly bonded with the metal center(s). The periphery domain is the outmost part of the complex, consisting of those parts of the ligand not strongly influenced by electronic interaction with the metal center.

Hydrogen bonding arising from donor groups (M)O-H and (M)N-H is commonly observed. The $\sigma$-type coordinated ligands are hydroxy $(\mathrm{OH})$, aqua $\left(\mathrm{OH}_{2}\right)$, alcohol ( ROH ), and amines $\left(\mathrm{NH}_{3}, \mathrm{NRH}_{2}, \mathrm{NR}_{2} \mathrm{H}\right)$. Acceptors include halide-type ( $\mathrm{M}-\mathrm{X}$ with $\mathrm{X}=\mathrm{F}, \mathrm{Cl}, \mathrm{Br}, \mathrm{I}$ ), hydride-type ( $\mathrm{D}-\mathrm{H} \cdots \mathrm{H}-\mathrm{M}$ and D-H $\cdots \mathrm{H}-\mathrm{E}$ with $\mathrm{E}=\mathrm{B}, \mathrm{Al}, \mathrm{Ga}$ ) and carbonyl-type ( $\mathrm{D}-\mathrm{H} \cdots \mathrm{OC}-\mathrm{M}$ ).

Some examples of the coordination polymers consolidated by hydrogen bonding are discussed below.

## (1) Chains

In the crystal structure of $\mathrm{Fe}\left[\eta^{5}-\mathrm{CpCOOH}\right]_{2}$, a hydrogen-bonded chain with carboxyl groups interacting via the $R_{2}^{2}(8)$ dimer synthon is formed [Fig. 20.4.12(a)]. The complex $\left[\mathrm{Ag}(\text { nicotinamide })_{2}\right] \mathrm{CF}_{3} \mathrm{SO}_{3}$ has a ladder structure propagated via the $\mathrm{N}-\mathrm{H} \cdots \mathrm{O}$ catemer with rungs comprising $\mathrm{R}_{2}^{2}(8)$ amide dimer interactions [Fig. 20.4.12(b)]. Two $\mathrm{CF}_{3} \mathrm{SO}_{3}^{-}$ions (not shown) lie inside each centrosymmetric macrocyclic ring, and their O atoms form $\mathrm{N}-\mathrm{H} \cdots \mathrm{O}-\mathrm{S}-\mathrm{O} \cdots \mathrm{H}-\mathrm{N}$ hydrogen-bonded and weak $\mathrm{Ag} \cdots \mathrm{O} \cdots \mathrm{Ag}$ bridges. The crystal structure of $\left[\mathrm{Ru}\left(\eta^{5}-\mathrm{Cp}\right)\left(\eta^{5}-1-p\right.\right.$-tolyl-2-hydroxyindenyl) $]$ features a zigzag chain linked by $\mathrm{O}-\mathrm{H} \cdots \pi(\mathrm{Cp})$ hydrogen bonds [Fig. 20.4.12(c)].

The crystal structures of $[\mathrm{Pt}(\mathrm{NCN}-\mathrm{OH}) \mathrm{Cl}]$ and $\left[\mathrm{Pt}\left(\mathrm{SO}_{2}\right)(\mathrm{NCN}-\mathrm{OH}) \mathrm{Cl}\right]$, where NCN is the tridentate pincer ligand $\left\{\mathrm{C}_{6} \mathrm{H}_{2}-4-(\mathrm{OH})-2,6-\left(\mathrm{CH}_{2} \mathrm{NMe}_{2}\right)_{2}\right\}^{-}$, are compared in Fig. 20.4.13. The colorless complex $[\mathrm{Pt}(\mathrm{NCN}-\mathrm{OH}) \mathrm{Cl}]$

(a)

(b)

Fig. 20.4.12.
Hydrogen-bonded chain in (a) $\mathrm{Fe}\left[\eta^{5}-\mathrm{CpCOOH}\right]_{2}$, (b) $\left[\mathrm{Ag}(\text { nicotinamide })_{2}\right]^{+}$, and (c) $\left[\mathrm{Ru}\left(\eta^{5}-\mathrm{Cp}\right)\left(\eta^{5}-1-p\right.\right.$-tolyl-2-hydroxyindenyl) (T stands for p-tolyl group).
consists of a sheet-like array of parallel zigzag chains connected via O $\mathrm{H} \cdots \mathrm{Cl}(\mathrm{Pt})$ hydrogen bonds. Reversible uptake of $\mathrm{SO}_{2}$ is accompanied by a color change, resulting in an orange complex $\left[\mathrm{Pt}\left(\mathrm{SO}_{2}\right)(\mathrm{NCN}-\mathrm{OH}) \mathrm{Cl}\right]$ in which the coordinated $\mathrm{SO}_{2}$ ligand is involved in a donor-acceptor $\mathrm{S} \cdots \mathrm{Cl}$ interaction.

## (2) Two-dimensional networks

The $\mathrm{O}-\mathrm{H} \cdots \mathrm{O}^{-}$hydrogen-bonded square grid found in $\left[\mathrm{Pt}\left(\mathrm{L}_{2}\right)(\mathrm{HL})_{2}\right] \cdot 2 \mathrm{H}_{2} \mathrm{O}$ ( $\mathrm{HL}=$ isonicotinic acid) is shown in Fig. 20.4.14(a). Water molecules (not shown) occupy channels in the threefold interpenetrated network. The crystal structure of $\left[\mathrm{Zn}\left(\mathrm{SC}\left(\mathrm{NH}_{2}\right) \mathrm{NHNH}_{2}\right)_{2}(\mathrm{OH})_{2}\right]\left[1,4-\mathrm{O}_{2} \mathrm{CC}_{6} \mathrm{H}_{4} \mathrm{CO}_{2}\right] \cdot 2 \mathrm{H}_{2} \mathrm{O}$ has a brick-wall sheet structure [Fig. 20.4.14(b)]. Each $N, S$-chelating thiosemicarbazide ligand forms two donor hydrogen bonds with one carboxylate group

Fig. 20.4.13.
(a) Zigzag chain of $[\mathrm{Pt}(\mathrm{NCN}-\mathrm{OH}) \mathrm{Cl}]$ held by $\mathrm{O}-\mathrm{H} \cdots \mathrm{Cl}$ hydrogen bonds. (b) Two-dimensional network of $\left[\mathrm{Pt}\left(\mathrm{SO}_{2}\right)(\mathrm{NCN}-\mathrm{OH}) \mathrm{Cl}\right]$ consolidated by additional $\mathrm{S} \cdot \mathrm{Cl}$ donor-acceptor interactions.

of a terephthalate ion and one donor hydrogen bond with another terephthalate ion. The layers are linked via $\mathrm{N}-\mathrm{H} \cdots \mathrm{O}$ and $\mathrm{O}-\mathrm{H} \cdots \mathrm{O}$ hydrogen bonds to the water molecules (not shown). The complex $\left.[\mathrm{Ag} \text { (nicotinamide) })_{2}\right] \mathrm{PF}_{6}$ has a cationic herringbone layer constructed from amide $\mathrm{N}-\mathrm{H} \cdots \mathrm{O}$ hydrogen bonds [Fig. 20.4.14(c)]. Such layers are further cross-linked by $\mathrm{N}-\mathrm{H} \cdots \mathrm{F}$ and $\mathrm{C}-\mathrm{H} \cdots \mathrm{F}$ hydrogen bonds involving the $\mathrm{PF}_{6}^{-}$ions (not shown).

## (3) Three-dimensional networks

In the complex $\left[\mathrm{Cu}(\mathrm{L})_{4}\right] \mathrm{PF}_{6}$ ( $\mathrm{L}=3$-cyano-6-methylpyrid-2(1H)-one), the hydrogen-bonded linkage involves the amido $\mathrm{R}_{2}^{2}(8)$ supramolecular synthon [Fig. 20.4.15(a)]. Each $\mathrm{Cu}(\mathrm{I})$ center serves as a tetrahedral node in a fourfold interpenetrated cationic diamondoid network. The tetrahedral metal cluster $\left[\mathrm{Mn}\left(\mu_{3}-\mathrm{OH}\right)(\mathrm{CO})_{3}\right]_{4}$ can be used to construct a diamondoid network with the linear 4,4'-bipyridine spacers [Fig. 20.4.15(b)].

(b)

### 20.4.4 Generation and stabilization of unstable inorganic/organic anions in urea/thiourea complexes

Urea, thiourea, or their derivatives are often employed as useful building blocks for supramolecular architectures because they contain amido functional group which can form moderately strong $\mathrm{N}-\mathrm{H} \cdots \mathrm{X}$ hydrogen bonds with rather well-defined and predictable hydrogen-bonding patterns. Furthermore, in the presence of anions, the hydrogen bond is strengthened by two to three times ( 40 to $190 \mathrm{~kJ} \mathrm{~mol}^{-1}$ ) compared with the bond strength involving uncharged molecular species ( 10 to $65 \mathrm{~kJ} \mathrm{~mol}^{-1}$ ). Hence, making use of this kind of chargeassisted $\mathrm{N}-\mathrm{H} \cdots \mathrm{X}^{-}$hydrogen bonding interactions and bulky tetraalkylammonium cations as guest templates, some unstable organic anions $\mathrm{A}^{-}$can be generated in situ and stabilized in urea/thiourea-anion host frameworks. A series of inclusion compounds of the type $\mathrm{R}_{4} \mathrm{~N}^{+} \mathrm{A}^{-} \cdot m\left(\mathrm{NH}_{2}\right)_{2} \mathrm{CX}$ (where $\mathrm{X}=$ O or S ) with novel topological features has been characterized.

## (1) Dihydrogen borate

As mentioned in Section 13.5.1, the transient species $\left[\mathrm{BO}(\mathrm{OH})_{2}\right]^{-}$ has been stabilized by hydrogen-bonding interactions with the nearest urea molecules in the host framework of the inclusion compound $\left[\left(\mathrm{CH}_{3}\right)_{4} \mathrm{~N}\right]^{+}\left[\mathrm{BO}(\mathrm{OH})_{2}\right]^{-} \cdot 2\left(\mathrm{NH}_{2}\right)_{2} \mathrm{CO} \cdot \mathrm{H}_{2} \mathrm{O}$. A perspective view of the crystal structure along the [010] direction is presented in Fig. 20.4.16. The host lattice consists of a parallel arrangement of unidirectional channels whose cross section has the shape of a peanut. The diameter of each spheroidal half is about 704 pm , and the separation between two opposite walls at the waist of the channel is about 585 pm . The well-ordered tetramethylammonium cations are accommodated in double columns within each channel.

Fig. 20.4.16.
Crystal structure of
$\left[\left(\mathrm{CH}_{3}\right)_{4} \mathrm{~N}\right]^{+}\left[\mathrm{BO}(\mathrm{OH})_{2}\right]^{-} \cdot 2\left(\mathrm{NH}_{2}\right)_{2} \mathrm{CO} \cdot \mathrm{H}_{2} \mathrm{O}$ showing the channels extending parallel to the $b$ axis and the enclosed cations. Broken lines represent hydrogen bonds, and the atoms are shown as points for clarity. From Q. Li, F. Xue and T. C. W. Mak, Inorg. Chem. 38, 4142-5 (1999).

## (2) Allophanate and 3-thioallophanate

Allophanate esters $\mathrm{H}_{2} \mathrm{NCONHCOOR}$ are among the oldest organic compounds recorded in the literature. The parent allophanic acid, $\mathrm{H}_{2} \mathrm{NCONHCOOH}$, is not known in the free state, whereas inorganic allophanate salts are unstable and readily hydrolyzed by water to carbon dioxide, urea, and carbonate. However, the elusive allophanate anion can be generated in situ and stabilized in the following three inclusion compounds:

$$
\left.\begin{array}{l}
{\left[\left(\mathrm{CH}_{3}\right)_{4} \mathrm{~N}\right]^{+}\left[\mathrm{NH}_{2} \mathrm{CONHCO}_{2}\right]^{-} \cdot 5\left(\mathrm{NH}_{2}\right)_{2} \mathrm{CO}} \\
{\left[( n - \mathrm { C } _ { 3 } \mathrm { H } _ { 7 } ) _ { 4 } \mathrm { N } ^ { + } \left[\mathrm{NH}_{2} \mathrm{CONHCO}\right.\right.} \\
2
\end{array}\right]^{-} \cdot 3\left(\mathrm{NH}_{2}\right)_{2} \mathrm{CO},\left[\begin{array}{l}
\text { and } \\
{\left[\left(\mathrm{CH}_{3}\right)_{3} \mathrm{~N}^{+} \mathrm{CH}_{2} \mathrm{CH}_{2} \mathrm{OH}\right]\left[\mathrm{NH}_{2} \mathrm{CONHCO}_{2}\right]^{-} \cdot\left(\mathrm{NH}_{2}\right)_{2} \mathrm{CO}}
\end{array}\right.
$$

A part of the host framework in $\left[\left(\mathrm{CH}_{3}\right)_{4} \mathrm{~N}\right]^{+}\left[\mathrm{NH}_{2} \mathrm{CONHCO}_{2}\right]^{-} \cdot 5\left(\mathrm{NH}_{2}\right)_{2} \mathrm{CO}$ is shown in Fig. 20.4.17. Two neighboring allophanate anions are arranged in a head-to-tail fashion and bridged by a urea molecule with $\mathrm{N}-\mathrm{H} \cdots \mathrm{O}$ and chargeassisted $\mathrm{N}-\mathrm{H} \cdots \mathrm{O}^{-}$hydrogen bonds to generate a zigzag ribbon. This ribbon is further joined to another ribbon related to it by an inversion center via pairs of $\mathrm{N}-\mathrm{H} \cdots \mathrm{O}^{-}$hydrogen bonds to form a double ribbon.

The hitherto unknown 3-thioallophanate anion has been trapped in the host lattice of $\left[\left(n-\mathrm{C}_{4} \mathrm{H}_{9}\right)_{4} \mathrm{~N}\right]^{+}\left[\mathrm{H}_{2} \mathrm{NCSNHCO}_{2}\right]^{-} \cdot\left(\mathrm{NH}_{2}\right)_{2} \mathrm{CS}$. The cyclic structure and molecular dimensions of the allophanate and 3-thioallophanate ions are compared in Fig. 20.4.18. As expected, the $\mathrm{C}-\mathrm{O}$ bond involved in intramolecular hydrogen bonding in the 3-thioallophanate anion is longer than that in the allophanate anion.

## (3) Valence tautomers of the rhodizonate dianion

The rhodizonate dianion $\mathrm{C}_{6} \mathrm{O}_{6}^{2-}$ (Fig. 20.4.19) is a member of a series of planar monocyclic oxocarbon dianions $\mathrm{C}_{n} \mathrm{O}_{n}^{2-}(n=3$, deltate; $n=4$, squarate; $n=5$, croconate; $n=6$; rhodizonate) which have been recognized as nonbenzenoid aromatic compounds. However, this six-membered ring species

Fig. 20.4.17.
Part of the host framework in $\left[\left(\mathrm{CH}_{3}\right)_{4} \mathrm{~N}\right]^{+}\left[\mathrm{H}_{2} \mathrm{NCONHCO}_{2}\right]^{-} \cdot 5\left(\mathrm{NH}_{2}\right)_{2} \mathrm{CO}$ showing the double ribbon constructed by allophanate anions and one of the independent urea molecules. ## Fig. 20.4.19.

Structural formulas of cyclic oxocarbon dianions.

is not stable in aqueous solution as it readily undergoes oxidative ring contraction reaction to the croconate dianion, and the decomposition is catalyzed by alkalis. Recently, this relatively unstable species has been generated in situ and stabilized by hydrogen bonding in two novel inclusion compounds [ $n$ $\left.\left.\mathrm{C}_{4} \mathrm{H}_{9}\right)_{4} \mathrm{~N}^{+}\right]_{2} \mathrm{C}_{6} \mathrm{O}_{6}^{2-} \cdot 2\left(m-\mathrm{OHC}_{6} \mathrm{H}_{4} \mathrm{NHCONH}_{2}\right) \cdot 2 \mathrm{H}_{2} \mathrm{O}$ (Fig. 20.4.20) and [ $(n-$ $\left.\left.\mathrm{C}_{4} \mathrm{H}_{9}\right)_{4} \mathrm{~N}^{+}\right]_{2} \mathrm{C}_{6} \mathrm{O}_{6}^{2-} \cdot 2\left(\mathrm{NH}_{2} \mathrm{CONHCH}_{2} \mathrm{CH}_{2} \mathrm{NHCONH}_{2}\right) \cdot 3 \mathrm{H}_{2} \mathrm{O}$ (Fig. 20.4.21), respectively.

(a)

(b)

The measured dimensions of the $\mathrm{C}_{6} \mathrm{O}_{6}^{2-}$ species in $\left[\left(n-\mathrm{C}_{4} \mathrm{H}_{9}\right)_{4} \mathrm{~N}^{+}\right]_{2} \mathrm{C}_{6} \mathrm{O}_{6}^{2-}$ $\cdot 2\left(m-\mathrm{OHC}_{6} \mathrm{H}_{4} \mathrm{NHCONH}_{2}\right) \cdot 2 \mathrm{H}_{2} \mathrm{O}$ and $\left[\left(n-\mathrm{C}_{4} \mathrm{H}_{9}\right)_{4} \mathrm{~N}^{+}\right]_{2} \mathrm{C}_{6} \mathrm{O}_{6}^{2-} \cdot 2\left(\mathrm{NH}_{2} \mathrm{CON}\right.$ $\left.\mathrm{HCH}_{2} \mathrm{CH}_{2} \mathrm{NHCONH}_{2}\right) \cdot 3 \mathrm{H}_{2} \mathrm{O}$ nearly conform to idealized $D_{6 \mathrm{~h}}$ and $C_{2 \mathrm{v}}$ molecular symmetry, corresponding to distinct valence tautomeric structures that manifest nonbenzenoid aromatic and enediolate character, respectively (Fig. 20.4.22).

deltate

squarate

croconate

rhodizonate

Occurrence of the charge-localized structure of $\mathrm{C}_{6} \mathrm{O}_{6}^{2-}$ in $[(n-$ $\left.\left.\mathrm{C}_{4} \mathrm{H}_{9}\right)_{4} \mathrm{~N}^{+}\right]_{2} \mathrm{C}_{6} \mathrm{O}_{6}^{2-} \cdot 2\left(\mathrm{NH}_{2} \mathrm{CONHCH}_{2} \mathrm{CH}_{2} \mathrm{NHCONH}_{2}\right) \cdot 3 \mathrm{H}_{2} \mathrm{O}$, as well as its

noticeable deviation from idealized $C_{2 \mathrm{v}}$ molecular symmetry, can be attributed to unequal hydrogen-bonding interaction with its two neighboring bisurea donors and a pair of water molecules (Fig. 20.4.21).

## (4) Valence tautomers of the croconate dianion

In the host lattice of $\left[\left(n-\mathrm{C}_{3} \mathrm{H}_{7}\right)_{4} \mathrm{~N}^{+}\right]_{2} \mathrm{C}_{5} \mathrm{O}_{5}^{2-} \cdot 3\left(\mathrm{NH}_{2}\right)_{2} \mathrm{CO} \cdot 8 \mathrm{H}_{2} \mathrm{O}$, the croconate anion resides in a rather symmetrical hydrogen-bonding environment (Fig. 20.4.23) and thus its measured dimensions are consistent with its expected charge-delocalized $D_{5 \mathrm{~h}}$ structure in the ground state, as shown in

(a)

## Structural Chemistry of Selected Elements

Fig. 20.4.24(a). In the host lattice of $\left[\left(\mathrm{C}_{2} \mathrm{H}_{5}\right)_{4} \mathrm{~N}^{+}\right]_{2} \mathrm{C}_{5} \mathrm{O}_{5}^{2-} \cdot 3\left(\mathrm{CH}_{3} \mathrm{NH}\right)_{2} \mathrm{CO}$, the croconate dianion resides on a twofold axis, being directly linked to three 1,3dimethylurea molecules through pairs of $\mathrm{N}-\mathrm{H} \cdots \mathrm{O}$ hydrogen bonds to form a semi-circular structural unit (Fig. 20.4.25). In particular, each type O1 oxygen atom forms two strong acceptor hydrogen bonds with the N-H donors from a pair of 1,3-dimethylurea molecules, while each type O 2 oxygen atom forms only one $\mathrm{N}-\mathrm{H} \cdots \mathrm{O}$ hydrogen bond. In contrast, the solitary type O 3 oxygen atom is stabilized by two weak $\mathrm{C}-\mathrm{H} \cdots \mathrm{O}$ hydrogen bonds with neighboring tetra- $n$ butylammonium cations. Such a highly unsymmetrical environment engenders a sharp gradient of hydrogen-bonding donor strength around the croconate ion, which is conducive to stabilization of its $C_{2 v}$ valence tautomer with significantly different $\mathrm{C}-\mathrm{C}$ and $\mathrm{C}-\mathrm{O}$ bond lengths around the cyclic system, as shown in Fig. 20.4.24(b).

Fig. 20.4.23.
Projection diagram on the (110) plane showing the hydrogen-bonding scheme for a portion of the host lattice in $\left[\left(n-\mathrm{C}_{3} \mathrm{H}_{7}\right)_{4} \mathrm{~N}^{+}\right]_{2} \mathrm{C}_{5} \mathrm{O}_{5}^{2-} \cdot 3\left(\mathrm{NH}_{2}\right)_{2} \mathrm{CO} \cdot 8 \mathrm{H}_{2} \mathrm{O}$. The slanted vertical (urea dimer-croconate-urea) $\infty$ chain constitutes a side wall of the [110] channel system. The parallel [urea dimer- $\left.\left(\mathrm{H}_{2} \mathrm{O}\right)_{2}\right]_{\infty}$ ABAB... and $\left[\text { croconate-urea- }\left(\mathrm{H}_{2} \mathrm{O}\right)_{4}\right]_{\infty}$ DCEDCE $\ldots$ ribbons define the channel system in the $c$ direction. From C.-K. Lam, M.-F. Cheng, C.-L. Li J.-P. Zhang, X.-M. Chen, W.-K. Li and T. C. W. Mak, Chem. Commun., 448-9 (2004).

The examples given in this section show that crystal engineering provides a viable route to breaking the degeneracy of canonical forms of a molecular species, and an elusive anion can be generated in situ and stabilized in a crystalline inclusion compound through hydrogen-bonding interactions with neighboring hydrogen-bond donors, such as urea/thiourea or their derivatives, which can function as supramolecular stabilizing agents.

### 20.4.5 Supramolecular assembly of silver(I) polyhedra with embedded acetylenediide dianion

Since 1998, a wide range of double, triple, and quadruple salts containing $\mathrm{Ag}_{2} \mathrm{C}_{2}$ (IUPAC name silver acetylenediide, commonly known as silver acetylide or silver carbide in the older literature) as a component have been synthesized and characterized (see Section 14.3.7 and the comprehensive review by Bruce and Low cited at the end of this chapter). Such $\mathrm{Ag}_{2} \mathrm{C}_{2}$-containing double, triple, and quadruple salts can be formulated as $\mathrm{Ag}_{2} \mathrm{C}_{2} \cdot n \mathrm{AgX}, \mathrm{Ag}_{2} \mathrm{C}_{2} \cdot m \mathrm{AgX} \cdot n \mathrm{AgY}$, and $\mathrm{Ag}_{2} \mathrm{C}_{2} \cdot l \mathrm{AgX} \cdot m \mathrm{AgY} \cdot n \mathrm{AgZ}$, respectively. The accumulated experimental data indicate that the acetylenediide dianion $\mathrm{C}_{2}^{2-}$ preferentially resides inside a silver(I) polyhedron of the type $\mathrm{C}_{2} @ \mathrm{Ag}_{n}(n=6-10)$, which is jointly stabilized by ionic, covalent ( $\sigma, \pi$, and mixed), and argentophilic interactions (see Section 19.6.2). However, the $\mathrm{C}_{2} @ \mathrm{Ag}_{n}$ cage is quite labile and its formation can be influenced by various factors such as solvent, reaction temperature, and the coexistence of anions, crown ethers, tetraaza macrocycles, organic cations, neutral ancillary ligands, and exo-bidentate bridging ligands, so that cage size and geometry are in general unpredictable.

Fig. 20.4.24.

$\left[\mathrm{Ag}_{2} \mathrm{C}_{2} \cdot 5 \mathrm{CF}_{3} \mathrm{CO}_{2} \mathrm{Ag} \cdot 2(15 \mathrm{C} 5) \cdot \mathrm{H}_{2} \mathrm{O}\right] \cdot 3 \mathrm{H}_{2} \mathrm{O}$. The F and H atoms have been omitted for clarity. (b) Space-filling drawing of the discrete supermolecule in $\left[\mathrm{Ag}_{14}\left(\mathrm{C}_{2}\right)_{2}\left(\mathrm{CF}_{3} \mathrm{CO}_{2}\right)_{14}(\text { dabcoH })_{4}\left(\mathrm{H}_{2} \mathrm{O}\right)_{1.5}\right] \cdot \mathrm{H}_{2} \mathrm{O} .($ dabco $=1,4$-diazabicyclo[2.2.2]octane $)$. The trifluoroacetate and aqua ligands have been omitted for clarity. (c) Space-filling drawing of the discrete supermolecule $\left[\mathrm{Ag}_{8}\left(\mathrm{C}_{2}\right)\left(\mathrm{CF}_{3} \mathrm{CO}_{2}\right)_{6}\left(\mathrm{~L}^{1}\right)_{6}\right]$ viewed along its $\overline{3}$ symmetry axis ( $\mathrm{L}^{1}=4$-hydroxyquinoline). The trifluoroacetate ligands have been omitted for clarity. From Q.-M. Wang and T. C. W. Mak, Angew. Chem. Int. Ed. 40, 1130-3 (2001); Q.-M. Wang and T. C. W. Mak, Inorg. Chem. 42, 1637-43 (2003); X.-L. Zhao, Q.-M. Wang and T. C. W. Mak, Inorg. Chem. 42, 7872-6 (2003).

## (1) Discrete molecules

To obtain discrete molecules, one effective strategy is to install protective cordons around the $\mathrm{C}_{2} @ \mathrm{Ag}_{n}$ moiety with neutral, multidentate ligands that can function as blocking groups or terminal stoppers.

Small crown ethers have been introduced as structure-directing agents into the $\mathrm{Ag}_{2} \mathrm{C}_{2}$-containing system to prevent catenation and interlinkage of silver polyhedra. Judging from the rather poor host-guest complementarity of $\mathrm{Ag}(\mathrm{I})$ (soft cation) with a crown ether (hard O ligand sites), the latter is expected not to affect the formation of $\mathrm{C}_{2} @ \mathrm{Ag}_{n}$, but to act as a capping ligand to an apex of the polyhedral silver cage.
$\left[\mathrm{Ag}_{2} \mathrm{C}_{2} \cdot 5 \mathrm{CF}_{3} \mathrm{CO}_{2} \mathrm{Ag} \cdot 2(15 \mathrm{C} 5) \cdot \mathrm{H}_{2} \mathrm{O}\right] \cdot 3 \mathrm{H}_{2} \mathrm{O}$ (15C5 $=$ [15]crown-5) can be obtained from an aqueous solution containing silver acetylenediide, silver trifluoroacetate, and 15C5. The discrete $\mathrm{C}_{2} @ \mathrm{Ag}_{7}$ moiety in [ $\left.\mathrm{Ag}_{2} \mathrm{C}_{2} \cdot 5 \mathrm{CF}_{3} \mathrm{CO}_{2} \mathrm{Ag} \cdot 2(15 \mathrm{C} 5) \cdot \mathrm{H}_{2} \mathrm{O}\right] \cdot 3 \mathrm{H}_{2} \mathrm{O}$ is a pentagonal bipyramid, with four equatorial edges bridged by $\mathrm{CF}_{3} \mathrm{CO}_{2}^{-}$groups while the two apical Ag atoms are each attached to a 15C5, as shown in Fig. 20.4.26(a). In this discrete molecule, one equatorial Ag atom is coordinated by a monodentate $\mathrm{CF}_{3} \mathrm{CO}_{2}^{-}$and the other by an aqua ligand.

In $\left[\mathrm{Ag}_{14}\left(\mathrm{C}_{2}\right)_{2}\left(\mathrm{CF}_{3} \mathrm{CO}_{2}\right)_{14}(\text { dabcoH })_{4}\left(\mathrm{H}_{2} \mathrm{O}\right)_{1.5}\right] \cdot \mathrm{H}_{2} \mathrm{O}$, the core is a $\mathrm{Ag}_{14}$ double cage constructed from edge-sharing of two triangulated dodecahedra. Apart from trifluoroacetate and aqua ligands, there are four monoprotonated dabco ligands surrounding the core unit, each being terminally coordinated to a silver(I) vertex, as shown in Fig. 20.4.26(b).

For the discrete molecule $\left[\mathrm{Ag}_{8}\left(\mathrm{C}_{2}\right)\left(\mathrm{CF}_{3} \mathrm{CO}_{2}\right)_{6}\left(\mathrm{~L}^{1}\right)_{6}\right] \quad\left(\mathrm{L}^{1}=4\right.$-hydroxyquinoline) of $\overline{3}$ symmetry displayed in Fig. 20.4.26(c), the encapsulated acetylenediide dianion in the rhombohedral $\mathrm{Ag}_{8}$ core is disordered about a crystallographic threefold axis that bisects the $\mathrm{C} \equiv \mathrm{C}$ bond and passes through two opposite corners of the rhombohedron. Apart from the $\mu_{2}-O, O^{\prime}$ trifluoroacetate
liagnds, there are six keto- ${ }^{1}$ ligands surrounding the polynuclear core, each bridging an edge in the $\mu-O$ mode.

In the structures shown in Fig. 20.4.26, the hydrophobic tails of perfluorocarboxylates, together with the bulky ancillary ligands, successfully prevent linkage between adjacent silver polyhedra, thus leading to discrete supermolecules.

## (2) Chains and columns

Free betaines are zwitterions bearing a carboxylate group and a quaternary ammonium group, and the prototype of this series is the trimethylammonio derivative commonly called betaine $\left(\mathrm{Me}_{3} \mathrm{~N}^{+} \mathrm{CH}_{2} \mathrm{COO}^{-}\right.$, IUPAC name trimethylammonioacetate, hereafter abbreviated as $\mathrm{Me}_{3}$ bet). Owing to their permanent bipolarity and overall charge neutrality, betaine and its derivatives (considered as carboxylate-type ligands) have distinct advantages over most carboxylates as ligands in the formation of coordination polymers:
(1) synthetic access to water-soluble metal carboxylates;
(2) generation of new structural varieties, such as complexes with metal centers bearing additional anionic ligands, and those with variable metal to carboxylate molar ratios; and
(3) easy synthetic modification of ligand property by varying the substituents on the quaternary nitrogen atom or the backbone between the two polar terminals.

The introduction of such ligands into the $\mathrm{Ag}_{2} \mathrm{C}_{2}$-containing system has led to isolation of supramolecular complexes showing chain-like or columnar structures.
$\left[\left(\mathrm{Ag}_{2} \mathrm{C}_{2}\right)_{2}\left(\mathrm{AgCF}_{3} \mathrm{CO}_{2}\right)_{9}\left(\mathrm{~L}^{2}\right)_{3}\right]$ has a columnar structure composed of fused silver(I) double cages: a triangulated dodecahedron and a bicapped trigonal prism, each encapsulating an acetylenediide dianion. Such a neutral column is coated by a hydrophobic sheath composed of trifluoroacetate and $\mathrm{L}^{2}$ ligands, as shown in Fig. 20.4.27(a).

The core in $\left[\left(\mathrm{Ag}_{2} \mathrm{C}_{2}\right)_{2}\left(\mathrm{AgCF}_{3} \mathrm{CO}_{2}\right)_{10}\left(\mathrm{~L}^{3}\right)_{3}\right] \cdot \mathrm{H}_{2} \mathrm{O}$ is a double cage generated from edge-sharing of a square-antiprism and a distorted bicapped trigonalprism, with each single cage encapsulating an acetylenediide dianion. Double cages of this type are fused together to form a helical column, which is surrounded by a hydrophobic sheath composed of trifluoroacetate and $\mathrm{L}^{3}$ ligands, as shown in Fig. 20.4.27(b).

The building unit in $\left[\left(\mathrm{Ag}_{2} \mathrm{C}_{2}\right)\left(\mathrm{AgC}_{2} \mathrm{~F}_{5} \mathrm{CO}_{2}\right)_{6}\left(\mathrm{~L}^{4}\right)_{2}\right]$ is a centrosymmetric double cage, in which each half encapsulates an acetylenediide dianion. Each single cage is an irregular monocapped trigonal prism with one appended atom. The $\mathrm{L}^{4}$ ligand acting in the $\mu_{2}-O, O^{\prime}$ coordination mode links a pair of double cages to form an infinite chain, as shown in Fig. 20.4.27(c).

In $\left[\left(\mathrm{Ag}_{2} \mathrm{C}_{2}\right)\left(\mathrm{AgCF}_{3} \mathrm{CO}_{2}\right)_{7}\left(\mathrm{~L}^{5}\right)_{2}\left(\mathrm{H}_{2} \mathrm{O}\right)\right]$, the basic building unit is a distorted monocapped cube. The trifluoroacetate and $\mathrm{L}^{5}$ ligands act as $\mu_{3}$-bridges across adjacent single cage blocks to form a bead-like chain [Fig, 20.4.27(d)].

## (3) Two-dimensional structures

The incorporation of ancillary $N, N^{\prime}$ - and $N, O$-donor ligands into the $\mathrm{Ag}_{2} \mathrm{C}_{2}-$ containing system has led to a series of two-dimensional structures.

(c)

Perspective view of the infinite silver(I) helical column with $\mathrm{C}_{2}^{2-}$ species embedded in its inner core and an exterior coat comprising anionic and zwitterionic carboxylates in $\left[\left(\mathrm{Ag}_{2} \mathrm{C}_{2}\right)_{2}\left(\mathrm{AgCF}_{3} \mathrm{CO}_{2}\right)_{10}\left(\mathrm{~L}^{3}\right)_{3}\right] \cdot \mathrm{H}_{2} \mathrm{O}$. (c) Infinite chain generated from the linkage of $\left(\mathrm{C}_{2}\right)_{2} @ \mathrm{Ag}_{16}$ double cages by $\mu_{2}-O, O^{\prime} \mathrm{L}^{4}$ ligands in $\left[\left(\mathrm{Ag}_{2} \mathrm{C}_{2}\right)\left(\mathrm{AgC}_{2} \mathrm{~F}_{5} \mathrm{CO}_{2}\right)_{6}\left(\mathrm{~L}^{4}\right)_{2}\right]$. (d) Infinite chain constructed from $\mathrm{C}_{2} @ \mathrm{Ag}_{9}$ polyhedra connected by $\mathrm{L}^{5}$ and trifluoroacetate bridges in $\left[\left(\mathrm{Ag}_{2} \mathrm{C}_{2}\right)\left(\mathrm{AgCF}_{3} \mathrm{CO}_{2}\right)_{7}\left(\mathrm{~L}^{5}\right)_{2}\left(\mathrm{H}_{2} \mathrm{O}\right)\right]$. From X.-L. Zhao, Q-M, Wang and T. C. W. Mak, Chem. Eur. J. 11, 2094-102 (2005).

In the synthesis of $\left[\left(\mathrm{Ag}_{2} \mathrm{C}_{2}\right)\left(\mathrm{AgCF}_{3} \mathrm{CO}_{2}\right)_{4}\left(\mathrm{~L}^{6}\right)\left(\mathrm{H}_{2} \mathrm{O}\right)\right] \cdot \mathrm{H}_{2} \mathrm{O}$ under hydrothermal reaction condition, the starting ligand 4-cyanopyridine undergoes hydrolysis to form 4-pyridine-carboxamide ( $\mathrm{L}^{6}$ ). The basic building unit is a $\mathrm{C}_{2} @ \mathrm{Ag}_{8}$ single cage in the shape of a distorted triangulated dodecahedron. Such dodecahedra share edges to form a zigzag composite chain, which are further linked via $L^{6}$ to generate a two-dimensional network Fig. 20.4.28(a).

The $\mathrm{L}^{1}$ ligand, $\mathrm{H}_{3} \mathrm{O}^{+}$species, and the anionic polymeric system $\left\{\left[\mathrm{Ag}_{11}\left(\mathrm{C}_{2}\right)_{2}\left(\mathrm{C}_{2} \mathrm{~F}_{5} \mathrm{CO}_{2}\right)_{9}\left(\mathrm{H}_{2} \mathrm{O}\right)_{2}\right]^{2-}\right\}_{\infty}$ comprise $\left(\mathrm{L}^{1} \cdot \mathrm{H}_{3} \mathrm{O}\right)_{2}\left[\mathrm{Ag}_{11}\left(\mathrm{C}_{2}\right)_{2}\right.$ $\left.\left(\mathrm{C}_{2} \mathrm{~F}_{5} \mathrm{CO}_{2}\right)_{9}\left(\mathrm{H}_{2} \mathrm{O}\right)_{2}\right] \cdot \mathrm{H}_{2} \mathrm{O}$. The basic building unit in the latter is a $\mathrm{Ag}_{12}$ double cage composed of two irregular monocapped trigonal antiprisms sharing an edge. The double cages are fused together to generate an infinite, sinuous anionic column. The oxygen atoms of $\mathrm{L}^{1}$ and the water molecule are bridged by a proton to give the cationic aggregate $\mathrm{L}^{1} \cdot \mathrm{H}_{3} \mathrm{O}^{+}$, which links the columns into a layer structure via hydrogen bonds with the pentafluoropropionate groups (Fig. 20.4.28(b)).
$\left[\mathrm{Ag}_{8}\left(\mathrm{C}_{2}\right)\left(\mathrm{CF}_{3} \mathrm{CO}_{2}\right)_{8}\left(\mathrm{H}_{2} \mathrm{O}\right)_{2}\right] \cdot\left(\mathrm{H}_{2} \mathrm{O}\right)_{4} \cdot\left(\mathrm{~L}^{7} \mathrm{H}_{2}\right)$ represents a rare example of a hydrogen-bonded layer-type host structure containing $\mathrm{C}_{2} @ \mathrm{Ag}_{n}$ that features
the inclusion of organic guest species. The core is a centrosymmetric $\mathrm{C}_{2} @ \mathrm{Ag}_{8}$ single cage in the shape of a slightly distorted cube. The trifluoroacetate ligands functioning in the $\mu_{3}$-coordination mode further interlink the single cages into an infinite zigzag silver(I) chain. Of the three independent water molecules, one forms an acceptor hydrogen bond with a terminal of the $\mathrm{L}^{7} \mathrm{H}_{2}$ dication, the other serves as an aqua ligand bonded to a silver atom, and the third lying on a two fold axis functions as a bridge between aqua ligands belonging to adjacent silver(I) chains. The centrosymmetric $\mathrm{L}^{7} \mathrm{H}_{2}$ ions each hydrogen-bonded to a pair of terminal water molecules are accommodated between adjacent layers, forming an inclusion complex, as shown in Fig. 20.4.28(c).

## (4) Three-dimensional structures

The strategy of using $\mathrm{C}_{2} @ \mathrm{Ag}_{n}$ polyhedra as building blocks for the assembly of new coordination frameworks via introduction of potentially exo-bidentate nitrogen/oxygen-donor bridging ligands between agglomerated components has led to the isolation of three-dimensional supramolecular complexes exhibiting interesting crystal structures.

In $\left(\mathrm{Ag}_{2} \mathrm{C}_{2}\right)\left(\mathrm{AgCF}_{3} \mathrm{CO}_{2}\right)_{8}\left(\mathrm{~L}^{8}\right)_{2}\left(\mathrm{H}_{2} \mathrm{O}\right)_{4}$, square-antiprismatic $\mathrm{C}_{2} @ \mathrm{Ag}_{8}$ cores are linked by trifluoroacetate groups to generate a columnar structure. Hydrogen bonds with the amino group of $\mathrm{L}^{8}$ and aqua ligands serving as donors and the oxygen atoms of the trifluoroacetate group as acceptors further connect the columns into a three-dimensional scaffold [Fig. 20.4.29(a)].

Fig. 20.4.29.
(a) Three-dimensional architecture of $\left(\mathrm{Ag}_{2} \mathrm{C}_{2}\right)\left(\mathrm{AgCF}_{3} \mathrm{CO}_{2}\right)_{8}\left(\mathrm{~L}^{8}\right)_{2}\left(\mathrm{H}_{2} \mathrm{O}\right)_{4}$ resulting from the linkage of silver columns via hydrogen bonds. (b) Three-dimensional architecture in $\left(\mathrm{L}^{9} \mathrm{H}\right)_{3} \cdot\left[\mathrm{Ag}_{8}\left(\mathrm{C}_{2}\right)\left(\mathrm{CF}_{3} \mathrm{CO}_{2}\right)_{9}\right] \cdot \mathrm{H}_{2} \mathrm{O}$ generated from covalent silver chains linked by hydrogen bonds. (c) The $(3,6)$ covalent network in $\left[\mathrm{Ag}_{7}\left(\mathrm{C}_{2}\right)\left(\mathrm{CF}_{3} \mathrm{CO}_{2}\right)_{2}\left(\mathrm{~L}^{10}\right)_{3}\right]$ constructed by the linkage of $\mathrm{L}^{10}$ with silver(I) columns. From X.-L.Zhao and T. C. W. Mak, Dalton Trans. 3212-7 (2004); X.-L. Zhao and T. C. W. Mak, Polyhedron 25, 975-82 (2006).

The building block in $\left(\mathrm{L}^{9} \mathrm{H}\right)_{3} \cdot\left[\mathrm{Ag}_{8}\left(\mathrm{C}_{2}\right)\left(\mathrm{CF}_{3} \mathrm{CO}_{2}\right)_{9}\right] \cdot \mathrm{H}_{2} \mathrm{O}$ is a $\mathrm{C}_{2} @ \mathrm{Ag}_{8}$ single cage in the shape of triangulated dodecahedron located on a twofold axis. Silver cages of such type are connected by $\mu_{3}-O, O, O^{\prime}$ trifluoroacetate ligands to form a zigzag anionic silver(I) column along the $a$ direction. All three independent $L^{9}$ molecules are protonated to satisfy the overall charge balance in the crystal structure. Notably, the resulting $\mathrm{L}^{9} \mathrm{H}$ cations play a key role in the construction of the three-dimensional architecture. As shown in Fig. 20.4.29(b), the silver(I) columns are interconnected by hydrogen bonding with the protonated $\mathrm{L}^{9}$ serving as donors and $\mathrm{O}, \mathrm{F}$ atoms of trifluoroacetate ligands as acceptors to form the three-dimensional network.

In $\left[\mathrm{Ag}_{7}\left(\mathrm{C}_{2}\right)\left(\mathrm{CF}_{3} \mathrm{CO}_{2}\right)_{2}\left(\mathrm{~L}^{10}\right)_{3}\right]$, the basic building block is a centrosymmetric $\left(\mathrm{C}_{2}\right)_{2} @ \mathrm{Ag}_{14}$ double cage, with each half taking the shape of a distorted bicapped trigonal prism. Such double cages are fused together to form an infinite column. Each silver(I) column is linked to six other radiative silver(I) columns via $L^{10}$, and every three neighboring silver columns encircle a triangular hole, thus resulting in a $(3,6)$ (or $3^{6}$ ) topology, as displayed in Fig. 20.4.29(c).

## (5) Mixed-valent silver(I,II) compounds containing $\mathrm{Ag}_{2} \mathrm{C}_{2}$

To investigate the effect of coexisting metal ions on the assembly of polyhedral silver(I) cages, macrocyclic $N$-donor ligand 1,4,8,11-tetramethyl-1,4,8,11-tetraazacyclotetradecane (tmc) has been used for in situ generation
of $\left[\mathrm{Ag}^{\mathrm{II}}(\mathrm{tmc})\right]$. Mixed-valent silver complexes $\left[\mathrm{Ag}^{\mathrm{II}}(\mathrm{tmc})\left(\mathrm{BF}_{4}\right)\right]\left[\mathrm{Ag}_{6}^{\mathrm{I}}\left(\mathrm{C}_{2}\right)\right.$ $\left.\left(\mathrm{CF}_{3} \mathrm{CO}_{2}\right)_{5}\left(\mathrm{H}_{2} \mathrm{O}\right)\right] . \quad \mathrm{H}_{2} \mathrm{O}$ and $\left[\mathrm{Ag}^{\mathrm{II}}(\mathrm{tmc})\right]\left[\mathrm{Ag}^{\mathrm{II}}(\mathrm{tmc})\left(\mathrm{H}_{2} \mathrm{O}\right)\right]_{2}\left[\mathrm{Ag}_{11}^{\mathrm{I}}\left(\mathrm{C}_{2}\right)\right.$ $\left.\left(\mathrm{CF}_{3} \mathrm{CO}_{2}\right)_{12}\left(\mathrm{H}_{2} \mathrm{O}\right)_{4}\right]_{2}$ have been isolated and structurally characterized.

In $\left[\mathrm{Ag}^{\mathrm{II}}(\mathrm{tmc})\left(\mathrm{BF}_{4}\right)\right]\left[\mathrm{Ag}_{6}^{\mathrm{I}}\left(\mathrm{C}_{2}\right)\left(\mathrm{CF}_{3} \mathrm{CO}_{2}\right)_{5}\left(\mathrm{H}_{2} \mathrm{O}\right)\right] \cdot \mathrm{H}_{2} \mathrm{O}$, the addition of tmc leads to disproportionation of silver(I) to give elemental silver and complexed silver(II), the latter being stabilized by tmc to form $\left[\mathrm{Ag}^{\mathrm{II}}(\mathrm{tmc})\right]^{2+}$. Weak axial interactions of the $\mathrm{d}^{9}$ silver(II) center with adjacent $\mathrm{BF}_{4}{ }^{-}$serve to link the complexed Ag (II) cations into a $\left[\mathrm{Ag}^{\mathrm{II}}(\mathrm{tmc})\left(\mathrm{BF}_{4}\right)\right]_{\infty}^{+1}$ column, which further induces the assembly of a novel anionic zigzag chain constructed from edgesharing of silver(I) triangulated dodecahedra, each enclosing a $\mathrm{C}_{2}^{2-}$ species (Fig. 20.4.30(a)).

In $\left[\mathrm{Ag}^{\mathrm{II}}(\mathrm{tmc})\right]\left[\mathrm{Ag}^{\mathrm{II}}(\mathrm{tmc})\left(\mathrm{H}_{2} \mathrm{O}\right)\right]_{2}\left[\mathrm{Ag}_{11}^{\mathrm{I}}\left(\mathrm{C}_{2}\right)\left(\mathrm{CF}_{3} \mathrm{CO}_{2}\right)_{12}\left(\mathrm{H}_{2} \mathrm{O}\right)_{4}\right]_{2}$, which lacks the participation of $\mathrm{BF}_{4}^{-}$ions, the cations do not line up in a one-dimensional array and instead a dimeric supramolecular cluster anion is generated [Fig. 20.4.30(b)].

## (6) Ligand-induced disruption of polyhedral $\mathbf{C}_{2} @ \mathrm{Ag}_{n}$ cage assembly

Attempts to interfere with the assembly process to open the $\mathrm{C}_{2} @ \mathrm{Ag}_{n}$ cage or construct a large single cage for holding two or more $\mathrm{C}_{2}^{2-}$ species were carried out via the incorporation of the multidentate ligand $\mathrm{pyzCONH}_{2}$ (pyrazine-2carboxamide) into the reaction system. Pyrazine-2-carboxamide was selected as a structure-directing component by virtue of its very short spacer length and chelating capacity, and the introduction of the amide functionality could conceivably disrupt the assembly of $\mathrm{C}_{2} @ \mathrm{Ag}_{n}$ via the formation of hydrogen bonds. The ensuing study yielded two silver(I) complexes $\mathrm{Ag}_{12}\left(\mathrm{C}_{2}\right)_{2}\left(\mathrm{CF}_{3} \mathrm{CO}_{2}\right)_{8}(2-$ pyzCONH$)_{3}$ and $\mathrm{Ag}_{20}\left(\mathrm{C}_{2}\right)_{4}\left(\mathrm{C}_{2} \mathrm{~F}_{5} \mathrm{CO}_{2}\right)_{8}(2-\text { pyzCOO })_{4}\left(2-\right.$ pyzCONH$\left._{2}\right)\left(\mathrm{H}_{2} \mathrm{O}\right)_{2}$ exhibiting novel $\mathrm{C}_{2} @ \mathrm{Ag}_{n}$ motifs.

The basic structural unit of $\mathrm{Ag}_{12}\left(\mathrm{C}_{2}\right)_{2}\left(\mathrm{CF}_{3} \mathrm{CO}_{2}\right)_{8}\left(2-\text { pyzCONH}_{2}\right)_{3}$ comprises the fusion of a distorted triangulated dodecahedral $\mathrm{Ag}_{8}$ cage containing an embedded $\mathrm{C}_{2}^{2-}$ dianion and an open fish-like $\mathrm{Ag}_{6}\left(\mu_{6}-\mathrm{C}_{2}\right)$ motif

Fig. 20.4.30.

(b) Perspective view of the structure of the dimeric supramolecular anion in $\left[\mathrm{Ag}^{\mathrm{II}}(\mathrm{tmc})\right]\left[\mathrm{Ag}^{\mathrm{II}}(\mathrm{tmc})\left(\mathrm{H}_{2} \mathrm{O}\right)\right]_{2}\left[\mathrm{Ag}_{11}^{\mathrm{I}}\left(\mathrm{C}_{2}\right)\left(\mathrm{CF}_{3} \mathrm{CO}_{2}\right)_{12}\left(\mathrm{H}_{2} \mathrm{O}\right)_{4}\right]_{2}$. The F atoms of the $\mathrm{CF}_{3} \mathrm{CO}_{2}^{-}$ligands and some $\mathrm{CF}_{3} \mathrm{CO}_{2}$ are omitted for clarity. From Q.-M. Wang and T. C. W. Mak, Chem. Commun., 807-8 (2001); Q.-M. Wang, H. K. Lee and T. C. W. Mak, New J. Chem. 26, 513-5 (2002).

Fig. 20.4.31.
(a) Basic building unit in $\mathrm{Ag}_{12}\left(\mathrm{C}_{2}\right)_{2}\left(\mathrm{CF}_{3} \mathrm{CO}_{2}\right)_{8}(2 \text {-pyzCONH} 2)_{3}$. (b) Open fish-like $\mathrm{Ag}_{6}\left(\mu_{6}-\mathrm{C}_{2}\right)$ motif coordinated by four pyrazine-2-carboxamide ligands in
$\mathrm{Ag}_{12}\left(\mathrm{C}_{2}\right)_{2}\left(\mathrm{CF}_{3} \mathrm{CO}_{2}\right)_{8}\left(2-\mathrm{pyzCONH}_{2}\right)_{3}$. (c) The $\left(\mathrm{C}_{2}\right)_{2} @ \mathrm{Ag}_{13}$ in
$\mathrm{Ag}_{20}\left(\mathrm{C}_{2}\right)_{4}\left(\mathrm{C}_{2} \mathrm{~F}_{5} \mathrm{CO}_{2}\right)_{8}(2 \text {-pyzCOO })_{4}(2-$ pyzCONH 2$)\left(\mathrm{H}_{2} \mathrm{O}\right)_{2}$. From X.-L. Zhao and T. C. W. Mak, Organometallics 24, 4497-9 (2005).
[Fig. 20.4.31(a)]. In the $\mathrm{Ag}_{6}\left(\mu_{6}-\mathrm{C}_{2}\right)$ motif, one carbon atom is embraced by four silver atoms in a butterfly arrangement and the other bonds to two silver atoms. Its existence can be rationalized by the fact that it is stabilized by four surrounding pyrazine-2-carboxamide ligands so that steric overcrowding obstructs the aggregation of silver(I) into a closed cage [Fig. 20.4.31(b)].

The basic building block in $\mathrm{Ag}_{20}\left(\mathrm{C}_{2}\right)_{4}\left(\mathrm{C}_{2} \mathrm{~F}_{5} \mathrm{CO}_{2}\right)_{8}(2$-pyz $\mathrm{COO})_{4}\left(2-\mathrm{pyzCONH}_{2}\right)\left(\mathrm{H}_{2} \mathrm{O}\right)_{2}$ is an aggregate composed of three polyhedral units: an unprecedented partially opened cage $\left(\mathrm{C}_{2}\right)_{2} @ \mathrm{Ag}_{13}$ [Fig.20.4.31(c)] and two similar distorted $\mathrm{C}_{2} @ \mathrm{Ag}_{6}$ trigonal prisms. A pair of $\mathrm{C}_{2}^{2-}$ dianions are completely encapsulated in the $\mathrm{Ag}_{13}$ cage. For simplicity, this single cage can be visualized as composed of two distorted cubes sharing a common face, with cleavage of four of the edges and capping of a lateral face. The two embedded $\mathrm{C}_{2}^{2-}$ dianions retain their triple-bond character with similar $\mathrm{C}-\mathrm{C}$ bond lengths of 118(2) pm.

### 20.4.6 Supramolecular assembly with the silver(I)-ethynide synthon

In 2004, the silver carbide $\left(\mathrm{Ag}_{2} \mathrm{C}_{4}\right)$ was synthesized as a light gray powder, which behaves like its lower homologue $\mathrm{Ag}_{2} \mathrm{C}_{2}$, being insoluble in most solvents and highly explosive in the dry state when subjected to heating or mechanical shock. Using $\mathrm{Ag}_{2} \mathrm{C}_{4}$ and the crude polymeric silver ethynide complexes $\left[\mathrm{R}-(\mathrm{C} \equiv \mathrm{CAg})_{m}\right]_{\infty}(\mathrm{R}=$ aryl; $m=1$ or 2$)$ as starting materials, a variety of double and triple silver(I) salts containing 1,3-butadiynediide and related carbon-rich ethynide ligands have been synthesized. Investigation of the coordination modes of the ethynide moiety in these compounds led to the recognition of a new class of supramolecular synthons $\mathrm{R}-\mathrm{C} \equiv \mathrm{C} \supset \mathrm{Ag}_{n}(n=4,5)$, which can be utilized to assemble a series of one-, two-, and three-dimensional networks together with argentophilic interactions, $\pi-\pi$ stacking, silver-aromatic interactions and hydrogen bonding.

Fig. 20.4.32.
Observed $\mu_{8}$-coordination modes of $\mathrm{C}_{4}^{2-}$ dianion. (a) Symmetrical mode with two butterfly-shaped baskets in $\mathrm{Ag}_{2} \mathrm{C}_{4} \cdot 6 \mathrm{AgNO}_{3} \cdot n \mathrm{H}_{2} \mathrm{O}(n=2$, 3). From L. Zhao and T. C. W. Mak, J. Am. Chem. Soc. 126, 6852-3 (2004). (b) Symmetrical mode only with Ag-C $\sigma$ bonds in $\mathrm{Ag}_{2} \mathrm{C}_{4} \cdot 16 \mathrm{AgC}_{2} \mathrm{~F}_{5} \mathrm{CO}_{2} \cdot 6 \mathrm{CH}_{3} \mathrm{CN} \cdot 8 \mathrm{H}_{2} \mathrm{O}$. (c) Barb-like $\mu_{8}$-coordination mode with two linearly coordinated $\mathrm{C} \equiv \mathrm{C}-\mathrm{Ag}$ bonds in triple salt $\mathrm{Ag}_{2} \mathrm{C}_{4} \cdot \mathrm{AgF} \cdot 3 \mathrm{AgNO}_{3} \cdot 0.5 \mathrm{H}_{2} \mathrm{O}$. (d) Symmetrical mode with two parallel planar $\mathrm{Ag}_{4}$ aggregates in $\mathrm{Ag}_{2} \mathrm{C}_{4} \cdot 16 \mathrm{AgC}_{2} \mathrm{~F}_{5} \mathrm{CO}_{2} \cdot 24 \mathrm{H}_{2} \mathrm{O}$. (e) Unsymmetrical $\mu_{8}$-coordination mode with one butterfly-shaped $\mathrm{Ag}_{4}$ basket and one planar $\mathrm{Ag}_{4}$ aggregate in $\mathrm{Ag}_{2} \mathrm{C}_{4} \cdot 6 \mathrm{AgCF}_{3} \mathrm{CO}_{2} \cdot 7 \mathrm{H}_{2} \mathrm{O}$. (f) Unsymmetrical $\mu_{8}$-coordination mode with two butterfly-shaped $\mathrm{Ag}_{4}$ baskets in quadruple salt $\mathrm{Ag}_{2} \mathrm{C}_{4} \cdot 4 \mathrm{AgNO}_{3} \cdot \mathrm{Ag}_{3} \mathrm{PO}_{4} \cdot \mathrm{AgPF}_{2} \mathrm{O}_{2}$.

## (1) Silver(I) complexes containing the $\mathrm{C}_{4}^{2-}$ dianion

In all of its silver(I) complexes, the linear ${ }^{-} \mathrm{C} \equiv \mathrm{C}-\mathrm{C} \equiv \mathrm{C}^{-}$dianion exhibits an unprecedented $\mu_{8}$-coordination mode, each terminal being capped by four silver(I) atoms (Fig. 20.4.32). However, the $\sigma$ - and $\pi$-type silver-ethynide interactions play different roles in symmetrical and unsymmetrical $\mu_{8}$-coordination. Furthermore, coexisting ancillary anionic ligands, nitrile groups, and aqua molecules also influence the coordination environment around each terminal ethynide, which takes the form of a butterfly-shaped, barb-like, or planar $\mathrm{Ag}_{4}$ basket. The carbon-carbon triple- and single-bond lengths in $\mathrm{C}_{4}^{2-}$ are in good agreement with those observed in transition-metal 1,3-butadiyne-1,4-diyl complexes. The $\mathrm{Ag} \cdots \mathrm{Ag}$ distances within the $\mathrm{Ag}_{4}$ baskets are all shorter than 340 pm , suggesting the existence of significant $\mathrm{Ag} \cdots \mathrm{Ag}$ interactions.

The $\left[\mathrm{Ag}_{4} \mathrm{C}_{4} \mathrm{Ag}_{4}\right]$ aggregates vide supra can be further linked by other anionic ligands such as nitrate and perfluorocarboxylate groups, and/or water molecules, to produce various two- or three-dimensional coordination networks. In the structure of $\mathrm{Ag}_{2} \mathrm{C}_{4} \cdot 6 \mathrm{AgNO}_{3} \cdot 2 \mathrm{H}_{2} \mathrm{O}$, the $\left[\mathrm{Ag}_{4} \mathrm{C}_{4} \mathrm{Ag}_{4}\right]$ aggregates arranged in a pseudo-hexagonal array are connected by one nitrate group acting in the $\mu_{3}-\mathrm{O}, \mathrm{O}^{\prime}, \mathrm{O}^{\prime \prime}$ plus $\mathrm{O}, \mathrm{O}^{\prime}$-chelating mode to form a thick layer normal to [100] [Fig. 20.4.33(a)]. Linkage of adjacent layers by the remaining two independent nitrate groups, abetted by $\mathrm{O}-\mathrm{H} \cdots \mathrm{O}$ (nitrate) hydrogen bonding involving the aqua ligand, then generates a three-dimensional network.

In the crystal structure of $\mathrm{Ag}_{2} \mathrm{C}_{4} \cdot 16 \mathrm{AgC}_{2} \mathrm{~F}_{5} \mathrm{CO}_{2} \cdot 24 \mathrm{H}_{2} \mathrm{O}$, each $\left[\mathrm{Ag}_{4} \mathrm{C}_{4} \mathrm{Ag}_{4}\right]$ unit connects with eight such units by eight $\left[\mathrm{Ag}_{2}\left(\mu-\mathrm{O}_{2} \mathrm{CC}_{2} \mathrm{~F}_{5}\right)_{4}\right]$ bridging ligands to form a $(4,4)$ coordination network [Fig. 20.4.33(b)]. Through the

Fig. 20.4.33.
Some examples of two- and three-dimensional coordination networks of $\mathrm{Ag}_{2} \mathrm{C}_{4}$ : (a) pseudohexagonal array of [ $\left.\mathrm{Ag}_{4} \mathrm{C}_{4} \mathrm{Ag}_{4}\right]$ aggregates linked by an independent nitrate group in $\mathrm{Ag}_{2} \mathrm{C}_{4} \cdot 6 \mathrm{AgNO}_{3} \cdot 2 \mathrm{H}_{2} \mathrm{O}$ : (b) $(4,4)$ network in $a b$ plane of $\mathrm{Ag}_{2} \mathrm{C}_{4} \cdot 16 \mathrm{AgC}_{2} \mathrm{~F}_{5} \mathrm{CO}_{2} \cdot 24 \mathrm{H}_{2} \mathrm{O}$, which is composed of $\left[\mathrm{Ag}_{4} \mathrm{C}_{4} \mathrm{Ag}_{4}\right]$ aggregates connected by bridging $\left[\mathrm{Ag}_{2}\left(\mu-\mathrm{O}_{2} \mathrm{CC}_{2} \mathrm{~F}_{5}\right)_{4}\right]$ groups: (c) three-dimensional coordination network in $\mathrm{Ag}_{2} \mathrm{C}_{4} \cdot \mathrm{AgF} \cdot 3 \mathrm{AgNO}_{3} \cdot 0 \cdot 5 \mathrm{H}_{2} \mathrm{O}$ through the coordination of $\mu_{3}$-fluoride ligands, (d) Rosette layer in $\mathrm{Ag}_{2} \mathrm{C}_{4} \cdot 10 \mathrm{AgCF}_{3} \mathrm{CO}_{2} \cdot 2\left[\left(\mathrm{Et}_{4} \mathrm{~N}\right) \mathrm{CF}_{3} \mathrm{CO}_{2}\right]$ $.4\left(\mathrm{CH}_{3}\right)_{3} \mathrm{CCN}$ composed of $\left[\mathrm{Ag}_{4} \mathrm{C}_{4} \mathrm{Ag}_{4}\right]$ aggregates linked by one external silver atom and two trifluoroacetate groups.
linkage of the $\mathrm{C}_{4}$ carbon chains perpendicular to this network, an infinite channel is aligned along the [001] direction, and each accommodates a large number of pentafluoroethyl groups.

In the crystal structure of $\mathrm{Ag}_{2} \mathrm{C}_{4} \cdot \mathrm{AgF} \cdot 3 \mathrm{AgNO}_{3} \cdot 0.5 \mathrm{H}_{2} \mathrm{O},\left[\mathrm{Ag}_{4} \mathrm{C}_{4} \mathrm{Ag}_{4}\right]$ aggregates are mutually connected through the linkage of nitrate groups and sharing of some silver atoms to form a silver column. The fluoride ions bridge these silver columns in the $\mu_{3}$-mode to produce a structurally robust three-dimensional coordination network [(Fig. 20.4.33(c)]). With an external silver atom and two carboxylato oxygen atoms as bridging groups, the $\left[\mathrm{Ag}_{4} \mathrm{C}_{4} \mathrm{Ag}_{4}\right]$ aggregates in $\mathrm{Ag}_{2} \mathrm{C}_{4} \cdot 10 \mathrm{AgCF}_{3} \mathrm{CO}_{2} \cdot 2\left[\left(\mathrm{Et}_{4} \mathrm{~N}\right) \mathrm{CF}_{3} \mathrm{CO}_{2}\right] \cdot 4\left(\mathrm{CH}_{3}\right)_{3} \mathrm{CCN}$ are linked to form a two-dimensional rosette layer, in which the $\mathrm{C}_{4}^{2-}$ dianion acts as the shared border of two metallacycles [Fig. 20.4.33(d)].
(2) Silver(I) complexes of isomeric phenylenediethynides with the supramolecular synthons $\mathrm{Ag}_{n} \subset \mathbf{C}_{2}-x-\mathbf{C}_{6} \mathbf{H}_{4}-\mathbf{C}_{2} \supset \mathrm{Ag}_{n}(x=p, m$, $o$; $n=4,5)$
The above study of silver(I) 1,3-butadiynediide complexes suggests that the $\mathrm{Ag}_{4} \subset \mathrm{C}_{2}-\mathrm{R}-\mathrm{C}_{2} \supset \mathrm{Ag}_{4}$ moiety may be conceived as a synthon for the assembly of coordination networks, by analogy to the plethora of wellknown supramolecular synthons that involve hydrogen bonding and other weak intermolecular interactions (see Section 20.1.5). With reference to 1,3butadiynediide as a standard, the p-phenylene ring was introduced as the bridging R group in the supramolecular synthon $\mathrm{Ag}_{n} \subset \mathrm{C}_{2}-\mathrm{R}-\mathrm{C}_{2} \supset \mathrm{Ag}_{n}$ with a lengthened linear $\pi$-conjugated backbone, and the aromatic ring of the resulting $p$-phenylenediethynide dianion could presumably partake in $\pi-\pi$ stacking and silver-aromatic interaction. The isomeric $m$ - and $o$-phenylenediethynides were also investigated in order to probe the influence of varying the relative orientation of the pair of terminal ethynide groups.

In $2\left[\mathrm{Ag}_{2}\left(p-\mathrm{C} \equiv \mathrm{CC}_{6} \mathrm{H}_{4} \mathrm{C} \equiv \mathrm{C}\right)\right] \cdot 11 \mathrm{AgCF}_{3} \mathrm{CO}_{2} \cdot 4 \mathrm{CH}_{3} \mathrm{CN} \cdot 2 \mathrm{CH}_{3} \mathrm{CH}_{2} \mathrm{CN}$, the $p$ phenylenediethynide ligand exhibits the highest ligation number reported to date for the ethynide moiety by adopting an unprecedented $\mu_{5-} \eta^{1}$ mode.

Fig. 20.4.34.
(a) Broken silver(I) double chain in $2\left[\mathrm{Ag}_{2}\left(p \mathrm{C} \equiv \mathrm{CC}_{6} \mathrm{H}_{4} \mathrm{C} \equiv \mathrm{C}\right)\right] \cdot 11 \mathrm{AgCF}_{3} \mathrm{CO}_{2} \cdot 4 \mathrm{CH}_{3} \mathrm{CN} \cdot 2 \mathrm{CH}_{3} \mathrm{CH}_{2} \mathrm{CN}$ stabilized by continuous $\pi-\pi$ stacking between parallel $p$-phenylene rings. (b) Silver double chain in $\mathrm{Ag}_{2}\left(m-\mathrm{C} \equiv \mathrm{CC}_{6} \mathrm{H}_{4} \mathrm{C} \equiv \mathrm{C}\right) \cdot 6 \mathrm{AgCF}_{3} \mathrm{CO}_{2} \cdot 3 \mathrm{CH}_{3} \mathrm{CN} \cdot 2.5 \mathrm{H}_{2} \mathrm{O}$ assembled by argentophilic interaction and $\pi-\pi$ interaction between adjacent pairs of $m$-phenylene rings. (c) Widened silver chain in
$3\left[\mathrm{Ag}_{2}\left(o-\mathrm{C} \equiv \mathrm{CC}_{6} \mathrm{H}_{4} \mathrm{C} \equiv \mathrm{C}\right)\right] \cdot 14 \mathrm{AgCF}_{3} \mathrm{CO}_{2} \cdot 2 \mathrm{CH}_{3} \mathrm{CN} \cdot 9 \mathrm{H}_{2} \mathrm{O}$ constructed through the cross-linkage of two narrow silver chains by bridging silver atoms with pairwise $\pi-\pi$ interaction between the $o$-phenylene rings. (d) Broken silver(I) double chain in
$\left.\mathrm{Ag}_{2}\left(m-\mathrm{C} \equiv \mathrm{CC}_{6} \mathrm{H}_{4} \mathrm{C} \equiv \mathrm{C}\right)\right] \cdot 5 \mathrm{AgNO}_{3} \cdot 3 \mathrm{H}_{2} \mathrm{O}$ stabilized by continuous $\pi-\pi$ stacking between parallel $m$-phenylene rings. From L. Zhao and T. C. W. Mak, J. Am. Chem. Soc. 127, 14966-7 (2005).

The $\mathrm{Ag}_{14}$ aggregate, being constructed essentially from two independent $\mathrm{Ag}_{n} \subset \mathrm{C}_{2}-\left(p-\mathrm{C}_{6} \mathrm{H}_{4}\right)-C_{2} \supset \mathrm{Ag}_{n}(n=4,5)$ synthons through argentophilic interaction and continuous $\pi-\pi$ stacking, is connected to its symmetry equivalents to form a broken silver(I) double chain along the $a$-axis. Adjacent $\mathrm{Ag}_{14}$ segments within a single chain are bridged by the oxygen atoms of two independent trifluoroacetate groups, and the pair of single chains are arranged in interdigitated fashion [Fig. 20.4.34(a)].

In contrast to the popular $\mu_{1}, \mu_{1}$-coordination mode of $m$-phenylenediethynide in most transition-metal complexes, this ligand exhibits two different terminal ethynide bonding modes, namely, $\mu_{4}-\eta^{1}, \eta^{1}, \eta^{1}, \eta^{1}$ and $\mu_{4}-\eta^{1}, \eta^{1}, \eta^{1}, \eta^{2}$, in the crystal structure of $\mathrm{Ag}_{2}\left(\mathrm{~m}-\mathrm{C} \equiv \mathrm{CC}_{6} \mathrm{H}_{4} \mathrm{C} \equiv \mathrm{C}\right) \cdot 6 \mathrm{AgCF}_{3} \mathrm{CO}_{2} \cdot 3 \mathrm{CH}_{3} \mathrm{CN} \cdot 2 \cdot 5 \mathrm{H}_{2} \mathrm{O}$. Through inversion centers located between successive pairs of $m$-phenylene rings, the $\mathrm{Ag}_{n} \subset \mathrm{C}_{2}-\left(m-\mathrm{C}_{6} \mathrm{H}_{4}\right)-\mathrm{C}_{2} \supset \mathrm{Ag}_{n}(n=4)$ synthon is extended along the $a$ direction by $\mathrm{Ag} \cdots \mathrm{Ag}$ interactions to form a silver double chain [Fig. 20.4.34(b)], which are further consolidated by $\pi-\pi$ interaction between adjacent $m$-phenylene rings protruding alternatively on either side.

In the crystal structure of $3\left[\mathrm{Ag}_{2}\left(o-\mathrm{C} \equiv \mathrm{CC}_{6} \mathrm{H}_{4} \mathrm{C} \equiv \mathrm{C}\right)\right] \cdot 14 \mathrm{AgCF}_{3} \mathrm{CO}_{2}$ $\cdot 2 \mathrm{CH}_{3} \mathrm{CN} \cdot 9 \mathrm{H}_{2} \mathrm{O}$, the ethynide moieties bond to silver atoms via three different coordination modes: $\mu_{4}-\eta^{1}, \eta^{1}, \eta^{1}, \eta^{2}, \mu_{4}-\eta^{1}, \eta^{1}, \eta^{2}, \eta^{2}$, and $\mu_{5}-\eta^{1}, \eta^{1}, \eta^{1}, \eta^{1}, \eta^{2}$ [Fig. 20.4.34(c)]. The two independent $\mathrm{Ag}_{n} \subset \mathrm{C}_{2}-\left(\mathrm{o}-\mathrm{C}_{6} \mathrm{H}_{4}\right)-\mathrm{C}_{2} \supset \mathrm{Ag}_{n}(n=4$, 5) synthons mutually associate to generate an undulating silver chain consolidated by argentophilic interaction, pairwise $\pi-\pi$ interaction between the $o$-phenylene rings, and linkage by silver atoms Ag 3 and Ag 9 across two silver single chains. Bridged by silver atom Ag 10 through $\mathrm{Ag} \cdots \mathrm{Ag}$ interaction and three oxygen atoms ( $\mathrm{O} 2 \mathrm{~W}, \mathrm{O} 4, \mathrm{O}$ ), the silver columns are linked to form a wave-like layer with $o$-phenylene groups protruding on both sides.

## Fig. 20.4.35.

Schematic diagram showing the structural relationship between the supramolecular synthons
$\mathrm{Ag}_{4} \subset \mathrm{C}_{2}-\mathrm{C}_{2} \supset \mathrm{Ag}_{4}, \mathrm{Ag}_{n} \subset$ $\mathrm{C}_{2}-\mathrm{R}-\mathrm{C}_{2} \supset \mathrm{Ag}_{n}\left(R=\mathrm{p}-, m-, o-\mathrm{C}_{6} \mathrm{H}_{4}\right.$; $n=4,5)$, and $\mathrm{C}_{2} @ \operatorname{Ag}_{n}(n=6-10)$. The circular arc represents a $\mathrm{Ag}_{n}(n=4,5)$ basket.

The decreasing separation of the pair of ethynide groups in the above three complexes is accompanied by strengthened argentophilic interaction at the expense of weakened $\pi-\pi$ stacking, yielding a broken double chain, a double chain and a silver layer, respectively. When the pair of ethynide vectors make an angle of $60^{\circ}$, sharing of a common silver atom for the $\mathrm{Ag}_{n}$ caps occurs in the o-phenylenediethynide complex.

The crystal structure of $\left.\mathrm{Ag}_{2}\left(m-\mathrm{C} \equiv \mathrm{CC}_{6} \mathrm{H}_{4} \mathrm{C} \equiv \mathrm{C}\right)\right] \cdot 5 \mathrm{AgNO}_{3} \cdot 3 \mathrm{H}_{2} \mathrm{O}$ features a broken silver(I) double chain analogous to that of the p-phenylenediethynide complex [see Fig. 20.4.34(a). However, the single chains containing the $\mathrm{Ag}_{14}$ aggregates are arranged in parallel fashion, each matching $\mathrm{Ag}_{14}$ pair being connected by two m-phenylenediethynide ligands [Fig. 20.4.34(d)]. Linkage of a series of $\mathrm{Ag}_{n} \subset \mathrm{C}_{2}-\left(m-\mathrm{C}_{6} \mathrm{H}_{4}\right)-\mathrm{C}_{2} \supset \mathrm{Ag}_{n}(n=4)$ fragments by intrachain bridging nitrate groups with continuous $\pi-\pi$ interaction between adjacent m phenylene rings engenders the broken silver(I) double chain.

The structural correlation between various silver-ethynide supramolecular synthons affords a rationale for the preponderant existence of $\mathrm{C}_{2} @ \mathrm{Ag}_{n}(n=$ $6-10$ ) polyhedra in $\mathrm{Ag}_{2} \mathrm{C}_{2}$ complexes (see Section 20.4.5). If the linear ${ }^{-} \mathrm{C} \equiv \mathrm{C}-$ $\mathrm{C} \equiv \mathrm{C}^{-}$chain were contracted to a $\mathrm{C}_{2}^{2-}$ dumbbell, further overlap between atoms of the terminal $\mathrm{Ag}_{n}$ caps would conceivably yield a closed cage with 6-10 vertices (Fig. 20.4.35).
(3) $\operatorname{Silver}(\mathbf{I})$ arylethynide complexes containing $\mathbf{R}-\mathrm{C}_{2} \supset \mathrm{Ag}_{n}\left(\mathbf{R}=\mathbf{C}_{6} \mathbf{H}_{5}\right.$,

$\pi-\pi$ Stacking or $\pi-\pi$ interactions are important noncovalent intermolecular interactions, which contribute much to self-assembly when extended structures are formed from building blocks with aromatic moieties. In relation to the rich variety of $\pi-\pi$ stacking in the crystal structure of silver(I) complexes of phenylenediethynide, related silver complexes of phenylethynide and its homologues with different substituents $\left(-\mathrm{CH}_{3},-\mathrm{C}\left(\mathrm{CH}_{3}\right)_{3}\right)$ or the $-\mathrm{CH}_{3}$ group in different positions ( $o-, m-, p$-) are investigated.

In the crystal structure of $2 \mathrm{AgC} \equiv \mathrm{CC}_{6} \mathrm{H}_{5} \cdot 6 \mathrm{AgC}_{2} \mathrm{~F}_{5} \mathrm{CO}_{2} \cdot 5 \mathrm{CH}_{3} \mathrm{CN}$, the ethynide group composed of C 1 and C 2 is capped by a square-pyramidal $\mathrm{Ag}_{5}$ basket in an unprecedented $\mu_{5}-\eta^{1}, \eta^{1}, \eta^{1}, \eta^{1}, \eta^{2}$ coordination mode and the other one comprising C9 and C10 by a butterfly-shaped $\mathrm{Ag}_{4}$ basket in a $\mu_{4}{ }^{-}$ $\eta^{1}, \eta^{1}, \eta^{1}, \eta^{2}$ coordination mode, as shown in Fig. 20.4.36(a). With an inversion center located at the center of the $\mathrm{Ag} 1 \cdots \mathrm{Ag} 1 \mathrm{~A}$ bond, two $\mathrm{Ag}_{5}$ baskets share an edge to engender $\mathrm{ag}_{8}$ aggregate, whereas another $\mathrm{Ag}_{8}$ aggregate results from fusion of a pair of inversion-related $\mathrm{Ag}_{4}$ baskets. Two adjacent $\mathrm{Ag}_{8}$ agregates

Fig. 20.4.36.
(a) Coordination modes of the independent phenylethynide ligands in $2 \mathrm{AgC} \equiv \mathrm{CC}_{6} \mathrm{H}_{5} \cdot 6 \mathrm{AgC}_{2} \mathrm{~F}_{5} \mathrm{CO}_{2} \cdot 5 \mathrm{CH}_{3} \mathrm{CN}$. (b) Coordination mode of the $\mathrm{C}_{6} \mathrm{H}_{5} \mathrm{C} \equiv \mathrm{C}^{-}$ligand in $\mathrm{AgC} \equiv \mathrm{CC}_{6} \mathrm{H}_{5} \cdot 3 \mathrm{AgCF}_{3} \mathrm{CO}_{2} \cdot \mathrm{CH}_{3} \mathrm{CN}$. The silver column is connected by edge-sharing between adjacent square-pyramidal $\mathrm{Ag}_{5}$ aggregates, and continuous $\pi-\pi$ stacking of phenyl rings occurs on one side of the column. From L. Zhao, W.-Y. Wong and T. C. W. Mak, Chem. Eur. J. 12, 4865-72 (2006).
are linked by two pentafluoropropionate groups via $\mu_{3}-\mathrm{O}, \mathrm{O}^{\prime}, \mathrm{O}^{\prime}$ and $\mu_{2}-O$, $\mathrm{O}^{\prime}$ coordination modes, respectively, to generate an infinite column along the [111] direction. No $\pi-\pi$ interaction is observed in this complex.

An infinite array of parallel phenyl rings stabilized by $\pi-\pi$ stacking (center-to-center distance 418.9 pm ) occurs in the complex $\mathrm{AgC} \equiv \mathrm{CC}_{6} \mathrm{H}_{5} \cdot 3 \mathrm{AgCF}_{3} \mathrm{CO}_{2}$ $\cdot \mathrm{CH}_{3} \mathrm{CN}$ [Fig. 20.4.36(b)]. The capping square-planar $\mathrm{Ag}_{5}$ baskets are fused through argentophilic interactions via edge-sharing to form an infinite coordination column along the [100] direction, with continuous $\pi-\pi$ stacking of phenyl rings lying on the same side of the column.

When substituents are introduced into the phenyl group, the $\pi-\pi$ stacking between consecutive aromatic rings is affected by the size of the substituted groups and their positions. In the crystal structure of $2 \mathrm{AgC} \equiv \mathrm{CC}_{6} \mathrm{H}_{4} \mathrm{Me}-4 \cdot 6 \mathrm{AgCF}_{3} \mathrm{CO}_{2} \cdot 1.5 \mathrm{CH}_{3} \mathrm{CN}$ [Fig. 20.4.37(a)], the methyl group has a little influence on the formation of a silver column stabilized by $\pi-\pi$ stacking, which is almost totally identical with the structure of $\mathrm{AgC} \equiv \mathrm{CC}_{6} \mathrm{H}_{5} \cdot 3 \mathrm{AgCF}_{3} \mathrm{CO}_{2} \cdot \mathrm{CH}_{3} \mathrm{CN}$ [see Fig. 20.4.36(b)]. However, when a more bulky tert-butyl group is employed, the $\pi-\pi$ stacking system is interrupted despite the formation of a similar silver chain [Fig. 20.4.37(b)]. The entire $\mathrm{C}_{6} \mathrm{H}_{4}^{t} \mathrm{Bu}-4$ moiety rotates around the $\mathrm{C}\left({ }^{t} \mathrm{Bu}\right)-\mathrm{C}$ (phenyl) single bond to generate a highly disordered structure. On the other hand, putting a meta-methyl group on the phenyl ring can form $\mathrm{C}-\mathrm{H} \cdots \pi$ interaction, but the constitution of the silver chain is changed from edge-sharing to vertex-sharing [Fig. 20.4.37(c)]. Finally, use of the 2-methyl-substituted phenyl ligand entirely destroys the $\pi-\pi$ stacking and even breaks the $\mathrm{Ag} \cdots \mathrm{Ag}$ interactions between $\mathrm{Ag}_{n}$ caps to form a silver chain connected by trifluoroacetate groups [Fig. 20.4.37(d)].

### 20.4.7 Self-assembly of nanocapsules with pyrogallol[4]arene macrocycles

Recent studies have shown that the bowl-shaped $C$-alkyl substituted pyrogallol[4]arene macrocycles readily self-assemble to form a gobular hexameric cage, which is structurally robust and remains stable even in aqueous media (Fig. 20.4.38). Slow evaporation of a solution of $C$-heptylpyrogallol[4]arene in ethyl acetate gives crystalline $\left[(C \text {-heptylpyrogallol[4]arene })_{6}(\mathrm{EtOAc})_{6}\right.$

Fig. 20.4.37.
(a) Silver column in $2 \mathrm{AgC} \equiv \mathrm{CC}_{6} \mathrm{H}_{4} \mathrm{Me}-4 \cdot 6 \mathrm{AgCF}_{3} \mathrm{CO}_{2} \cdot 1.5 \mathrm{CH}_{3} \mathrm{CN}$ connected by the fusion of square-pyramidal $\mathrm{Ag}_{5}$ baskets and stabilized by continuous $\pi-\pi$ stacking of phenyl rings. (b) Similar silver column in $\mathrm{AgC} \equiv \mathrm{CC}_{6} \mathrm{H}_{4}^{t} \mathrm{Bu}-4 \cdot 3 \mathrm{AgCF}_{3} \mathrm{CO}_{2} \cdot \mathrm{CH}_{3} \mathrm{CN}$ connected only by argentophilic interaction. (c) Silver chain in $\mathrm{AgC} \equiv \mathrm{CC}_{6} \mathrm{H}_{4} \mathrm{Me}-3 \cdot 2 \mathrm{AgCF}_{3} \mathrm{SO}_{3}$ through atom sharing. (d) Silver chain in $\mathrm{AgC} \equiv \mathrm{CC}_{6} \mathrm{H}_{4} \mathrm{Me}-2 \cdot 4 \mathrm{AgCF}_{3} \mathrm{CO}_{2} \cdot \mathrm{H}_{2} \mathrm{O}$ through the connection of trifluoroacetate groups.
$\left.\left(\mathrm{H}_{2} \mathrm{O}\right)\right] \cdot 6 \mathrm{EtOAc}$, and X-ray analysis revealed that the large spheroidal supermolecule is stabilized by a total of $72 \mathrm{O}-\mathrm{H} \cdots \mathrm{O}$ hydrogen bonds (four intramolecular and eight intermolecular per macrocycle building block). The nano-sized molecular capsule, having an internal cavity volume of about 1.2 $\mathrm{nm}^{3}$, contains six ethyl acetate molecules and one water molecule; the methyl terminal of each encapsulated ethyl acetate guest molecule is orientated toward a bulge on the surface, and the single guest water molecule resides at the center of the capsule. In the crystal structure, the external ethyl acetate solvate molecules are embedded within the lower rim alkyl legs at the base of each of the macrocycles, and the nanocapsules are arranged in hexagonal closest packing.

Fig. 20.4.38.
Assembly of six $C$-heptylpyrogallol[4]arene molecules by intra- and intermolecular hydrogen bonds to form a globular supermolecule with a host cavity of volume $\sim 1.2 \mathrm{~nm}^{3}$. H atoms are omitted for clarity, and hydrogen bonds are represented by dotted lines. From G. V. C. Cave, J. Antesberger, L. J. Barbour, R. M. McKinley and J. L. Atwood, Angew. Chem. Int. Ed. 43, 5263-6 (2004).

With reference to the unique architecture of this hydrogen-bonded hexameric capsule $\mathbf{I}$ [Fig. 20.4.39(a)], it was noted that the pyrogallol[4]arene building block has the potential of serving as a multidentate ligand through deprotonation of some of the upper rim phenolic groups. As envisaged, treatment of

capsule I

capsule II
$C$-propan-3-ol pyrogallol[4]arene with four equivalents of $\mathrm{Cu}\left(\mathrm{NO}_{3}\right)_{2} \cdot 3 \mathrm{H}_{2} \mathrm{O}$ in a mixture of acetone and water yielded a large neutral coordination capsule II $\left.\left[\mathrm{Cu}_{24}\left(\mathrm{H}_{2} \mathrm{O}\right)_{x}\left(\mathrm{C}_{40} \mathrm{H}_{40} \mathrm{O}_{16}\right)_{6} \text { (acetone) }\right)_{n}\right]$ where $x \geq 24$ and $n=1-6$. Singlecrystal X-ray analysis established that retro-insertion of 24 Cu (II) metal centers into the hexameric framework results in substitution of 48 of the 72 phenolic protons, leaving the remaining 24 intact for intramolecular hydrogen bonding ( $\mathrm{O} \cdots \mathrm{O} 0.2400-0.2488 \mathrm{~nm}$ ). As shown in Fig. 20.4.39(b), the large coordination capsule II may be viewed as an octahedron with the six 16 -membered macrocylic rings located at its corners, and each of its eight faces is capped by a planar cyclic $\left[\mathrm{Cu}_{3} \mathrm{O}_{3}\right.$ ] unit of dimensions $\mathrm{Cu}-\mathrm{O} 0.1911$ to $0.1980 \mathrm{~nm}, \mathrm{O}-\mathrm{Cu}-\mathrm{O}$ $85.67^{\circ}$ to $98.23^{\circ}$, and $\mathrm{Cu}-\mathrm{O}-\mathrm{Cu} 140.96^{\circ}$ to $144.78^{\circ}$.

Definitive location of all guest molecules inside the cavity is somewhat ambiguous owing to inexact stoichiometry and disorder. However, the (+)MALDI mass spectra of II indicate that each individual capsule encloses different mixtures of water and acetone. In particular, two peaks implicated the presence of 24 entrapped water molecules that occupy axial coordination sites orientated toward the center of the cavity.

The pair of supramolecular capsules I and II represents a landmark in the construction of large coordination cages using multicomponent ligands. This elegant blueprint approach is facilitated by the robustness of the hydrogenbonded assembly I, which serves as a template for metal-ion insertion at specific sites with conservation of structural integrity. Notably, capsule size is virtually unchanged as the center-to-corner distance of the four phenolic O atoms belonging to the eight-membered intermolecular hydrogen-bonded ring ( $0.1883-0.1976 \mathrm{~nm}$ ) in I closely matches the $\mathrm{Cu}-\mathrm{O}$ bond distance of $0.1913-0.1978 \mathrm{~nm}$ in II.

### 20.4.8 Reticular design and synthesis of porous metal-organic frameworks

The design and synthesis of metal-organic frameworks (MOFs) has yielded a large number of solids that possess useful gas and liquid adsorption properties. In particular, highly porous structures constructures constructed from discrete

Fig. 20.4.39.
Hydrogen-bonded supramolecular capsule I compared with coordination capsule II. The external aliphatic groups are omitted for clarity. Note that a pair of intermolecular $\mathrm{O}-\mathrm{H} \cdots \mathrm{O}$ hydrogen bonds is replaced by four square-planar $\mathrm{Cu}-\mathrm{O}$ coordination bonds in the metal-ion insertion process that generates the isostructural inorganic analog. From R. M. McKinley, G. V. C. Cave and J. L. Atwood, Proc. Nat. Acad. Sci. 102, 5944-8 (2005).

## Fig. 20.4.40.

Crystal structure of MOF-5. (a) $\mathrm{Zn}_{4} \mathrm{O}$ tetrahedra joined by benzenedicarboxylate linkers. H atoms are omitted for clarity. (b) The topology of the framework (primitive cubic net) shown as an assembly of $\left(\mathrm{Zn}_{4} \mathrm{O}\right) \mathrm{O}_{12}$ clusters (represented as truncated tetrahedra) and $p$-phenylene $\left(-\mathrm{C}_{6} \mathrm{H}_{4}-\right)$ links (represented by rods). From O. M. Yaghi, M. O'Keeffe, N. W. Ockwig, H. K. Chae, M. Eddaoudi, and J. Kim, Nature 423, 705-14 (2003).

metal-carboxylate clusters and organic links have been demonstrated to be amenable to systematic variation in pore size and functionality.

Consider the structure of the discrete tetranuclear $\mathrm{Zn}_{4} \mathrm{O}\left(\mathrm{CH}_{3} \mathrm{CO}_{2}\right)_{6}$ molecule, which is isostructural with $\mathrm{Be}_{4} \mathrm{O}\left(\mathrm{CH}_{3} \mathrm{CO}_{2}\right)_{6}$, the structure of which is shown in Fig. 9.5.2. Replacement of each acetate ligand by one half of a linear dicarboxylate produces a molecular entity that can conceivably be interconnected to identical entities to generate an infinite coordination network. An illustrative example is $\mathrm{Zn}_{4} \mathrm{O}(\mathrm{BDC})_{6}$, referred to as MOF-5, which is prepared from $\mathrm{Zn}(\mathrm{II})$ and benzene-1,4-dicarboxylic acid $\left(\mathrm{H}_{2} \mathrm{BDC}\right)$ under solvothermal conditions. In the crystal structure, a $\mathrm{Zn}_{4} \mathrm{O}\left(\mathrm{CO}_{2}\right)_{6}$ fragment comprising four fused $\mathrm{ZnO}_{4}$ tetrahedra sharing a common vertex and six carboxylate C atoms constitute a "secondary building unit" (SBU). Connection of such octahedral SBUs by mutually perpendicular $p$-phenylene $\left(-\mathrm{C}_{6} \mathrm{H}_{4}-\right)$ links leads to an infinite primitive cubic network, as shown in Fig. 20.4.40. Alternatively, the smaller $\mathrm{Zn}_{4} \mathrm{O}$ fragment (an oxo-centered $\mathrm{Zn}_{4}$ tetrahedron) can be regarded as the SBU and the corresponding organic linker is the whole benzene-1,4-dicarboxylate dianion.

The resulting MOF-5 structure has exceptional stability and porosity as both the SBU and organic link are relatively large and inherently rigid. This reticular [which means 'having the form of a (usually periodic) net] design strategy, based on the concept of discrete SBUs of different shapes (triangles, squares, tetrahedra, octahedra, etc.) considered as "joints" and organic links considered as "struts", has been applied to the synthesis and utilization of a vast number of MOF structures exhibiting varying geometries and network topologies. Based on the $\mathrm{Zn}_{4} \mathrm{O}\left(\mathrm{CO}_{2}\right)_{6} \mathrm{SBU}$ in the prototype MOF-5 (also designated as IRMOF1), a family of isoreticular and isostructural cubic frameworks with diverse pore sizes and functionalities has been constructed, including IRMOF-6, IRMOF-8, IRMOF-11, and IRMOF-16, which are illustrated in Fig. 20.4.41.

An example of a porous framework that is isoreticular, but not isostructural, with MOF-5 is MOF-177, which incorporates the extended organic linker 1,3,5-benzenetribenzoate (BTB). The framework of crystalline MOF$177, \mathrm{Zn}_{4} \mathrm{O}(\mathrm{BTB})_{2} \cdot(\mathrm{DEF})_{15}\left(\mathrm{H}_{2} \mathrm{O}\right)_{3}$, where $\mathrm{DEF}=$ diethyl formamide, has an ordered structure with an estimated surface area of $4,500 \mathrm{~m}^{2} \mathrm{~g}^{-1}$, which greatly exceeds those of zeolite $\mathrm{Y}\left(904 \mathrm{~m}^{2} \mathrm{~g}^{-1}\right)$ and carbon $\left(2,030 \mathrm{~m}^{2} \mathrm{~g}^{-1}\right)$.

IRMOF-8

As shown in Fig. 20.4.42, the underlying topology of MOF-177 is a (6,3)net with the center of the octahedral $\mathrm{Zn}_{4} \mathrm{O}\left(\mathrm{CO}_{2}\right)_{6}$ cluster as the six-connected node and the center of the BTB unit as the three-connected node. Its exceptionally large pores are capable of accommodating polycyclic organic guest molecules such as bromobenzene, 1-bromonaphthalene, 2-bromonaphthalene, 9 -bromoanthracene, C60, and the polycyclic dyes Astrazon Orange R and Nile Red.

Furthermore, the ability to prepare these kinds of MOFs in high yield and with adjustable pore size, shape, and functionality has led to their exploration as gas storage materials. Thermal gravimetric and gas sorption experiments have shown that IRMOF-6, bearing a fused hydrophobic unit $\mathrm{C}_{2} \mathrm{H}_{4}$ in its organic link, has the optimal pore aperture and rigidity requisite for maximum uptake of methane. Activation of the porous framework was achieved by exchanging the included guest molecules with chloroform, which was then removed by

Fig. 20.4.41.

Fig. 20.4.42.
Crystal structure of MOF-177. (a) A central $\mathrm{Zn}_{4} \mathrm{O}$ unit coordinated by six BTB ligands. (b) The structure viewed down [001]. From H. K. Chae, D. Y. Siberio-Pérez, J. Kim, Y. B. Go, M. Eddaoudi, A. J. Matzger, M. O'Keeffe and O. M. Yaghi, Nature 427, 523-7 (2004).

gradual heating to $800^{\circ} \mathrm{C}$ under an inert atmosphere. The evacuated framework has a stability range of $100-400^{\circ} \mathrm{C}$, and the methane sorption isotherm measured in the range $0-40 \mathrm{~atm}$ at room temperature has an uptake of $240 \mathrm{~cm}^{3}(\mathrm{STP}) / \mathrm{g}$ $\left[155 \mathrm{~cm}^{3}(\mathrm{STP}) / \mathrm{cm}^{3}\right]$ at 298 K and 36 atm . On a volume-to-volume basis, the amount of methane sorbed by IRMOF-6 at 36 atm amounts to $70 \%$ of that stored in compressed methane cylinders at $\sim 205 \mathrm{~atm}$. As compared to IRMOF6 , IRMOF-1 under the same conditions has a smaller methane uptake of 135 $\mathrm{cm}^{3}$ (STP)/g.

The isoreticular MOFs based on the $\mathrm{Zn}_{4} \mathrm{O}\left(\mathrm{CO}_{2}\right)_{6} \mathrm{SBU}$ also possesses favorable sorption properties for the storage of molecular hydrogen. At 77 K , microgravimetric sorption measurements gave $\mathrm{H}_{2}(\mathrm{mg} / \mathrm{g})$ values of 13.2, 15.0, 16.0, and 12.5 for IRMOF-1, IRMOF-8, IRMOF-11, and MOF-177, respectively. At the highest pressures attained in the measurements, the maximum uptake values for these frameworks are $5.0,6.9,9.3$, and 7.1 molecules of $\mathrm{H}_{2}$ per $\mathrm{Zn}_{4} \mathrm{OL}_{x}$ unit where L stands for a linear dicarboxylate.

MOF-177 has been demonstrated to act like a super sponge in capturing vast quantities of carbon dioxide at room temperature. At moderate pressure (about 35 bar ), its voluminous pores result in a gravimetric $\mathrm{CO}_{2}$ uptake capacity of $33.5 \mathrm{mmol} / \mathrm{g}$, which far exceeds those of the benchmark adsorbents zeolite 13X ( $7.4 \mathrm{mmol} / \mathrm{g}$ at 32 bar ) and activated carbon MAXSORB ( $25 \mathrm{mmol} / \mathrm{g}$ at 35 bar). In terms of volume capacity, a container filled with MOF-177 can hold about twice the amount of $\mathrm{CO}_{2}$ versus the benchmark materials, and 9 times the amount of $\mathrm{CO}_{2}$ stored in an empty container under the same conditions of temperature and pressure.

The previous structural and sorption studies of MOFs are all based on the discrete $\mathrm{Zn}_{4} \mathrm{O}\left(\mathrm{CO}_{2}\right)_{6} \mathrm{SBU}$. Recent development has demonstrated that rod-shaped metal-carboxylate SBUs can also give rise to a variety of stable solid-state architectures and permanent porosity. Three illustrative examples are presented below.

In the crystal structure of $\mathrm{Zn}_{3}(\mathrm{OH})_{2}(\mathrm{BPDC})_{2} \cdot(\mathrm{DEF})_{4}\left(\mathrm{H}_{2} \mathrm{O}\right)_{2}$ where BPDC $=4,4^{\prime}$-biphenyldicarboxylate (MOF-69A), there are tetrahedral and octahedral $\mathrm{Zn}(\mathrm{II})$ centers coordinated by four and two carboxylate groups, respectively,
in the syn,syn mode, with each $\mu_{3}$-hydroxide ion bridging three metal centers [Fig. 20.4.43(a)]. The infinite $\mathrm{Zn}-\mathrm{O}-\mathrm{C}$ rods are aligned in parallel fashion and laterally connected to give a three-dimensional network [Fig. 20.4.43(b)], forming rhombic channels of edge 1.22 nm and 1.66 nm along the longer diagonal, into which the DMF and water guest molecules are fitted.

Fig. 20.4.43.
Channel structure of MOF-69A: (a) ball-and-stick representation of inorganic SBU; (b) SBUs connected by biphenyl links. The DEF and water molecules have been omitted for clarity. From N. L. Rosi, J. Kim, M. Eddaoudi, B. Chen, M. O'Keeffe and O. M. Yaghi, J. Am. Chem. Soc. 127, 1504-18 (2005).

The Mn-O-C rods in MOF-73, $\mathrm{Mn}_{3}(\mathrm{BDC})_{3} \cdot(\mathrm{DEF})_{2}$, are constructed from a pair of linked six-coordinate Mn (II) centers [Fig. 20.4.44(a)]. One metal center is bound by two carboxylate groups acting in the syn,syn mode, one in the bidentate chelating mode, and a fourth one in the syn, anti mode. The other metal center has four carboxylates bound in the syn,syn mode and two in the syn,anti mode. Each rod is built of corner-linked and edge-linked

Fig. 20.4.44.
Channel structure of MOF-73: (a)
ball-and-stick representation of inorganic SBU; (b) SBUs connected by $p$-phenylene links. The DEF molecules have been omitted for clarity. From N. L. Rosi, J. Kim, M. Eddaoudi, B. Chen, M. O'Keeffe and O. M. Yaghi, J. Am. Chem. Soc. 127, 1504-18 (2005).
$\mathrm{MnO}_{6}$ octahedra, and is connected to four neighboring rods by $p$-phenylene links. The resulting three-dimensional host framework [Fig. 20.4.44(b)] has rhombic channels of dimensions $1.12 \times 0.59 \mathrm{~nm}$ filled by the DEF guest molecules.
The structure of MOF-75, $\mathrm{Tb}(\mathrm{TDC}) \cdot\left(\mathrm{NO}_{3}\right)(\mathrm{DMF})_{2}$ where $\mathrm{TDC}=2,5-$ thiophenedicarboxylate, contains eight-coordinate Tb (III) bound by four carboxylate groups all acting in the syn,syn mode, one bidentate nitrate ligand, and two terminal DMF ligands [Fig. 20.4.45(a)]. The Tb-O-C rod orientated in the $a$ direction consists of linked $\mathrm{TbO}_{8}$ bisdisphenoids with the carboxyl carbon atoms forming a twisted ladder. Lateral linkage of rods in the $b$ and $c$ directions by the thiophene units generate rhombic channels measuring $0.97 \times 0.67 \mathrm{~nm}$, as illustrated in Fig. 20.4.45(b), which accommodate the DMF guest molecules and nitrate ions.

### 20.4.9 One-pot synthesis of nanocontainer molecule

Dynamic covalent chemistry has been used in an atom-efficient self-assembly process to achieve a nearly quantitative one-pot synthesis of a nanoscale molecular container with an inner cavity of approximately $1.7 \mathrm{~nm}^{3}$.

In a thermodynamically driven, trifluoroacetic acid catalyzed reaction in chloroform, six cavitands 1 and twelve ethylenediamine linkers condense to generate an octahedral nanocontainer 2, as shown in Fig. 20.4.46. Each cavitand has 4 formyl groups on its rim, and these react with the 24 amino groups of the linkers to form 24 imine bonds. After reduction of all the imine bonds with $\mathrm{NaBH}_{4}$, the hexameric nanocontainer can be isolated via reversed-phase HPLC as the trifluoroacetate salt $\mathbf{2} \cdot 24 \mathrm{CF}_{3} \mathrm{COOH}$ in $63 \%$ yield based on $\mathbf{1}$. Elemental analysis of the white solid corresponds to the stoichiometric formula $\mathbf{2} \cdot 24 \mathrm{CF}_{3} \mathrm{COOH} \cdot 9 \mathrm{H}_{2} \mathrm{O}$. The simplified ${ }^{1} \mathrm{H}$ and ${ }^{13} \mathrm{C}$ NMR spectra of 2 and $\mathbf{2} \cdot 24 \mathrm{CF}_{3} \mathrm{COOH}$ are consistent with their octahedral symmetry.

If the same reaction is carried out with either 1,3-diaminopropane or 1,4diaminobutane in place of ethylenediamine, the product is an octaimino hemicarcerand composed of two face-to-face cavitands connected by four diamino bridging units.

### 20.4.10 Filled carbon nanotubes

Much research has been devoted to the insertion of different kinds of crystalline and non crystalline material into the hollow interior of carbon nanotubes. The encapsulated species include fullerenes, clusters, one-dimensional (1D) metal nanowires, binary metal halides, metal oxides, and organic molecules.

The left side of Fig. 20.4.47 illustrates the van der Waals surfaces of the $(10,10)$ and $(12,12)$ armchair SWNTs with diameters of 1.36 and 1.63 nm and corresponding internal diameters of approximately 1.0 and 1.3 nm , respectively, as specified by the van der Waals radii of the $\mathrm{sp}^{2}$ carbon atoms forming the walls. The $(10,10)$ tube has the right size to accommodate a linear array of $\mathrm{C}_{60}$ molecules, as shown by the HRTEM images marked (a) and (b) on the right side of Fig. 20.4.47. Parts (c) and (d) show the HRTEM image and modeling of an interface between four fullerene molecules and a 1D FeI ${ }_{2}$ crystal.

Fig. 20.4.45.

(b) Second image from the same specimen as in (a), showing a cross-sectional view of an ordered bundle of SWNTs, some of which are filled with fullerene molecules. (c) HRTEM image (scale bar $=1.5 \mathrm{~nm}$ ) of a filled SWNT showing an interface between four $\mathrm{C}_{60}$ molecules (a possible fifth molecule is obscured at the left) and a $1 \mathrm{DFeI}_{2}$ crystal. (d) Schematic structural representation of $(\mathrm{c})(\mathrm{Fe}$ atoms $=$ small spheres; I atoms $=$ large spheres $)$. Courtesy of Professor M. L. H. Green.

The formation of an ordered $2 \times 2$ KI crystal column within a $(10,10)$ SWNT with $D \sim 1.4 \mathrm{~nm}$ is shown in Fig. 20.4.48. The structural model is illustrated in (a), and a cross-sectional view is shown in (b). The coordination numbers of the cation and anion are changed from 6:6 in bulk KI to $4: 4$ in the $2 \times 2$ column. Each dark spot in the HRTEM image (c) represents an overlapping I-K or K-I arrangement viewed in projection, which matches the simulated image (d). The spacing between spots along the SWNT is $\sim 0.35 \mathrm{~nm}$, corresponding to the $\{200\}$ spacing in bulk KI, whereas across the SWNT capillary the spacing increases to $\sim 0.4 \mathrm{~nm}$, representing a $\sim 17 \%$ tetragonal expansion.
The incorporation of a $3 \times 3 \mathrm{KI}$ crystal in a wider $\operatorname{SWNT}(D \sim 1.6 \mathrm{~nm}$ ) is depicted in Fig. 20.4.49. In this case, three different coordination types (6:6, 5:5, and 4:4) are exhibited by atoms forming the central, face, and corner $\cdots$ I-$\mathrm{K}-\mathrm{I}-\mathrm{K} \cdots$ rows of the $3 \times 3$ column, respectively, along the tube axis. The $<110>$ projection shows the $\mathrm{K}^{+}$and $\mathrm{I}^{-}$sublattices as pure element columns,

Fig. 20.4.49.
(a) Reconstructed HRTEM image (averaged along the tube axis) of the $<110>$ projection of a $3 \times 3 \mathrm{KI}$ crystal in a $D \sim 1.6 \mathrm{~nm}$ diameter SWNT. Note that the contrast in this image is reversed so that regions of high electron density appear bright and low electron density appear dark. (b) Structural model derived from (a). Courtesy of Professor M. L. H. Green.

Fig. 20.4.50.
(a) An isolated DWNT filled with KI. (b) Reconstructed image of the KI@DWNT composite; the marked area was structurally analyzed in detail. (c) Crystal model showing the distortions imposed and the three subsections considered for its construction. (d) Structural model of the marked section in (b). (e) Reconstructed versus simulated image of the three sections. Courtesy of Professor M. L. H. Green.

which are distinguishable by their scattering powers. The iodine atoms located along $<110\rangle$ all show a slight inward displacement relative to their positions in bulk KI, whereas the K atoms located along the same cell diagonal exhibit a small expansion.

It was found that KI can also be used to fill a DWNT, as shown in Fig. 20.4.50. The HRTEM image (a) and reconstructed image (b) of the KIDWNT composite was analysed using a model composed of an inner $(11,22)$ SWNT ( $D \sim 2.23 \mathrm{~nm}$ ) and an outer $(18,26)$ SWNT ( $D \sim 3.04 \mathrm{~nm}$ ). The measured averaged spacings between the atomic columns gave values of 0.37 nm across the DWNT axis and 0.36 nm along it, which agree well with the $\{200\}$ d-spacing of rock-salt KI ( 0.352 nm ). In the simulation calculation, the encapsulated fragment was divided into three sections in order to model the lattice defects such as plane shear and plane rotation.

[^0]:    ${ }^{*} \mathrm{H}_{\mathrm{t}}$, terminal hydrogen
    ${ }^{\dagger} \mathrm{H}_{\mathrm{b}}$, bridging hydrogen.

[^1]:    * Glide planes $d$ occur only in orthorhombic $F$ space groups, in tetragonal $I$ space groups, and in cubic $I$ and $F$ space groups. They always occur in pairs with alternating glide vectors, for instance $\frac{1}{4}(\mathbf{a}+\mathbf{b})$ and $\frac{1}{4}(\mathbf{a}-\mathbf{b})$. The second power of a glide reflection $d$ is a centering vector.

[^2]:    ${ }^{*}$ The 230 space groups include 11 enantiomorphous pairs: $P 3_{1}\left(P 3_{2}\right), P 3_{1} 12\left(P 3_{2} 12\right), P 3_{1} 21\left(P 3_{2} 21\right), P 4_{1}\left(P 4_{3}\right), P 4_{1} 22\left(P 4_{3} 22\right), P 4_{1} 2_{1} 2\left(P 4_{3} 2_{1} 2\right)$, $P 6_{1}\left(P 6_{5}\right), P 6_{2}\left(P 6_{4}\right), P 6_{1} 22\left(P 6_{5} 22\right), P 6_{2} 22\left(P 6_{4} 22\right)$, and $P 4_{1} 32\left(P 4_{3} 32\right)$. If the $(+)$-isomer of an optically active molecule crystallizes in an enantiomorphous space group, the (-)-isomer will crystallize in the related one. Although both members of an enantiomorphous pair are distinguishable by X-ray diffraction (using anomalous dispersion), they can be counted together for classification purposes if the absolute chirality sense (handedness) is unknown or irrelevant, leading to 219 "distinct" space groups. However, once the chirality sense of the asymmetric unit is specified, repetition of that unit in one enantiomorphous space group is quite distinct from repetition in the other. It is therefore virtually impossible for a given chiral compound to crystallize in both enantiomorphous space groups because the resulting packing arrangements (and energies) would be completely different.

    Space groups (or enantiomorphous pairs) that are uniquely determined from the symmetry of the diffraction pattern and systematic absences are shown in boldface type.

    Recent adoption of the double glide plane $e$ as a symmetry element leads to changes in the international symbols for five $A$ - and $C$-centered orthorhombic space groups: No. 39, Abm2 $\rightarrow$ Aem 2 ; No. 41, Aba $2 \rightarrow$ Aea $2 ;$ No. 64, Cmca $\rightarrow$ Cmce ; No. 67, Cmma $\rightarrow$ Cmme; No. 68, Ccca $\rightarrow$ Ccce .

[^3]:    * The symbol $\square$ indicates a position for a possible point symmetry element.
    ${ }^{\dagger}$ For orthorhombic space groups, the standard Hermann-Mauguin symbol for a different choice of axes is enclosed in parentheses.

[^4]:    * This table is not complete; equivalent positions with multiplicities $>32$ are not listed.

[^5]:    * Data are not available for francium, of which only artificial isotopes are known.

[^6]:    * For $\beta$-rhombohedral boron

[^7]:    (3) Phosphaalkynes, $\mathrm{RC} \equiv \mathrm{P}$

    Phosphaalkynes are compounds of tervalent phosphorus which contain a $\mathrm{P} \equiv \mathrm{C}$

[^8]:    * Acids only exist as salts.

[^9]:    * The polyhedron may exhibit regular or distorted geometry.
    ${ }^{\dagger} \mathrm{L}=1$-methyl-1,4,7,10-tetraazacyclododecane
